APPENDICES

Preface

The third edition of the *SFPE Handbook of Fire Protection Engineering* represents an update of existing material with the addition of some important new subject matter. The rapid assimilation of performance-based design in fire protection has underscored the importance of this handbook. While the process of performance-based design has been documented in detail, the fundamental knowledge base has remained fragmented. This handbook, as it has been from its inception, is a contribution toward documenting and integrating the theoretical and applied bases of fire safety engineering. The need for concise description of the theoretical basis of fire protection engineering in conjunction with material on engineering calculations and practice is clear. Significant effort was made to provide a more useful and direct link from some of the fundamental chapters to actual use in practice. Examples include a new chapter on calculation of heat fluxes to surfaces and new treatment of ignition phenomena.

The changes in many chapters reflect the incremental and slow progress made in improving the knowledge base in the area of fire dynamics. One notable exception to this slow change has been in the area of egress and human movement. Significant new material in this area was prepared by Guylène Proulx. The challenges and complexities of introducing a new fire suppression technology, water mist systems, are covered in a new chapter. The widespread use of field modeling as a practical tool in engineering design motivated the inclusion of a new chapter on that subject. Additional treatment of risk assessment methodologies, particularly as they are applied, is included as sectors of the profession move more quickly in that direction.

Another significant modification in this edition is the inclusion of new material in the chapter on radiation heat transfer calculations. This new material reflects, in part, the results of a technical committee of the SFPE directed toward developing consensus on engineering methods. It is anticipated that future editions will include the work of several engineering consensus groups directed at establishing a consensus-based standard of care in fire safety engineering. This, in turn, will provide a firmer technical basis for design while preserving the necessary level of public safety.

The generous contribution of the individual authors is gratefully acknowledged. Without their donation of time, energy, and expertise, this handbook would not be possible. While they are owed a debt that cannot be paid outright, we trust that the application of their work in solving fire safety engineering problems worldwide will serve as some reward for their efforts. As the fire protection engineering discipline expands, the need for additional authors and expertise will become a significant limitation in future editions.

This edition of the handbook is the first to be published without Jim Linville, who retired from NFPA during its preparation. Pam Powell has ably assumed the role of managing editor, providing guidance, encouragement, and the motivation necessary to complete and publish this edition.

The editors and the Society of Fire Protection Engineers welcome the comments and suggestions of readers as we seek to improve and expand this handbook in future editions.

Philip J. DiNenno, P.E.

Metrication

The editors of the *SFPE Handbook of Fire Protection Engineering* have worked toward expanded use of SI units for this third edition. In some instances, however, U.S. customary units have been retained. For example, when equations, correlations, or design methodologies have input variables or constants that have been developed from data originally in U.S. customary units, those units are retained. This is also the case for certain tables, charts, and nomographs. Where equations employing U.S. customary units are used in worked examples, the results are presented as SI units as well.

Fundamentals

Section 1 Fundamentals

CHAPTER 1

Introduction to Mechanics of Fluids

B. S. Kandola

Fluid Properties

A fluid is defined as a substance that has the capacity to flow freely and as a consequence deform continuously when subjected to a shear stress. A fluid can be either a liquid, a vapor, or a gas.

For the purposes of fluid flow studies, a very important distinction is made between compressible fluids and incompressible fluids. In general, the compressibility effects of liquids are so small that they can be regarded as incompressible, whereas gases and vapors can be either compressible or incompressible depending on the forces involved.

To simplify analytical investigation of fluid motion, the intermolecular forces of the fluids are ignored, and such a fluid is known as *inviscid* (i.e., zero viscosity).

An incompressible, inviscid fluid is called a *perfect fluid.* In reality no real fluid is a perfect fluid, but the effects of viscosity are so small in a perfect fluid that they can be ignored.

Density: The density of a fluid is defined as the mass of the fluid per unit volume. The density, ρ, is therefore defined as

$$\rho = \frac{\text{mass}}{\text{volume}} = \frac{m}{v}$$

where m is the mass of fluid of volume, v. If the units of mass are kilograms (kg) and the volume m^3, then the units of density are kg/m^3.

Specific volume: Specific volume is the reciprocal of density, that is, specific volume (m^3/kg)

$$v = \frac{1}{\rho}$$

Shear force: The component of total force, F, in a direction tangential to the surface of a body is called the shear force. Similarly, the component perpendicular to the tangent is called the normal force. Force is measured in newtons (N, or 1 kg m/s^2).

Shear stress: The shear stress, τ, at a point is defined as the limiting value of shear force per unit area as the area is reduced to a point, or

$$\tau = \frac{\text{shear force}}{\text{area}}$$

Pressure: The pressure, P, at a point in a fluid is defined as the limiting value of normal force to area as the area is reduced to the point, or

$$P = \frac{\text{normal force}}{\text{area}}$$

where the units are N/m^2, or pascals (Pa).

Physical Properties of Fluids

Viscosity: All real fluids offer some resistance, however small, to applied shear stresses. This resistance results from the property of the fluid called viscosity. According to Newton's law, the rate at which a fluid element deforms for a given shear stress is inversely proportional to the fluid viscosity.

For a two-dimensional flow between two parallel plates, the rate of deformation is the rate of change of x-component of velocity, u, with y-direction, that is, $\partial u/\partial y$. If τ is the frictional shearing stress, then according to the above definition

$$\tau \propto \frac{\partial u}{\partial y} \tag{1}$$

Dr. B. S. Kandola, formerly a member of the unit of fire safety engineering, Edinburgh University, and a senior consultant with AEA Technology and Lloyd's Register, is an independent safety and risk management consultant. He has worked on a range of research projects involving fire and smoke movement modeling on offshore oil and gas installations and for the nuclear industry. His current activities include risk assessment, consequence modeling, hazard analysis, and the development of safety cases for the petrochemical, offshore, and nuclear industries.

or

$$\tau = \mu \frac{\partial u}{\partial y} \tag{1a}$$

where μ is the coefficient of viscosity. The units of viscosity are Ns/m^2. In general, the viscosity of a gas increases with temperature, while the viscosity of a liquid decreases with temperature.

Kinematic viscosity: In all real fluid motions the frictional and inertia forces interact. The ratio of μ to ρ is important and is known as the kinematic viscosity, ν.

$$\nu = \frac{\mu}{\rho} \tag{2}$$

The units of ν are m^2/s.

The Equation of State

For a fluid in which the properties are the same at all points (i.e., uniform fluid) and having definite chemical composition, experimental evidence indicates that the fluid density, ρ, is a function only of the pressure, p, and temperature, T.

$$\rho = f(p, T) \tag{3}$$

According to this relation, any one property, that is, p, T, or ρ, is determined by any of the other two. For a gas at temperatures and pressures well away from liquefaction or dissociation, the following relationship holds with good approximation:

$$\frac{p}{\rho} = \frac{\overline{R}}{M} \cdot T \tag{4}$$

where

$\overline{R}$ = universal gas constant

M = molecular weight of the particular gas

T = absolute temperature (K)

The value of the universal gas constant, $\overline{R}$, is 8.315×10^3 m^2/s^2K (or $J/kg \cdot K$), and the molecular weights for various gases are shown in Table 1-1.1.

A gas that obeys Equation 4 is called a *perfect gas* (also sometimes referred to as *ideal gas*). With an acceptable degree of accuracy, this relationship is also assumed to apply for the calculation of air flows, although air is, in reality, a mixture of various gases. It is assumed that the equation of state holds when the gas is in motion as well as at rest.

Table 1-1.1 ***Molecular Weight of Gases***

Gas	Molecular Weight (M)
Hydrogen (H_2)	2.0
Carbon monoxide (CO)	28.0
Methane (CH_4)	16.0
Ethane (C_2H_6)	30.0
Propane (C_3H_8)	44.0
Air	28.9

Compressibility and Thermal Expansion

Equation 4 describes the compressibility of a gas. According to this equation, the volume is decreased with the increase in pressure, provided the process takes place under isothermal conditions.

If the volume changes from v to $v + \partial v$ due to the change in pressure from p to $p + \partial p$, the coefficient of compressibility is then defined as

$$\beta = \frac{1}{v}\left(\frac{\partial v}{\partial p}\right)_T \tag{5}$$

Similarly, at constant pressure

$$\beta_1 = \frac{1}{v}\left(\frac{\partial v}{\partial T}\right)_p \tag{6}$$

where β_1 is called the coefficient of thermal expansion. This equation describes the resulting change of volume due to any change in temperature occurring under isobaric conditions.

The compressibility of a liquid is described by its bulk modulus, K, which is the inverse of coefficient of compressibility, β;

that is,
$$K = \frac{1}{\beta} \tag{7}$$

For a perfect gas (i.e., a gas that obeys Equation 4)

$$\beta = \beta_1 = \frac{1}{T} \tag{8}$$

Specific heat: The specific heat of a substance (or gas) is defined as the quantity of heat required to raise the temperature of a unit mass of the substance by one degree. The specific heat depends on whether the process takes place under conditions of constant pressure, C_p, or constant volume, C_v. If q is the quantity of heat supplied per unit mass of gas, then

$$C_p = \left(\frac{\partial q}{\partial T}\right)_p \quad \text{constant pressure} \tag{9}$$

$$C_v = \left(\frac{\partial q}{\partial T}\right)_v \quad \text{constant volume} \tag{10}$$

Vapor pressure: When the temperature of a liquid increases, its molecular activity is also increased. With the sufficient rise in temperature, the molecules begin to escape from the surface of the liquid. The pressure exerted by these molecules just above the surface is called the vapor pressure of the liquid. The vapor pressure increases with the increase in temperature, and boiling occurs when the vapor pressure becomes equal to the pressure above the liquid surface.

Surface tension: The molecular attraction of liquids causes the free surface of a liquid to act as a stretched membrane in such a way that work is required to change the shape of its free surface.

The surface tension coefficient of a liquid is then defined as the force per unit length of any line on the free

surface of a liquid necessary to hold that surface together at that line

$$F = \int \sigma \, dl \tag{11}$$

The quantity σ is the surface tension coefficient and depends on the properties of the free surface of a liquid and its surroundings.

Fluid Statics and Buoyancy

When a fluid system is in motion, shear stresses develop in the fluid if one layer of fluid moves at a different velocity from an adjacent layer. These stresses are proportional to the velocity gradient. In the case of a static fluid (zero velocity), the shear stresses are zero.

Forces Acting on Fluid Systems

Forces acting on fluid systems are classified according to the geometry on which they act.

1. Body force is the force resulting from the total mass of the fluid system. For example, the body force of a solid object at rest equals its weight acting at its center of gravity.
2. Surface force (shear force) acts on a surface and is proportional to the extent of the surface. Such a force can be resolved into its normal and tangential components.
3. Line force (surface tension) depends on the extent of the line perpendicular to which the force acts.

Pressure at a Point

The pressure at a point is defined as the normal component of surface force acting on a unit area of the surface, or the limit of the ratio of normal force per unit area as the area approaches zero at the point. For a fluid system in equilibrium, the pressure is a scalar quantity, as it is independent of orientation.

For an imaginary wedge-shaped element in a static fluid, the forces acting on each side are due to body and surface forces, as shown in Figure 1-1.1.

Since the fluid is assumed to be in equilibrium, the sum of the horizontal forces and the vertical forces is zero, that is,

$$\sum F_x = 0 \tag{12}$$

$$\sum F_y = 0 \tag{13}$$

Resolving the forces shown in Figure 1-1.1, horizontally and vertically, it can be shown that in the limit as $\partial x \rightarrow 0$, $\partial y \rightarrow 0$

$$p_x = p_y = p_s \tag{14}$$

This result is sometimes referred to as Pascal's law, which states that for a fluid system in static equilibrium, the pressure at a point is the same in all directions.

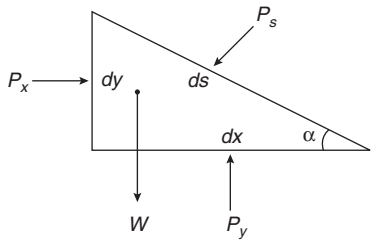

Figure 1-1.1. ***Wedge-shaped imaginary fluid element.***

Hydrostatic Equation

Within a static fluid, the rate of change of static pressure with height, z, from a datum level is given by

$$\frac{dp}{dz} = -\rho g \tag{15}$$

Integrating Equation 15 for constant ρ gives

$$p + \rho g z = C \tag{16}$$

where g is the acceleration due to gravity, and C is the constant of integration.

This equation is generally known as the hydrostatic equation or Torricelli's principle, which states that, at every elevation within a static, homogeneous, and incompressible fluid, the static pressure plus the head of fluid above a given datum line, $\rho g z$, is constant.

Forces on Submerged Surfaces

In numerous engineering design problems involving submerged surfaces (containers, offshore oil rigs, walls of a dam, the walls of a liquid-filled tank, etc.), it is necessary to know the magnitude of forces and the point of action of these forces that act on the surfaces. The total force acting on a submerged surface is obtained by integrating the pressure over the entire surface area.

$$F = \int_A p \, dA \tag{17}$$

If the pressure is constant, then the force on a submerged horizontal surface is given by

$$F = pA \tag{18}$$

where A is the total surface area.

The point on the surface at which this resultant force acts is called the center of pressure. It can be shown that the center of pressure for a horizontal submerged surface is at the centroid of the area. This result is arrived at by considering the moment of the distributed force about any axis through the center of pressure to be zero.

Forces on Plane-Inclined and Submerged Curved Surfaces

Consider an inclined plane surface, as shown in Figure 1-1.2.

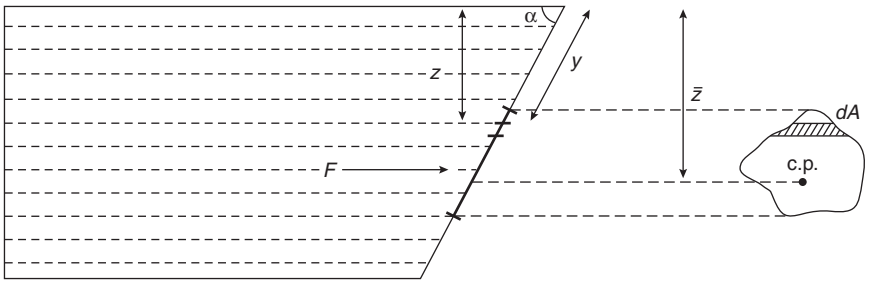

Figure 1-1.2. ***Plane-inclined surface.***

Force, dF, acting on elemental area, dA, at depth z from the free surface is given by

$$dF = \rho g z\, dA = \rho g y \sin \alpha\, dA \tag{19}$$

and the total force is given by

$$F = \rho g \sin \alpha \int_A y\, dA \tag{20}$$

If the y-coordinate of the centroid is defined as

$$\bar{y} = \frac{1}{A}\int_A y\, dA \tag{21}$$

then the total force can be written as

$$F = \rho g \bar{y} A \sin \alpha = \rho g \bar{z} A$$

or

$$F = p_{\bar{z}} A \tag{22}$$

This equation shows that for a plane-inclined surface the magnitude of the force on the surface is the product of the pressure at the centroid of the surface and its area.

For a curved surface, as shown in Figure 1-1.3, it can be shown that the horizontal and vertical components of force are

$$dF_x = \rho g y \sin \theta\, dA \tag{23}$$

$$dF_y = \rho g y \cos \theta\, dA \tag{24}$$

However, $\sin \theta\, dA$ is the projection of the elemental area, dA, onto a plane perpendicular to x-direction. Equation 23, therefore, shows that the horizontal component of pressure force on a curved surface is equal to the pressure force exerted on a projection of the curved surface.

The y-component of the force reduces to

$$F_y = \rho g \int_A dV \tag{25}$$

where $dV = y \cos \theta\, dA$.

Integration of Equation 25 gives

$$F_y = \rho g V \tag{26}$$

where V is the volume of fluid above the surface.

Equation 26 shows that the vertical component of pressure force on a curved surface is equal to the weight of liquid that is vertically above the curved surface extending up to free surface.

Buoyant Force on Submerged Bodies

As seen earlier in this chapter, a body submerged in a static fluid experiences a net force as a result of the pressure variation at its surface. The vertical component of this force is called the buoyant force and always acts vertically upward.

The magnitude of the buoyant force is expressed as the difference between the vertical component of the pressure force on the upper and the lower surfaces of the body. This fact is expressed in the form of Archimedes' principle, which states: "Any body submerged in a fluid experiences

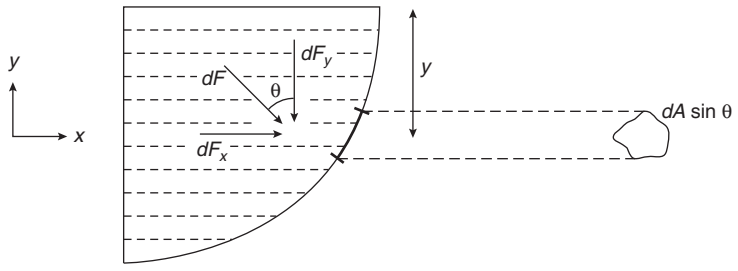

Figure 1-1.3. ***Submerged curved surface.***

a lift in a direction opposite to its weight and equal in magnitude to the weight of displaced volume of fluid."[1] If a submerged body is in equilibrium, it can be shown that

$$\rho = \rho_b \tag{27}$$

where ρ is the density of fluid and ρ_b is the density of body.

If the buoyant force is greater than the weight of the body, the body will float; but if the force is less, the body will sink.

Center of buoyancy: The center of buoyancy is the point on the body at which the buoyant force acts. The precise location of this point can be found by taking the integrated moments of the elementary buoyant forces and equating them to the moment of the total buoyant force or the weight of the displaced fluid.

It can be shown that the center of buoyany lies at the centroid of the displaced volume of fluid.

Stability of Floating and Submerged Bodies

From the previous text it is clear that a floating body in a static fluid is in equilibrium, provided (1) buoyant force is equal to the weight of the body and (2) center of buoyancy lies on the same vertical line as the center of gravity.

If a body is in such a stable equilibrium with respect to vertical displacement, then any upward or downward displacement sets up a force that tends to return the body to its original position.

In general, floating bodies are in a stable configuration if the center of gravity, *CG*, is lower than the center of buoyancy, *CB*. This relationship does not imply that stability may not exist when the opposite situation occurs.

Conversely, a completely submerged body is only rotationally stable if its center of gravity is below the center of buoyancy, as illustrated in Figure 1-1.4.

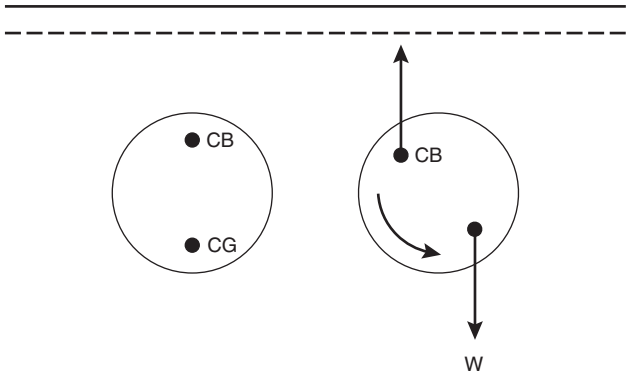

Figure 1-1.4. ***Rotationally stable submerged body.***

Kinematics of Fluid Motion

In general, kinematics of particle or fluid motion is concerned with the effects of motion on quantities derivable from displacement and time, such as velocity and acceleration. Although these motions are caused by external forces, they are studied in isolation from these forces.

In analyzing the motion of a rigid body or a fluid system, the space-time quantities are expressed in terms of a convenient coordinate system. The choice of this system is quite arbitrary and depends only on the nature of the problem investigated.

Two methods can be used to describe fluid motion: (1) the Langrangian method describing the motion of a particle in terms of a coordinate system that moves with the particle and (2) the Eulerian method describing the motion of a particle in terms of a fixed coordinate system. The Eulerian method is more commonly used to analyze fluid mechanics problems.

Classification of Fluid Motion

To simplify the analysis of fluid motion, various assumptions are made about the nature of fluid and its motion.

A *perfect fluid* is defined as that fluid which does not sustain shear stresses. A perfect fluid is inviscid ($\mu = 0$), and irrotational with constant density.

A *real fluid* is one in which the effects of viscosity are of paramount importance (i.e., $\mu \neq 0$). It is only in real fluids that a boundary layer is developed adjacent to a body over which the fluid flows.

Incompressible fluid motion is a motion in which the density remains unaltered (i.e., the time derivative of density is zero, $\partial\rho/\partial t = 0$).

With a *compressible fluid motion,* if the density of a fluid in motion is a function of time, the flow is termed as compressible (time derivative of density is nonzero, i.e., $\partial\rho/\partial t \neq 0$).

When a real fluid is in motion, two basic forces determine the nature of flow: (1) inertial forces, which arise as a result of the velocity of the fluid, and (2) viscous forces, which arise as a result of the viscosity of the fluid.

The ratio of inertial to viscous forces is known as the Reynolds number and is defined as

$$\mathrm{Re} = \frac{Vd}{\nu}$$

where

V = velocity

d = some characteristic length

ν = kinematic viscosity

For a fluid motion in which the value of Re is so small that the layers of flow are smooth and laminar, the flow is then referred to as laminar. As the velocity is increased (i.e., the inertial forces are increased), the layers start to break up and the flow is then said to be turbulent.

At a critical Reynolds number, the fluid flow becomes fully turbulent. For example, for a sharp-edged entry flow in a pipe, the critical Reynolds number is 2700.

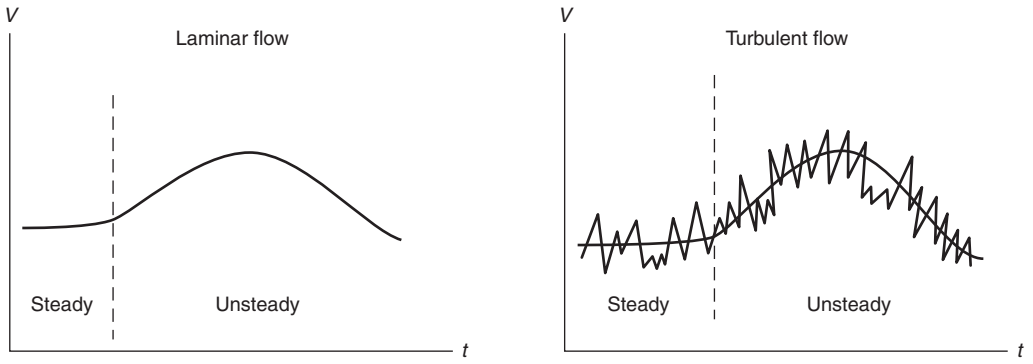

Figure 1-1.5. ***Steady and unsteady flows.***

Steady and unsteady motion: A flow in which the properties of the fluid do not vary with time is called the steady flow (i.e., $\partial V/\partial t = 0$). On the other hand, a flow regime in which these properties vary with time as well as space is characterized as unsteady (e.g., $\partial V/\partial t \neq 0$). A turbulent flow can either be steady or unsteady, as illustrated in Figure 1-1.5.

A turbulent flow is composed of the mean (average) component and a fluctuating component

$$u = \overline{u} + u' \tag{28a}$$

$$v = \overline{v} + v' \tag{28b}$$

where $\overline{u}$ and $\overline{v}$ are mean values of u and v, and u' and v' are the fluctuating components. The fluctuations u' and v' are such that their time average is zero.

Flow Concepts

Various flow concepts are used to make the mathematical analysis of fluid motion easier.

A *streamline* in a flow is defined as an imaginary curve in which the tangent at every point on this curve gives the direction of the fluid velocity at that point. Therefore there is no flow in the direction normal to the streamline. When the motion is steady, the streamlines are the same at all times.

Pathline is defined as a line in the flow field describing the path or trajectory of a given fluid element.

Streakline is defined as the locus in a flow field at a given time of all the fluid particles that have passed through a given point within the fluid. A smoke trail in the atmosphere at a given time is an example of a streakline.

For a steady motion the streamlines, streaklines, and pathlines are identical.

A stream filament is a group of neighboring streamlines forming a cylindrical passage with an infinitesimal cross section. A group of stream filaments is called a streamtube. The cross section of a streamtube is finite, and its surface across which there is no flow is called a stream surface. These concepts are illustrated in Figure 1-1.6.

Equation of Continuity

The flow through a streamtube (i.e., no flow through the stream surface) is shown in Figure 1-1.7.

Since there is no flow through the surface of the tube, and if the flow is steady, the mass of fluid flowing through area A_1 must equal the mass flowing through area A_2; that is, mass inflow equals mass outflow, or

$$\rho_1 A_1 u_1 = \rho_2 A_2 u_2 \tag{29}$$

For an incompressible flow, $\rho_1 = \rho_2$ and the previous equation then becomes

$$u_1 A_1 = u_2 A_2 \tag{30}$$

This relationship is known as the equation of continuity and, in general, can also be written as

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0 \tag{31}$$

where for an incompressible flow, u, v, and w are the velocity components in the x, y, and z directions.

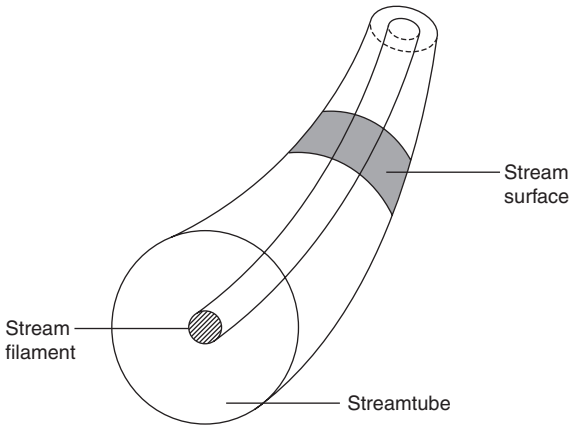

Figure 1-1.6. ***Basic concepts of stream filaments.***

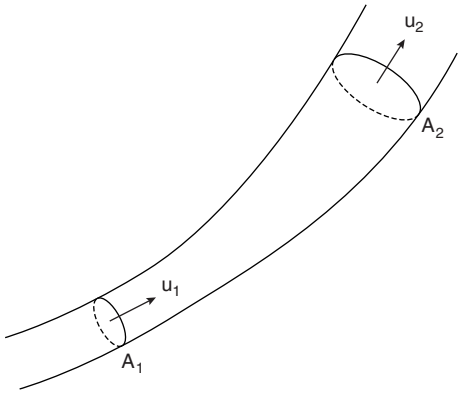

Figure 1-1.7. ***A streamtube.***

The Stream Function

Consider a two-dimensional incompressible flow in which the equation of continuity can be written as

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \tag{32}$$

From this equation it follows that there exists a function, ψ, such that

$$u = \frac{\partial \psi}{\partial y} \quad \text{and} \tag{33a}$$

$$v = \frac{\partial \psi}{\partial x} \tag{33b}$$

The function ψ is called the stream function, which satisfies the continuity equation. In cylindrical coordinates this relationship can be written as

$$v_r = \frac{1}{r}\frac{\partial \psi}{\partial \theta}, \quad v_\theta = -\frac{\partial \psi}{\partial r} \tag{34}$$

where v_r and v_θ are the velocity components in the r and θ directions.

Sources, Sinks, and Doublets

A point within a fluid from which fluid emanates and spreads radially outward in a uniform fashion is called a source. On the other hand, a sink is the opposite of a source, and the flow is inward into the point.

The strength of a source or sink is equal to the volume of fluid that issues from a source or to a sink per unit time. When a source-sink pair is separated by a distance, δx, such that $\delta x \rightarrow 0$, then this arrangement is called a doublet or a dipole.

Stream Function of a Two-Dimensional Source

Since the flow from a source is radially outward, the flux per unit time is the strength of the source. (See Figure 1-1.8.)

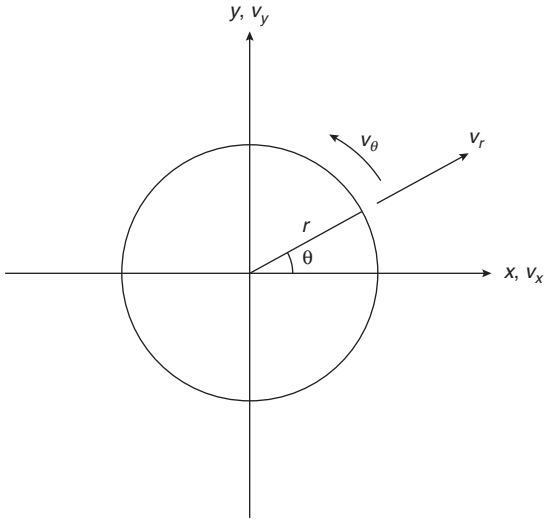

Figure 1-1.8. ***A two-dimensional source.***

If the flow is steady and incompressible, the strength, m, per unit length of cylinder is given by

$$m = 2\pi r v_r \tag{35}$$

where v_r is the radial velocity component.

Since the flow is completely radial, $v_\theta = 0$.

The radial component, v_r, is given by

$$v_r = \frac{1}{r}\frac{\partial \psi}{\partial \theta} = \frac{1}{r}\frac{d\psi}{d\theta} \tag{36}$$

Combining the two equations and integrating for ψ gives

$$\psi = \frac{m}{2\pi}\theta \tag{37}$$

This equation shows that the streamlines for a source are radial lines as shown in Figure 1-1.9.

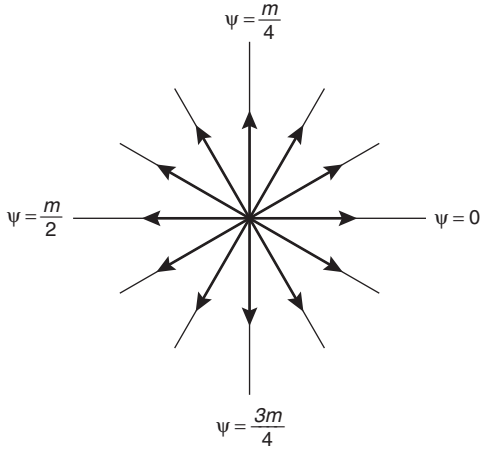

Figure 1-1.9. ***Streamlines of a two-dimensional source.***

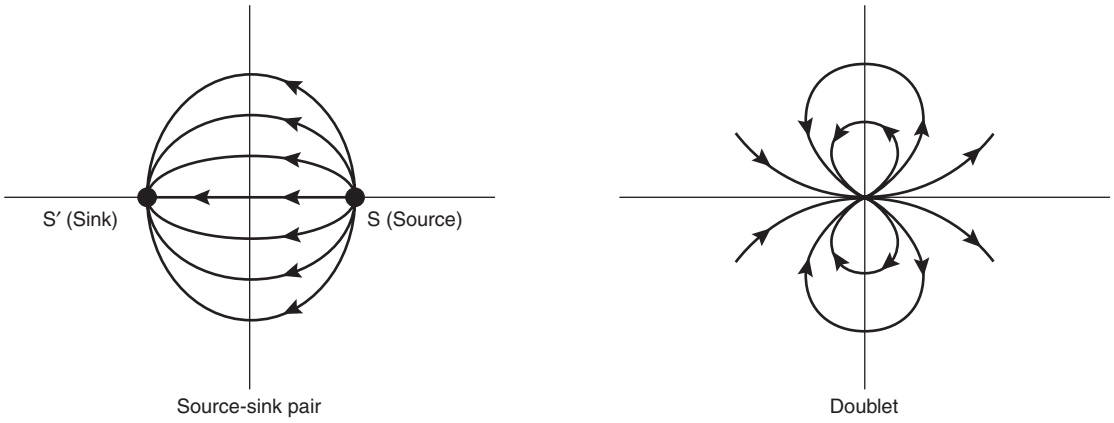

Figure 1-1.10. ***Streamlines of a source-sink pair and a doublet.***

Similarly, the streamlines for a two-dimensional source-sink pair and a two-dimensional doublet are shown in Figure 1-1.10.

Fluid Rotation

For a rigid body, if each particle of the body describes a circle about its axis of rotation, the body is said to be rotating.

But since in a fluid each particle is free to move in any direction, the fluid may not describe a perfect circle about the axis of rotation. Consequently, the rotation of a fluid element at a point is defined as the average angular velocity of the element.

An element of fluid is shown in Figure 1-1.11.

The average angular velocity of the element can be shown to be

$$2\omega_z = \frac{\partial v_y}{\partial x} - \frac{\partial v_x}{\partial y} \tag{38}$$

where $2\omega_z$ is called the *vorticity*, ζ_z.

The direction of the vorticity, by convention, is given by the right-hand screw rule. In this case ζ_z is positive in an upward direction, perpendicular to the plane of paper.

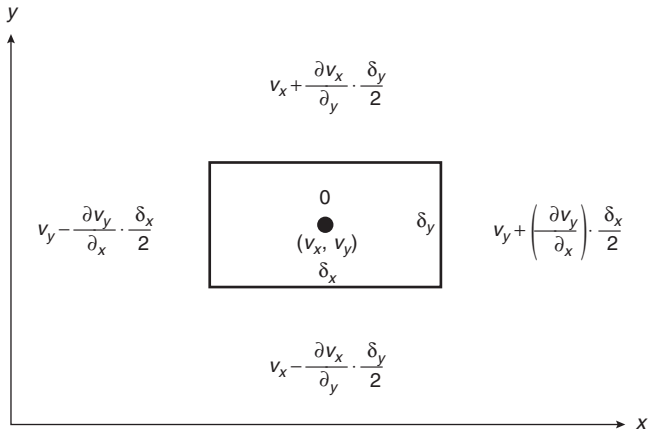

Figure 1-1.11. ***A fluid element.***

Similarly, the other components can be written as

$$\zeta_y = \frac{\partial v_x}{\partial z} - \frac{\partial v_z}{\partial x} \tag{39a}$$

$$\zeta_z = \frac{\partial v_z}{\partial y} - \frac{\partial v_y}{\partial z} \tag{39b}$$

The components of vorticity in cylindrical coordinates are

$$\zeta_z = \frac{1}{r}\left[\frac{\partial}{\partial r}\left(r v_\theta\right) - \frac{\partial v_\theta}{\partial \theta}\right] \tag{40a}$$

$$\zeta_\theta = \frac{\partial v_r}{\partial z} - \frac{\partial v_z}{\partial r} \tag{40b}$$

$$\zeta_r = \left(\frac{1}{r}\frac{\partial v_z}{\partial \theta}\right) - \frac{\partial v_\theta}{\partial z} \tag{40c}$$

The total vorticity of the fluid at a given point is obtained by vectorially adding the three components.

Irrotational fluid motion: If the vorticity at a given point within the fluid is zero, the fluid motion is said to be irrotational. For example, a uniform parallel flow with no velocity gradients is irrotational. The condition for irrotationality of flow in terms of stream function is

$$v_r = 0 \tag{41}$$

$$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} = 0 \tag{42}$$

This equation is known as the Laplace equation.

Free Vortex

The type of motion in which the vorticity is zero and the peripheral velocity varies inversely with the radial distance is called the free vortex, that is,

$$v_r = 0 \tag{43a}$$

$$\zeta_z = 0 \tag{43b}$$

that is,

$$\frac{\partial v_\theta}{\partial r} + \frac{v_\theta}{r} = 0 \tag{43c}$$

This equation gives

$$v_\theta r = \text{constant} \tag{44}$$

From Equation 34

$$v_\theta = -\frac{\partial \psi}{\partial r} \tag{45}$$

Combining Equations 44 and 45 gives

$$\psi = k \ln r \tag{46}$$

where k is a constant.

The streamlines for a vortex, then, are circles as shown in Figure 1-1.12.

Velocity Potential

For an irrotational flow, all the components of vorticity are zero, that is,

$$\zeta_z = \zeta_y = \zeta_x = 0 \tag{47}$$

From Equations 38, 39a and 39b, and 47 it follows that there exists a function $\phi(x, y)$ such that

$$v_x = \frac{\partial \phi}{\partial x}, \quad v_y = \frac{\partial \phi}{\partial y}, \quad v_z = \frac{\partial \phi}{\partial z} \tag{48}$$

in cylindrical coordinates

$$v_r = \frac{\partial \phi}{\partial r}, \quad v_\theta = \frac{1}{r}\frac{\partial \phi}{\partial \theta} \tag{49}$$

These relationships generate

$$\frac{\partial^2 \phi}{\partial x^2} + \frac{\partial^2 \phi}{\partial y^2} = 0 \tag{50}$$

This equation shows that the velocity potential, ϕ, also satisfies Laplace's law.

It must be noted that the velocity components can only be expressed in terms of a velocity potential if the flow is irrotational. For ψ to exist continuity must be satisfied, and for ϕ to exist flow must be irrotational.

For a pure vortex

$$v_r = 0 \tag{51}$$

Therefore

$$v_\theta = \frac{1}{r}\frac{\partial \phi}{\partial \theta}$$

or

$$\phi = k\theta \tag{52}$$

where k is a constant.

The equipotential (constant ϕ) lines for a vortex are shown in Figure 1-1.13.

Circulation

The circulation around a closed contour within a flow field is defined as the sum of the product of the tangential velocity and the elemental length at every point on the contour. (See Figure 1-1.14.)

For a closed contour, C, the circulation is given by

$$\Gamma = \oint_c U \cos\theta \, ds \tag{53}$$

It can be shown that for an element of fluid $(\partial x, \partial y)$ the total circulation is given by

$$\Gamma = \int\int \zeta_z \, dx \, dy \tag{54}$$

This result is known as Stokes's theorem.

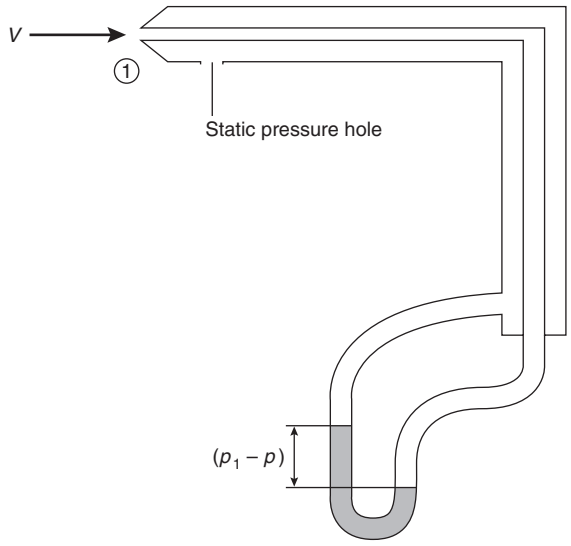

Figure 1-1.15. ***Pitot-static tube.***

Dynamics of Incompressible Fluids

Kinematics of fluid motion only deals with the general characteristics of flow of fluids. It does not answer the question of how fluids will move under given conditions (e.g., flow of real fluids over bodies of varying shapes). In other words, it is necessary to establish the relationship between the force and the resulting motion. This relationship is covered under the general heading of fluid dynamics.

The Bernoulli Equation

The Bernoulli equation expresses the relationship between the pressure and velocity within a fluid flow. The general form of the equation is

$$p + \frac{1}{2}\rho V^2 + \rho g z = \text{constant} \tag{55}$$

where

p = static pressure at the pressure head
$\frac{1}{2}(\rho V^2)$ = dynamic head
gz = position head

The constant is usually called the Bernoulli constant.

In some applications the position head term is considerably smaller, and therefore, the Bernoulli equation simplifies to

$$p + \frac{1}{2}\rho V^2 = \text{constant} \tag{56}$$

From Equation 56 it is clear that the static pressure, p, decreases with the increase in velocity, V. It should be remembered that the Bernoulli equation applies only to a streamline. It follows that this relationship enables the flow velocity to be calculated from the measurement of pressure. This application is the function of the pitot-static tube.

Figure 1-1.15 shows a typical arrangement of a pitot-static tube. When pointing in the direction of the flow, this tube allows the magnitude of the velocity to be determined through the measurement of pressures.

If V is the free stream velocity, then according to the Bernoulli equation

$$\frac{1}{2}\rho V^2 + p = \frac{1}{2}\rho V_1^2 + p_1 \tag{57}$$

At point 1 at the mouth of the tube the velocity $V_1 = 0$; that is, the stagnation point, and p_1 is the stagnation pressure at that point.

Equation 57 then becomes

$$V = \sqrt{\frac{2(p_1 - p)}{\rho}} \tag{58}$$

where $(p_1 - p)$ is pressure measured by the manometer.

Another application of the Bernoulli relation is to the flow of water under pressure from a tank. (See Figure 1-1.16.)

In Figure 1-1.16, p_1 is the atmospheric pressure.

Applying the Bernoulli equation at points 1 and 2 gives

$$p_1 + \frac{1}{2}\rho V_1^2 + \rho g z_1 = p_2 + \frac{1}{2}\rho V_2^2 + \rho g z_2 \tag{59}$$

If $V_1 \ll V_2$ then

$$\frac{1}{2}\rho V_2 = [p_2 - p_1 + \rho g(z_2 - z_1)] \tag{60a}$$

but $p_1 = p_2$ = atmospheric pressure.

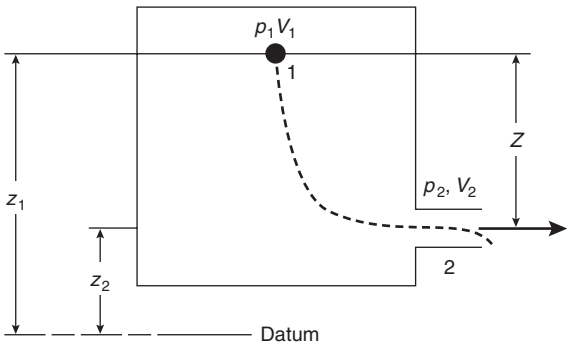

Figure 1-1.16. ***Efflux from a large tank.***

Therefore,

$$\frac{1}{2}\rho V_2^2 = \rho g(z_2 - z_1) = \rho g z \tag{60b}$$

or

$$V_2 = \sqrt{2gz} \tag{61}$$

This relationship is known as Torricelli's law for efflux from a container.

The Venturi meter, which measures the volume flow rate in a pipe, basically consists of a converging cone that merges into a parallel throat with a minimal cross-sectional area. (See Figure 1-1.17.) From the measurement of the static pressures in the parallel region and the converging region, the volume flow rate can be calculated as shown below.

Applying the Bernoulli equation at Points 1 and 2 gives

$$\frac{1}{2}\rho V_1^2 + p_1 = \frac{1}{2}\rho V_2^2 + p_2 \tag{62}$$

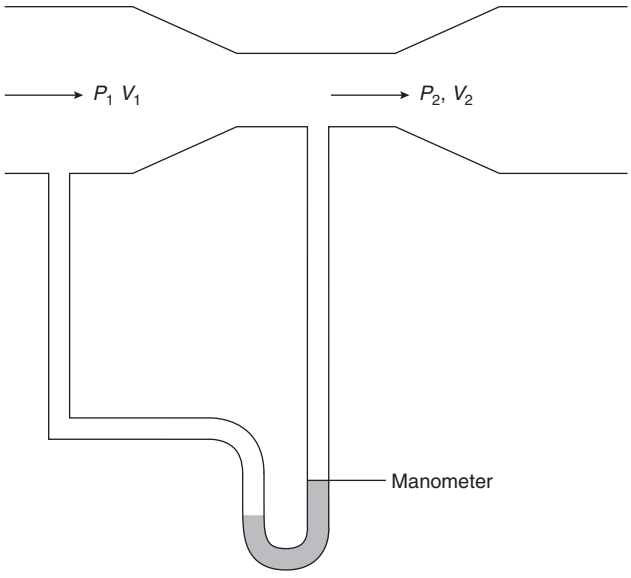

Figure 1-1.17. ***Venturi meter.***

But from continuity

$$\rho V_1 A_1 = \rho V_2 A_2 \tag{63}$$

Combining Equations 62 and 63 results in

$$V_2 = \sqrt{\frac{2}{\rho}\frac{A_1^2(p_2 - p_1)}{(A_2^2 - A_1^2)}} \tag{64}$$

Therefore the volume flow rate, Q, is given by

$$Q = V_2 A_2$$

or

$$Q = A_2\left[\frac{2A_1^2(p_2 - p_1)}{\rho(A_2^2 - A_1^2)}\right]^{1/2} \tag{65}$$

The Navier-Stokes Equations

The Navier-Stokes (N-S) equations are the exact equations describing the fluid motion. They are valid for both the laminar and turbulent flows. They are derived from Newton's second law of motion, which states that the sum of the external forces acting on a body is equal to the product of the mass and acceleration of the body. In the case of a fluid, this body is assumed to be a fixed control volume within which the fluid properties remain unchanged. To account for the fluid viscosity (i.e., stickiness of the fluid), it is further assumed that the instantaneous rate of strain (distortion) of the fluid element (body) is a simple linear function of the stresses (forces) in the fluid. Two types of forces are considered important: (1) the body forces (e.g., gravitation) and (2) the surface forces (e.g., pressure and friction).

The Navier-Stokes equations can be viewed as the transport equations that equate the net rate of transport of some quantity Q (momentum or enthalpy). For momentum transport the second law of motion is utilized, and for the enthalpy transport, the principle of first law of thermodynamics is used.

For momentum rate of transport, the general form of the N-S equations is

$$\frac{Du}{Dt} = X - \frac{1}{\rho}\frac{\partial p}{\partial x} + \nu\nabla^2 u \tag{66a}$$

$$\frac{Dv}{Dt} = Y - \frac{1}{\rho}\frac{\partial p}{\partial y} + \nu\nabla^2 v \tag{66b}$$

$$\frac{Du}{Dt} = Z - \frac{1}{\rho}\frac{\partial p}{\partial z} + \nu\nabla^2 w \tag{66c}$$

where

X, Y, Z = the body forces in the x, y, z directions
ρ = fluid density
p = pressure
ν = fluid kinematic viscosity
u, v, w = velocity components

D/Dt is the substantive derivative consisting of the non-steady and convective components.

For example

$$\frac{Du}{Dt} = \frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} + w\frac{\partial u}{\partial z}$$

The Laplace's operator ∇^2 (also known as del squared) is defined as

$$\nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$$

The Navier-Stokes equations, together with the continuity Equation 31, form four simultaneous differential equations from which the four unknowns (u, v, w, and p) could, in principle, be solved. However, the non-linear nature of these equations makes the task prohibitively complex. But for very simple cases of laminar flow, analytical solutions are possible, as demonstrated in Example 1. For more practical applications involving complex turbulent flows, the computer-based numerical techniques are used. In computational fire modeling, these computer codes are generally referred to as *field models.*

EXAMPLE 1: Flow in a Channel.

Consider the steady, incompressible viscous flow in an infinitely long two-dimensional stationary channel with two parallel flat plates. (See Figure 1-1.18.)

The flow everywhere is parallel to the x-axis. Since the flow is considered to be steady, the components of velocity in the y and z directions are zero; that is, $v = 0$, $w = 0$. The Navier-Stokes equations then become

$$-\frac{1}{\rho}\frac{\partial p}{\partial x} + \nu\frac{\partial^2 u}{\partial y^2} = 0 \tag{67}$$

$$-\frac{1}{\rho}\frac{\partial p}{\partial y} = 0 \tag{68}$$

From the continuity equation

$$\frac{\partial u}{\partial x} = 0 \tag{69}$$

These two equations are solved, subject to the boundary conditions

$$\begin{aligned} u &= 0, \quad y = b \\ u &= 0, \quad y = -b \end{aligned} \tag{70}$$

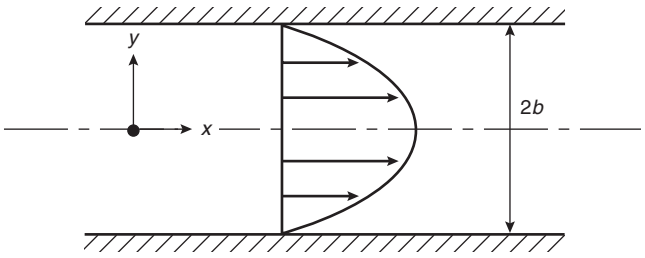

Figure 1-1.18. ***Flow in a channel.***

Equation 68 shows that the pressure, p, is a function of x only, while Equation 69 shows that u only varies with y.

Equation 67 therefore becomes

$$-\frac{1}{\rho}\frac{dp}{dx} + \nu\frac{d^2u}{dy^2} = 0$$

When solved for the given boundary conditions (Equation 70), the velocity component u becomes

$$\frac{dp}{dx} = \mu\frac{d^2u}{dy^2} \tag{71}$$

$$u = -\frac{1}{2\mu}\frac{dp}{dx}(b^2 - y^2) \tag{72}$$

Thus, the velocity profile is parabolic and the corresponding shear stress is given by

$$\tau = \mu\frac{du}{dy} = -\frac{1}{2\mu}\frac{dp}{dx}(b^2 - 2y) \tag{73}$$

The Energy Equation

As stated above, the N-S equations are basically the transport equations. As such, they apply to both the transport of momentum as well as the transport of heat (enthalpy). The transfer of heat between a solid body and a gaseous flow involves the conservation equations of motion and that of heat. In fire problems, the transfer of heat energy from a fire source and the resulting rise in temperature are of great importance, for example, the assessment of a fire barrier performance and fire detection. In the smoke transport problems, the temperature distribution throughout a building, contributing to the stack effect, is also of major importance. To calculate this distribution, it is necessary to solve the energy conservation equation along with the momentum transfer N-S equations.

For an incompressible fluid the energy balance is determined by the internal energy, the conduction of heat, the convection of heat and the generation of heat through friction, and by a heat source.

According to the First Law of Thermodynamics, the energy balance can be written as

$$\underset{\text{rate of heat input}}{\frac{dQ}{dt}} = \underset{\text{rate of change of internal energy}}{\frac{dE}{dt}} + \underset{\text{work done}}{\frac{dW}{dt}} \tag{74}$$

In Equation 74, the radiative heat transfer is neglected.

For a constant property fluid, the energy equation is given by

$$\frac{\partial\theta}{\partial t} + u\frac{\partial\theta}{\partial x} + v\frac{\partial\theta}{\partial y} + w\frac{\partial\theta}{\partial z} = \frac{k}{\rho c_p}\nabla^2\theta \tag{75}$$

where

θ = temperature rise above datum value (e.g., ambient)

k = thermal conductivity

c_p = specific heat at constant pressure

Turbulence

Randomness is the necessary and sufficient condition for turbulent motion. A fluid flow that is highly disordered, rotational, and three-dimensional has all the essential characteristics of turbulence. These features, at first glance, may point to the unpredictability of turbulent flow. Indeed, in reality, it is not possible either to define turbulence in precise terms or to predict precisely its flow characteristics. However, in practice, what is of importance is the effect of turbulence; that is, the way it manifests itself in the flow phenomenon. From this standpoint its definition in precise terms is neither essential nor desirable.

In nature, there is underlying order and regularity; that is, perpetual striving for local equilibrium (harmony). Instability is only a transition (intermediate stage) from one stable state to another. The macroscopic worldview of chaos and randomness pertains to human perception and is a consequence of human inability to relate the intrinsic stability at the infinitesimal scale to the finite world of the observed physical phenomena. It is for this reason that the empirical option of "lumped parameter" is the approach used for statistical descriptions.

On this basis and in order to make any meaningful progress in the treatment of turbulent flow, it is important to recognize that turbulent motion is effectively made up of (1) a mean component, which is intelligible, and (2) a fluctuating component, which is random. In terms of the mean flow, there are very little qualitative differences between the laminar and turbulent flows; that is, the mean motion is fully described. In contrast, fluctuations are based solely on statistical information.

One of the main observed features of turbulence is that it causes diffusion. In other words, it transports the fluid itself and any characteristic associated with it, such as the airborne pollution or smoke particles. In this respect, turbulence is a feature of the flow and not of the fluid. Experimental evidence shows that turbulent fluctuations result from the highly disordered array of eddies of widely different sizes that transport the fluid elements. These turbulent eddies, as they are swept along by the mean flow, undergo both the translational and rotational motion. During this process the larger eddies are distorted and stretched, and consequently break up into smaller ones.

As described, the turbulent motion can be broken down into mean and fluctuating components. Thus, the instantaneous value of a quantity, q, can be written as

$$q = \overline{q} + q'$$

where $\overline{q}$ is the mean with respect to time (time-average), defined as

$$\overline{q} = \frac{1}{\Delta t} \cdot \int_{t_0}^{t_0+\Delta t} q(t)\, dt$$

According to this definition, the time-average of all fluctuating quantities is equal to zero, that is,

$$\overline{q}' = 0$$

Accordingly, the instantaneous velocity and pressure components can be written as

$$u = \overline{u} + u', \quad v = \overline{v} + v', \quad w = \overline{w} + w', \quad p = \overline{p} + p'$$

By substituting these quantities into the continuity equation, it can readily be shown that

$$\frac{\partial \overline{u}}{\partial x} + \frac{\partial \overline{v}}{\partial y} + \frac{\partial \overline{w}}{\partial z} = 0$$

and

$$\frac{\partial u'}{\partial x} + \frac{\partial v'}{\partial y} + \frac{\partial w'}{\partial z} = 0$$

This result shows that the time-average velocity field and the fluctuating velocity components satisfy the same continuity equation as the actual velocity field.

Now, when the above definitions of the instantaneous velocity are substituted in the Navier-Stokes equations and the continuity equation is utilized, the x-direction turbulent form of the Navier-Stokes equation reduces to

$$\overline{u}\frac{\partial \overline{u}}{\partial x} + \overline{v}\frac{\partial \overline{v}}{\partial y} + \overline{w}\frac{\partial \overline{u}}{\partial z} = X - \frac{1}{\rho}\frac{\partial \overline{p}}{\partial x} + \nu\nabla^2\overline{u} - \left(\frac{\partial \overline{u}'^2}{\partial x^2} + \frac{\partial \overline{u}'\overline{v}'}{\partial y^2} + \frac{\partial \overline{u}'\overline{w}'}{\partial z^2}\right)$$

The y- and z-direction equations are of similar form.

From the comparison of the laminar and turbulent forms of these equations, it is clear that, in addition to the usual non-linearities, extra terms involving fluctuating velocity products ($\overline{u}'^2$, $\overline{u}'\overline{v}'$, $\overline{u}'\overline{w}'$) appear on the right-hand side. These terms, which account for the effects of turbulence, are generally known as the *Reynolds stresses* (also sometimes referred to as *apparent* or *virtual stresses*). These additional stresses arise from the turbulent fluctuations and have a similar influence as the viscous terms in the laminar flow case. It is for this reason they are often said to be caused by the *eddy viscosity.* In almost all turbulent flows of practical interest, Reynolds stresses are much larger than the viscous stresses. This relationship is one reason why turbulence is of such great practical importance.

The Navier-Stokes equations, as described, are the exact equations describing the fluid motion. However, in the solution of these equations a formidable mathematical difficulty arises due to the non-linearity of the relation between the velocity and momentum flux, as reflected in the Reynolds stress terms. An approach is therefore used that solves these equations over a numerical grid or mesh within the specified region having prescribed boundary conditions. The exact equations are averaged over a time scale. The Reynolds stresses are expressed in terms of known quantities under the framework of a "turbulence model." Appropriate turbulence models are selected depending on the nature and complexity of the flow phenomena. The so-called k-ε turbulence model is by far the most common and is shown to give the satisfactory answers for engineering applications. For fire applications,

this approach is referred to as "field modeling" in contrast to "zone modeling," which is purely an empirical approach. A detailed discussion of the numerical techniques and the turbulence models is beyond the scope of this text. However, a useful and comprehensive review of these models is given by Kumar.[2]

Flow Similarity and Dimensional Analysis

It is clear so far that the flow characteristics of any fluid flow system are determined not only by the properties of the fluid but also by the geometry of flow. For example, the flow through an open channel and tube will differ because the two flow regimes are not geometrically similar. This statement does not imply that any geometric similarity will produce flow similarity (i.e., dynamic similarity). For a process or physical system to be dynamically similar, the ratios of the forces involved, in addition to the geometrical similarity, must be equal.

In the experimental investigation of the underlying fluid flow phenomena, the small-scale "physical modeling" approach is often used. The basis of this approach relies on the hypothesis that the full-scale physical phenomena can be simulated in a model scale (i.e., small scale) experiment, provided certain non-dimensional parameters (or ratios) are preserved. In other words, provided the physical similarity (e.g., geometric, kinematic, and dynamic similarity) is maintained, the results of the small-scale experiments are assumed to be equally valid for the full-scale case. Table 1-1.2 outlines the physical significance of important dimensionless groups.

Kinematic similarity exists if the particle paths are geometrically similar. Dynamic similarity exists between two geometrically and kinematically similar systems if the ratios of all the forces are equal.

If F_p, F_μ, and F_u are denoted as the pressure, viscous, and inertial forces, respectively, for dynamic similarity

$$\frac{(F_p)_1}{(F_p)_2} = \frac{(F_\mu)_1}{(F_\mu)_2} = \frac{(F_u)_1}{(F_u)_2}$$

or

$$\left(\frac{F_p}{F_\mu}\right)_1 = \left(\frac{F_p}{F_u}\right)_2 = \text{constant}$$

or

$$\left(\frac{F_\mu}{F_u}\right)_1 = \left(\frac{F_\mu}{F_u}\right)_2 = \text{constant}$$

This relationship means that a flow over two spheres of different radii will be dynamically similar, provided

$$\left(\frac{F_u}{F_\mu}\right)_{\text{sphere 1}} = \left(\frac{F_u}{F_\mu}\right)_{\text{sphere 2}} = \text{Re}$$

where Re is a constant.

This constant is generally known as the Reynolds number and is defined as

$$\text{Re} = \frac{\rho V L}{\mu}$$

where

ρ = density of fluid
V = velocity
μ = viscosity
L = sphere diameter

If Re for two kinematically similar flows is the same, the flows are then said to be dynamically similar. Other similarity parameters are given in Table 1-1.2.

Dimensions and Units

There are three fundamental units of measure in fluid mechanics. These fundamental units are mass, *M;* length, *L;* and time, *T.* All the other quantities, such as force and pressure can be expressed in terms of these fundamental units.

If a quantity is capable of being expressed in these fundamental units, the resulting function of *M, L,* and *T* is then termed the dimensions of the quantity.

From Newton's second law of motion, force is given by $F = ma$, where m = mass and a = acceleration.

The dimensions of m are $[M]$ and are written as

$$[m] \triangleq [M]$$

the symbol $\triangleq$ means "has the dimensions of."

Table 1-1.2 ***Important Dimensionless Groups***

Name	Group	Physical Significance
Reynolds number	$\text{Re} = \frac{\rho u l}{\nu}$	Ratio of the inertia force to the friction force
Froude number	$\text{Fr} = \frac{u^2}{lg}$	Ratio of the inertia force to the gravity force—relevant to buoyant flows associated with fires
Grashof number	$\text{Gr} = \frac{gl^3\beta T}{\nu^2}$	Ratio of buoyancy to force to viscous forces, as in fire plumes
Prandtl number	$\text{Pr} = \frac{\mu c_p}{k}$	Ratio of momentum diffusivity to thermal diffusivity

Table 1-1.3 ***Measure Formula or Physical Dimensions of Quantities Occurring in Mechanics (based on mass, length, and time as fundamental units)***

Quantity	Measure Formula	Quantity	Measure Formula
Mass	M	Mass per unit area	ML^{-2}
Length	L	Mass moment	ML
Time	T	Moment of inertia and product of inertia	ML^2
Speed or velocity	LT^{-1}	Stress and pressure	$ML^{-1}T^{-2}$
Acceleration	LT^{-2}	Strain	$M^0L^0T^0$
Momentum and impulse	MLT^{-1}	Elastic modulus	$ML^{-1}T^{-2}$
Force	MLT^{-2}	Flexural rigidity of a beam E1	ML^3T^{-2}
Energy and work	ML^2T^{-3}	Torsional rigidity of a shaft GJ	ML^3T^{-2}
Power	ML^2T^{-2}	Linear stiffness (force per unit displacement)	MT^{-2}
Moment of force	ML^2T^{-2}	Angular stiffness (moment per radian)	ML^2T^{-2}
Angular momentum or moment of momentum	ML^2T^{-1}	Linear flexibility or receptance (displacement per unit force)	$M^{-1}T^2$
Angle	$M^0L^0T^0$	Vorticity	T^{-1}
Angular velocity	T^{-1}	Circulation (hydrodynamics)	L^2T^{-1}
Angular acceleration	T^{-2}	Viscosity	$ML^{-1}T^{-1}$
Area	L^2	Kinematic viscosity	L^2T^{-1}
Volume and first moment of area	L^3	Diffusivity of any quantity	L^2T^{-1}
Second moment of area	L^4	Coefficient of solid friction	$M^0L^0T^0$
Density	ML^{-3}	Coefficient of restitution	$M^0L^0T^0$

Similarly

$$[a] = \left[\frac{L}{T^2}\right] \triangleq [LT^{-2}]$$

and, therefore,

$$F \triangleq MLT^{-2}$$

A table of dimensions for other physical quantities is given in Table 1-1.3.

Dimensional Analysis

When a physical phenomenon is represented by an equation, it is absolutely necessary that all the terms in the equation have the same units, that is, that the equation be dimensionally homogeneous. A quick dimensional analysis of the parameters involved in an equation provides a powerful clue to the homogeneities of the equation.

EXAMPLE 2:

Find the expression for discharge, Q, through a horizontal capillary tube.

The discharge, Q, depends on the following parameters:

pressure drop per unit length	$\Delta p/\ell$
diameter of the tube	D
fluid viscosity	μ

These parameters have the following dimensions:

$$\frac{\Delta p}{\ell} \triangleq ML^{-2}T^{-2}, \qquad D \triangleq L$$

$$\mu \triangleq ML^{-1}T^{-1}$$

Therefore,

$$Q = k\left(\frac{\Delta p}{\ell}\right)^{\alpha} \cdot D^{\beta} \cdot \mu^{\gamma}$$

that is,

$$[L^3T^{-1}] = k[ML^{-2}T^{-2}]^{\alpha} \cdot [L]^{\beta} \cdot [ML^{-1}T^{-1}]^{\gamma}$$

From the principle of homogeneity and by comparing the exponents of each dimension

$$\gamma + \alpha = 0 \quad \text{from } [M]$$

$$\beta - 2\alpha - \gamma = 3 \quad \text{from } [L]$$

$$2\alpha + \gamma = 1 \quad \text{from } [T]$$

Solving these equations gives

$$\alpha = 1, \quad \gamma = 1, \quad \beta = 4$$

Therefore, the equation for discharge, Q, becomes

$$Q = k\left(\frac{\Delta p}{\ell}\right)^{1} \cdot D^4 \cdot \mu^{-1} = k\,\frac{\Delta p}{\ell} \cdot \frac{D^4}{\mu}$$

No information about the numerical value of the dimensionless constant k can be obtained from the equation. This information can be obtained, however, from the experiment.

Boundary Layers

When a fluid flows over a solid boundary (surface), the velocity at the surface is zero (no-slip condition). This

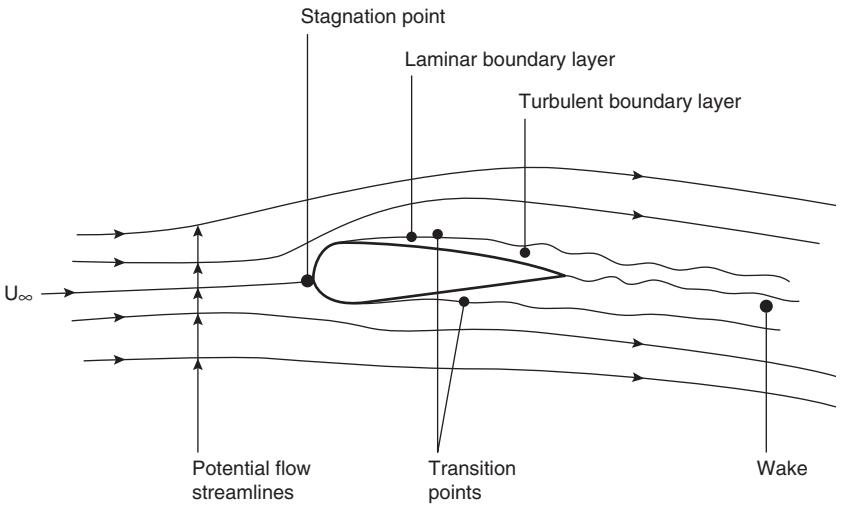

Figure 1-1.19. ***Flow over a two-dimensional aerofoil.***

velocity increases with the distance away from the surface and eventually becomes equal to the free stream velocity. Therefore, a region exists close to the surface of the body in which the velocity varies with distance. This region is called the boundary layer. Within this region each layer of fluid moves relative to the adjacent layer, and as a result large shear stresses are set up within the boundary layer. An important approximation can be made in solving the Navier-Stokes equations such that viscosity only plays a role within the boundary layer, while outside this layer the fluid can be treated as inviscid ($\mu = 0$).

Physics of Boundary Layers

The flow over a two-dimensional aerofoil is shown in Figure 1-1.19.

It can be observed that over the forward part, the flow is smooth and the streamlines are parallel to the surface. This region is known as the laminar boundary layer.

But as the flow progresses over the surface of the aerofoil toward the trailing edge, the streamlines break up, and there are random fluctuations in velocity, direction, and magnitude, even though the general mean motion remains roughly parallel to the surface. This region is called the turbulent boundary layer. As the flow leaves the surface behind the body, it merges to form a stream of relatively slow-moving fluid, which is known as the wake. Consequently, the velocity profiles in the turbulent and laminar boundary layers are quite different. The measurements of velocity profiles on a flat plate are shown in Figure 1-1.20.

This figure shows that the velocity gradient at the surface ($\partial u/\partial y$) is much greater in the turbulent boundary layer than in the laminar boundary layer. It follows that the frictional stresses, τ_w,

$$\tau_w = \mu\left(\frac{\partial u}{\partial y}\right)_{y=0} \tag{76}$$

at the wall surface, that is, the drag, are much greater for the turbulent than the laminar boundary layer.

As the pressure increases downstream along the surface, the velocity is decreased within the boundary layer. Thus, as $\partial p/\partial x$ increases, $\partial u/\partial y$ decreases. With any further increases in this pressure gradient a stage may be reached where $\partial u/\partial y$ at the wall is zero, and the fluid adjacent to the surface is then on the point of reversing its direction of flow. The boundary layer is then said to be on the point of separation, as illustrated in Figure 1-1.21.

Subsequently, the velocity gradient (du/dy) at the wall becomes negative downstream of separation, and an inner portion of the boundary layer then flows against the stream. This reversed flow forms a large eddy under the outer part of the boundary layer. These eddies carry a large amount of energy, which results in the increase of drag on the body.

A body with extensive boundary layer separation and a wake with large-scale eddies is referred to as a bluff body. In contrast, a body on which the boundary layer remains attached over the whole surface to the rearmost point and then merges smoothly into the wake without the formation of any large-scale eddies is referred to as a streamline body.

The nature and magnitude of drag on these two shapes of bodies are quite different. The drag of a bluff body is usually very large and is almost entirely due to the energy wasted in the castoff eddies. Drag can be determined fairly accurately from the pressure distribution acting normal to its surface. The drag of a streamline body is relatively small and is mainly due to the viscous or frictional stresses that act tangential to its surface.

Boundary Layer Thickness

The velocity within a boundary layer varies from zero at the surface to free-stream velocity just outside the boundary layer. The boundary layer thickness, δ, is defined as the distance from the wall at which the velocity reaches 99 percent of the free-stream velocity (at $y = \delta$, $u = 0.99U_\infty$).

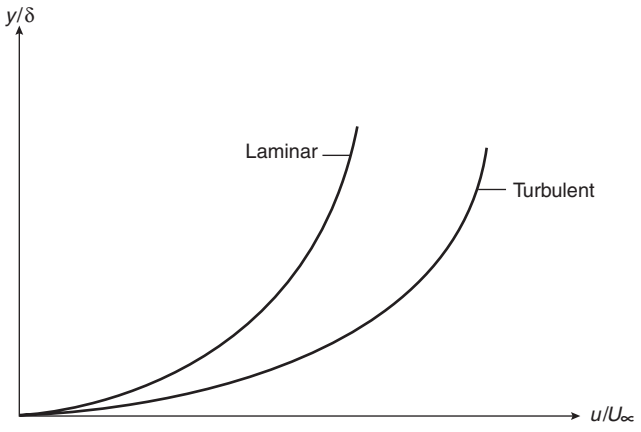

Figure 1-1.20. ***Velocity profiles over a flat plate.***

The displacement thickness, δ^*, is defined as that distance by which the external potential field of flow is displaced outward as a consequence of the decrease in velocity in the boundary layer. The precise form of displacement thickness is

$$\delta^* = \int_{y=0}^{\infty} \left(1 - \frac{u}{U_\infty}\right) dy \tag{77}$$

Momentum thickness, θ, is defined as

$$\theta = \int_{y=0}^{\infty} \frac{u}{U_\infty}\left(1 - \frac{u}{U_\infty}\right) dy \tag{78}$$

From this equation it is clear that $\rho U_\infty^2 \theta$ represents the defect in the rate of transport of momentum in the boundary layer as compared with the rate of transport of momentum in the absence of the boundary layer.

Energy thickness, δ_E, is defined as

$$\delta_E = \int_{y=0}^{\infty} \frac{u}{U_\infty}\left[1 - \left(\frac{u}{U_\infty}\right)^2\right] dy \tag{79}$$

The quantity $\rho U_\infty^3 \delta_E/2$ represents the defect in rate of transport of kinetic energy in the boundary layer when compared with the rate of transport in the absence of the boundary layer.

Flows in Pipes and Ducts

The flow in the inlet length of a circular pipe of constant cross section is shown in Figure 1-1.22. Initially, at distances very close to the inlet, the flow is uniform with a boundary layer of very small thickness forming very close to the wall surface.

The velocity profile across the pipe changes continuously downstream. As the boundary layer on the wall grows downstream, the velocity in the central region increases to compensate for this growth, since the equation of continuity must hold true. At some distance from the inlet the boundary layers merge and the flow becomes fully developed. Onward from this distance, the velocity profile remains the same. Since the velocity profile in the fully developed flow is constant, it follows that the force due to friction at the pipe wall exactly balances that force due to the pressure gradient down the pipe required to maintain the flow.

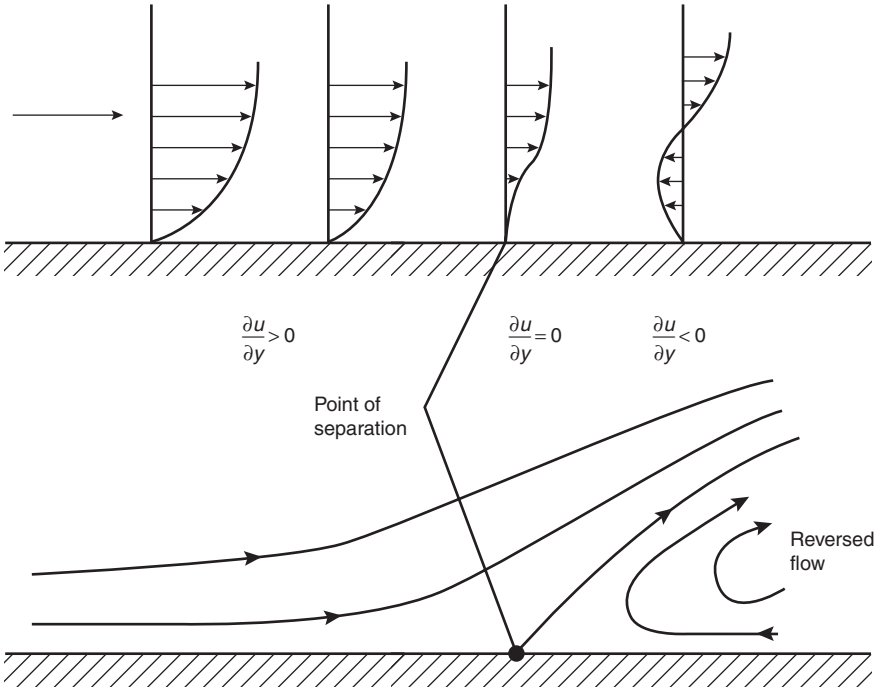

Figure 1-1.21. ***Point of separation and flow reversal.***

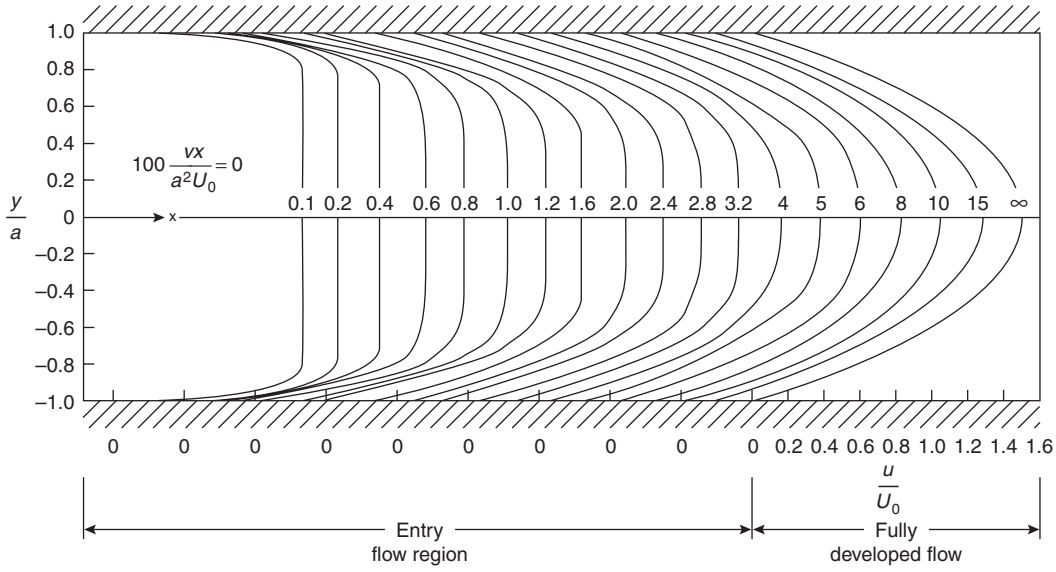

Figure 1-1.22. ***Development of laminar boundary layer in a pipe.***

Laminar Flow in a Pipe

With fully developed laminar flow in a smooth-walled pipe, the fluid moves under the influence of the pressure gradient and is retarded by the frictional forces acting on the wall surface. (See Figure 1-1.23.)

For equilibrium in the x-direction, the pressure force must balance the shear force, that is,

$$2\pi y\ell \cdot \tau = (p_2 - p_1)\pi y^2 \tag{80}$$

since

$$\tau = -\mu \frac{du}{dy} \tag{81}$$

Therefore,

$$\frac{du}{dy} = -\frac{p_2 - p_1}{\mu\ell} \cdot \frac{y}{2} \tag{82}$$

Integrating Equation 80 with 81 and 82 gives

$$u(y) = \frac{p_1 - p_2}{\mu\ell}\left(C - \frac{y^2}{4}\right) \tag{83}$$

The constant of integration, C, is obtained from the no-slip condition at the wall.

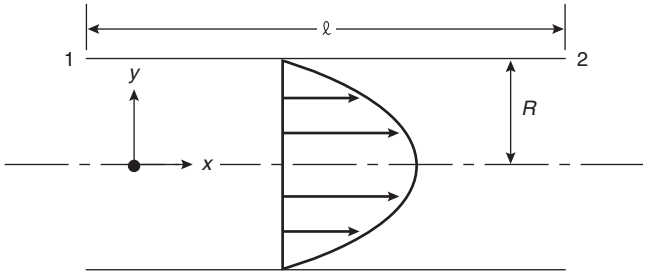

Figure 1-1.23. ***Fully developed laminar flow in a pipe.***

Thus, $u = 0$, $y = R$, so that $C = R^2/4$. Hence

$$u(y) = \frac{p_1 - p_2}{4\mu\ell}(R^2 - y^2) \tag{84}$$

This equation shows that the velocity is distributed parabolically over the radius. The same result is arrived at using the method of dimensional analysis (see the dimensional analysis example in this chapter) and also using the Bernoulli equation (Equation 55).

The maximum velocity on the pipe axis is

$$u_{\max} = \frac{p_1 - p_2}{4\mu\ell} R^2 \tag{85}$$

The volume of fluid passing in unit time is

$$Q = \frac{\pi}{2} R^2 U_{\max} = \frac{\pi R^4}{8\mu\ell}(p_1 - p_2) \tag{86}$$

The average velocity of flow is

$$\overline{u} = \frac{Q}{\pi R^2} \tag{87}$$

The expression for Q is known as the Hagen-Poiseuille equation of laminar flow through a pipe. This expression is only valid if the flow Reynolds number is less than the critical Reynolds number for a pipe (i.e., $\overline{u}d/\nu \leq 2300$, with $d = 2R$).

Turbulent Flow in a Pipe

Measurement of velocity profiles for a fully developed turbulent flow in a pipe shows that it is very different from the parabolic laminar profile just discussed. This difference results because in turbulent flow extra shear stresses are developed due to the turbulent momentum transfer from one layer to the other.

The shear stresses in the turbulent flow can be expressed as

$$\frac{\tau}{\rho} = \nu \frac{d\overline{u}}{dy} + \varepsilon \frac{d\overline{u}}{dy} \tag{88}$$

where

ν = kinematic viscosity

ε = eddy viscosity

$\overline{u}$ = mean velocity

For a smooth pipe, ε is very nearly equal to zero.

From the experimental measurements of turbulent flow in pipes conducted by Nikuradse,[3] three regions of flow can be identified. (See Figure 1-1.24.)

The profile is expressed in terms of the shearing or friction velocity, defined as

$$U_* = \left(\frac{\tau_w}{\rho}\right)^{1/2} \tag{89}$$

In a region very close to the surface, the velocity is proportional to the radial distance measured from the wall, y, and

$$\frac{u}{U_*} = \frac{yU_*}{v} \tag{90}$$

This region is called the laminar sublayer. In this region

$$\mu\left(\frac{d\overline{u}}{dy}\right) \gg \varepsilon\left(\frac{du}{dy}\right) \tag{91}$$

In the transition region the turbulent friction and the laminar friction are of the same order of magnitude. This result is true for the following range.

$$5 < \frac{yU_*}{v} < 70 \tag{92}$$

In the turbulent region the laminar contribution is negligible compared with the turbulent friction. This result occurs when

$$\frac{yU_*}{v} \geq 70 \tag{93}$$

For this region the following semi-empirical relation holds very well for the velocity profile. The contribution from eddy viscosity is also higher.

$$\frac{\overline{u}(y)}{U_\tau} = 5.75 \log_{10}\left(\frac{yU_\tau}{v}\right) + 5.5 \tag{94}$$

Duct Flows

In dealing with flow through noncircular cross section ducts, a parameter called the hydraulic radius, R_h, is defined as

$$R_h = \frac{2A}{C} \tag{95}$$

where A denotes the cross-sectional area and C is the wetted perimeter of the duct.

In the case of a circular cross section the hydraulic radius is equal to the radius of the circle.

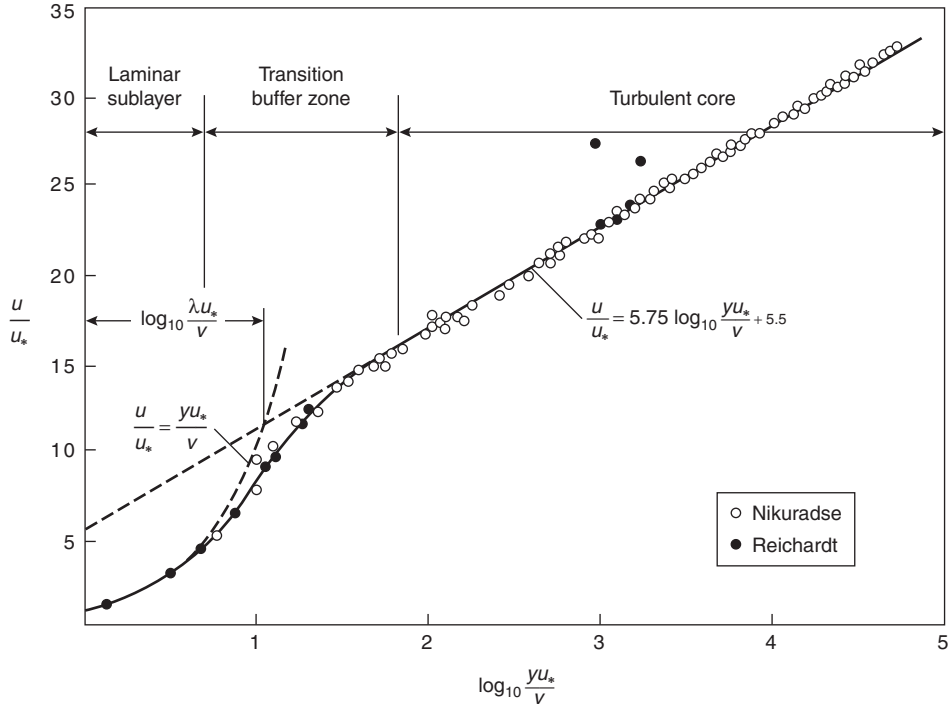

Figure 1-1.24. ***Measurement of turbulent velocity profile in a pipe.[1]***

Table 1-1.4 ***Laminar Flow Through Rectangular Ducts[4]***

Laminar flow: For a circular cross section pipe of diameter, d, of length, L, with pressure difference $(p_1 - p_2)$, the friction factor, λ, is defined as

$$\lambda = \frac{p_1 - p_2}{L} \cdot \frac{d}{1/2\rho\overline{u}^2} \tag{96}$$

Similarly, for noncircular cross section pipe, friction factor can be defined based on the hydraulic radius as

$$\lambda' = \frac{p_1 - p_2}{L} \cdot \frac{R_h}{1/2\rho\overline{u}^2} \tag{97}$$

For any noncircular shape the relationship between the friction factor and Reynolds number can be expressed in the form

$$\lambda' = \lambda C_1 \tag{98}$$

where C_1 is a function of geometry and λ is the friction factor for the flow in a circular pipe of the same Reynolds number, $\mathrm{Re} = uR_h/\nu$.

The values of C_1 for rectangular cross section ducts are given in Table 1-1.4.

Turbulent flow: Turbulent flow measurements show that for noncircular cross section ducts, the velocities at the corners are comparatively very large. This increase in velocity results because of secondary flows, which arise because all three components of the fluctuating velocity are nonzero. These flows are not present in the corresponding laminar motion because the fluctuating velocity components are not present. The secondary flows continually transport momentum from the center to the corners and generate high velocities there as shown in Figure 1-1.25.

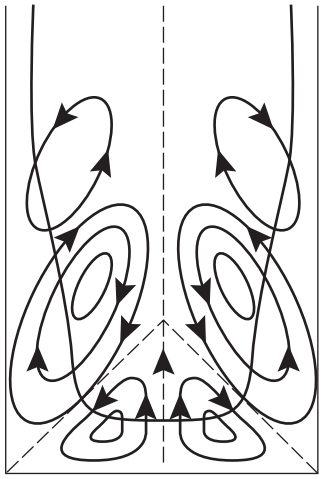

Figure 1-1.25. ***Secondary flows in the corners of a rectangular duct.[3]***

Turbulent velocity measurements in a rectangular duct made by Nikuradse are shown in Figure 1-1.26.

Building Aerodynamics and Applications to Fire Engineering

In general, building aerodynamics is concerned with the study of atmospheric wind flows and wind loading on buildings and structures. Such a study is important in building design, as large wind-induced loads may result in the instability and eventual collapse of a structure. Collapse of chimney stacks and suspension bridges are examples of such failures.

In fire engineering, obvious applications of such studies are in the problems relating to smoke control and buoyancy-driven roof vent design. Other applications may include the ingress of smoke and other contaminants from external sources and the effects of wind on fire spread.

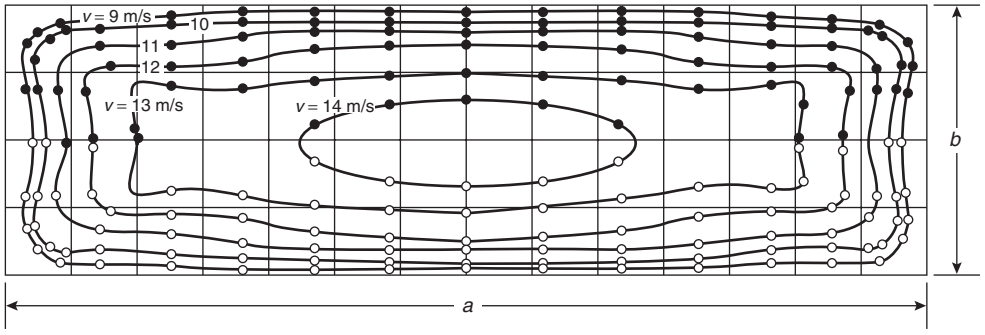

Figure 1-1.26. ***Axial turbulent contours in a rectangular duct.[3]***

Over the past two decades a large amount of experimental data, both in the wind-tunnel studies and full-scale measurements, has been collected for a wide range of building shapes and structures.[5–7] Initially, because of their immediate applications to structural design, most of the information was presented in the form of the wind loads. However, in recent years, attention has also been focused on the effects of wind on internal environment systems, such as ventilation and air conditioning. This research is important in controlling the spread of contaminants (such as smoke and other airborne particles generated by fire or explosion) to other parts of the building. Various smoke-control measures that are currently in use require the effects of wind to be taken into account in their design. It is essential that large pressure differentials do not hinder escape while serving to confine smoke to the fire areas. The design of a pressurization system, therefore, requires information on the flow field around, as well as inside, the building.

The wind-induced internal and external pressure distribution for a given building is determined not only by the building shape or size, but also by the wind characteristics. These characteristics include the wind velocity profile (which is terrain specific) and the level of turbulence (generated by the adjacent buildings) of the approaching wind.

Natural Wind Characteristics

On the global scale the movement of wind and weather systems is dependent on such factors as the location, vertical temperature gradient, the earth's rotation, etc.[8] In a region very close to the earth's surface the variation of wind velocity with height is considerable and is influenced by the surface roughness. This region is usually referred to as the terrestrial boundary layer. The height at which the velocity becomes independent of the surface roughness is called the gradient height (boundary layer thickness), Z_G, and the corresponding wind speed is called the gradient wind speed.

Figure 1-1.27 shows the terrestrial boundary layer velocity profile for a range of terrain (surface roughness) categories. Category 1 refers to plain areas such as deserts and the open sea, while Category 4 refers to the high-roughness city centers with numerous tall buildings. The other categories lie between these two limits.[9]

For the purposes of wind-tunnel investigations, the wind velocity profile is usually represented by a power law profile of the type,

$$\frac{\overline{V}_Z}{V_{Z_G}} = \left(\frac{Z}{Z_G}\right)^{\beta} \tag{99}$$

where $\overline{V}_Z$ is the mean wind speed at height Z and β is a constant, which varies for different terrain categories. For example, for Category 1, $\beta = 0.11$; and for Category 4, $\beta = 0.36$.

Wind Flow over Buildings

Wind-tunnel studies show that when buildings of rectangular cross section are subjected to a power law velocity profile, as shown in Figure 1-1.27, the windward surface of the building experiences positive pressures (i.e., higher than the atmospheric pressure) while all the other surfaces, including the roof, experience negative pressures (i.e., lower than the atmospheric pressure). These pressures are illustrated in Figure 1-1.28.

As the air flows toward the building it is slowed down and comes to rest at a point "*S*," called the stagnation point, on the windward surface. The total pressure increases with height up to the stagnation point and begins to decrease toward the roof. Below this point the pressure gradient down the face of the building causes air to flow down the building. At the ground level the flow

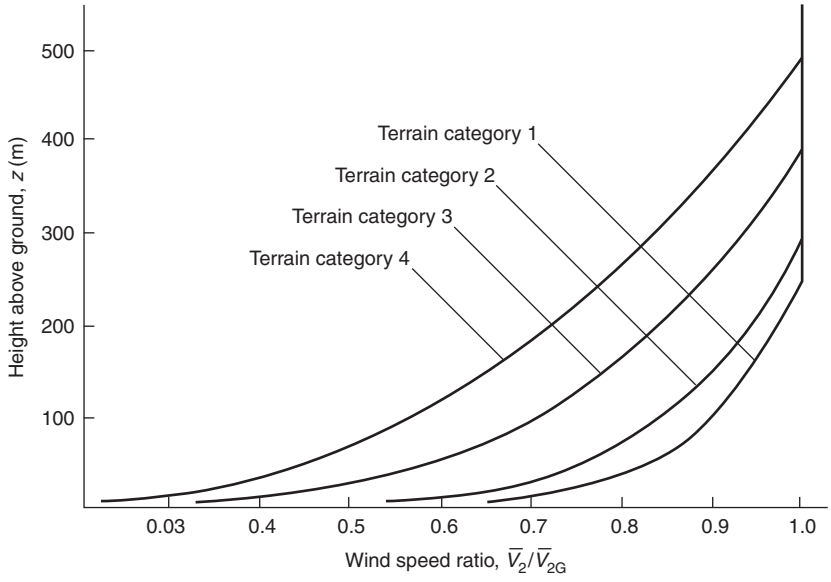

Figure 1-1.27. ***Velocity profile in the terrestrial boundary layer.[8]***

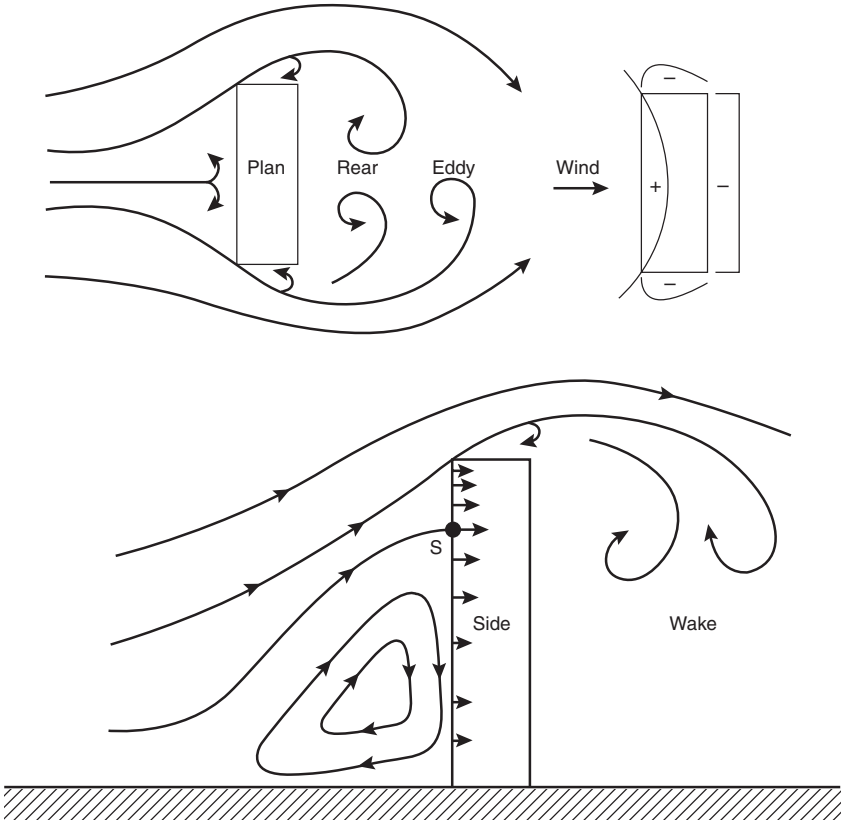

Figure 1-1.28. ***Flow over a tall building.***

turns and starts to flow upwind. At some distance from the building the flow is opposed by the oncoming wind and once again turns and starts to flow up toward the building. This way a vortex is set up in front of the building as illustrated in Figure 1-1.28.

The pressure measurements are usually expressed in terms of a pressure coefficient defined as

$$C_p = \frac{p - p_0}{1/2\rho V_H^2} \tag{100}$$

where

p = total pressure at a point
p_0 = static pressure at that point
V_H = wind speed at building height
ρ = air density

Figures 1-1.29(a) and 1-1.29(b) show wind-tunnel pressure measurements on the walls of a model building shown in Figure 1-1.29(c).[10] It is clear that, on the windward side [Figure 1-1.29(b)], the pressure is the highest at a point on the fourth-floor level (the stagnation point). This point usually occurs at about four-fifths the height of the building. On the rear wall (side R, for wind incidence $\alpha = 0$ degrees) the pressure distribution is negative but fairly constant. These negative pressures on the walls are caused by the eddies generated as a result of flow separation at the sharp corners of the building. Because of these marked pressure variations on the walls, internal flow patterns are set according to these variations.

Wind-Induced Internal Flows

For completely sealed buildings, the outside wind has no effect on the internal flow patterns in a building. The internal flows are greatly influenced by the outside wind for a building with outside doors and windows. The magnitude of internal pressure distribution is a function of wind speed, building geometry, and building leakage characteristics. Wind-tunnel experiments[11] show that the wind-induced internal pressures are determined by the outside pressures on the wall with highest leakage. The results are summarized in Figure 1-1.30, in which the leakage ratio, R, is defined as the ratio of the total leakage area of the windward wall to the total leakage area of the rear wall.

The curve for $\alpha = 0$ degrees clearly shows that as the windward wall leakage area is increased, the internal pressure is also increased. For the case of $\alpha = 90$ degrees, both the leaky walls are under negative outside pressure and the internal pressure is negative, as expected, and does not change very much with the leakage ratio.

Such a marked change in internal pressure due to the outside wind can have serious implications for the functioning of smoke extract vents used in these types of buildings.

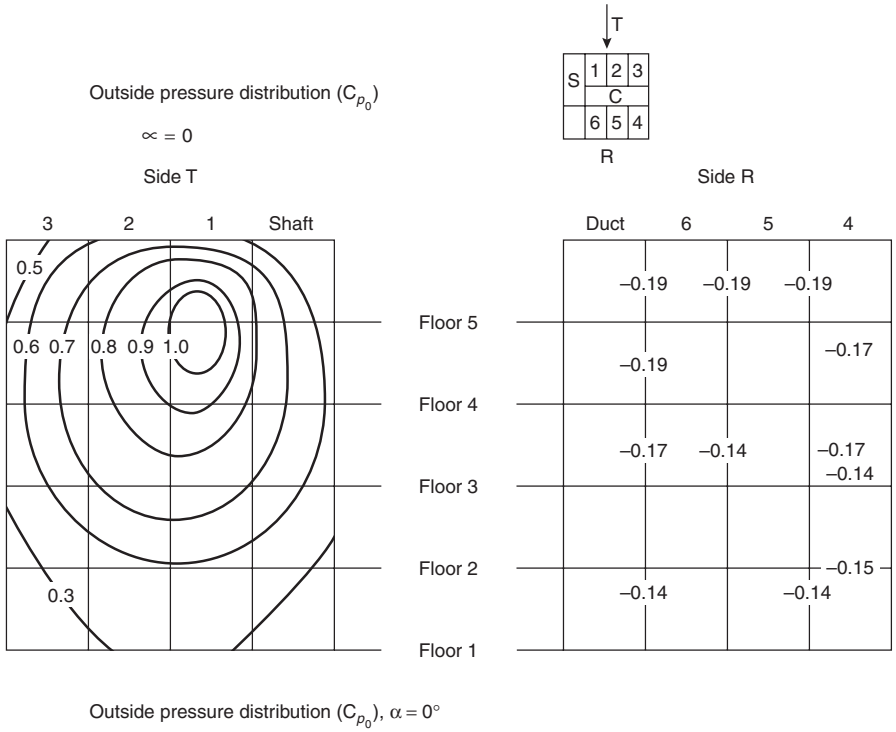

Figure 1-1.29(a). ***Outside pressure distribution (C_p), α = 0 degrees.***

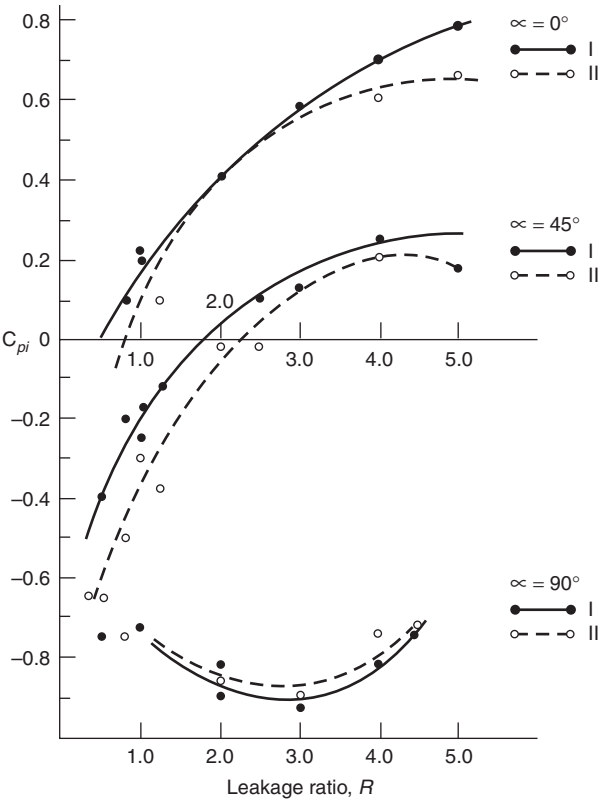

Figure 1-1.30. ***Variation of internal pressure, C_{pi}, with leakage ratio, R, for wind direction α = 0 degrees, 45 degrees, and 90 degrees.[11]***

Smoke Movement in Tall Buildings

When fire occurs in a building, smoke or toxic gases are carried to other parts of the building interior by the preexisting airflows. These flows are a function of the outside wind as well as the building leakage characteristics. For the example of a high-rise building (Figure 1-1.31), if fire occurs in a room that has window openings on a wall

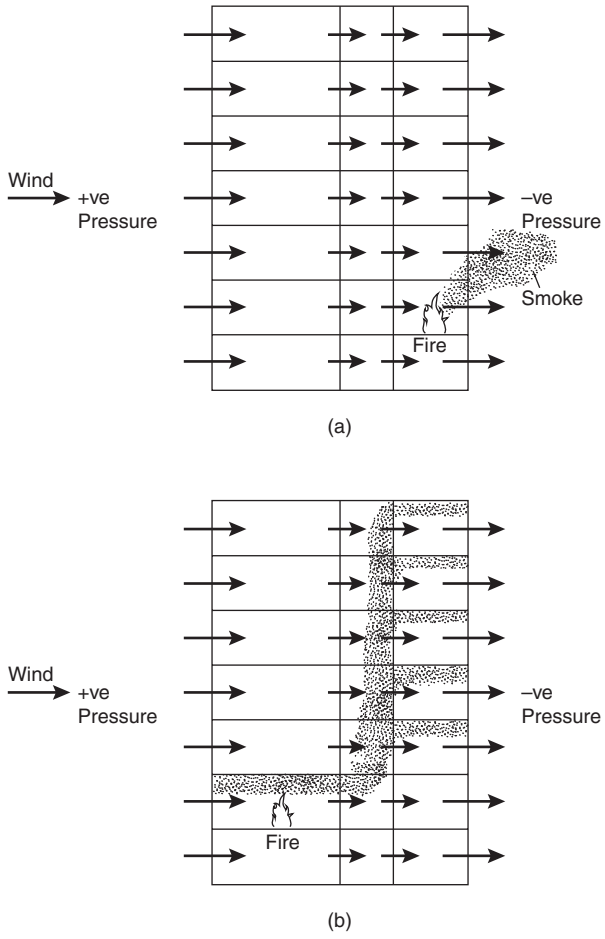

Figure 1-1.31. ***Smoke movement in a high-rise building.***

subjected to negative wind-induced pressures, most of the smoke will be drawn out of the building by the prevailing negative pressures on that wall. Smoke will be prevented from flowing into the building by the positive pressure there (Figure 1-1.31b).

However, the situation is reversed if the fire room has its window openings on the windward wall. The prevailing positive pressure on this wall will push the smoke into the building, where it will spread to other parts of the building, carried there by pre-existing flows.

If under such conditions a smoke control pressurization system is used, the design of such a system must account for the wind-induced pressures. Otherwise, the system may cause overpressure (preventing escape of occupants) or underpressure (rendering the system ineffective) within the building.

Roof Vent Design

For large single-space buildings (warehouses and factories, etc.), roof vents are used to extract smoke in fire situations. Usually, the design of these vents is based on the assumption that smoke buoyancy is the only force driving the smoke out. This assumption may not be true for very

tall buildings because the smoke cools very quickly as it moves up toward the ceiling. When this situation happens, the buoyant force of the smoke can be negligibly small, reducing the rate of flow through the vent.

If a sufficiently strong wind is blowing, the roof is subjected to considerable, high, wind-induced, negative pressures. These pressures can add to the buoyancy of the smoke with a subsequent increase in the extract flow velocity and mass rate. A situation may arise when the vent starts extracting clear air from underneath the hot layer. Under such conditions (Figure 1-1.32), the efficiency of the vent is decreased.

Therefore, a critical mass flow rate or cirtical vent area exists which must not be exceeded or the vent will be ineffective.[11] Figure 1-1.33 shows the variation of calculated critical vent area with leakage ration. These calculations were performed on the basis of roof pressure distribution shown in Figure 1-1.34.

Nomenclature

A	Area
b	Channel width (Figure 1-1.8)
C	A constant
C_p, C_p	Specific heat at constant pressure, or pressure coefficient
C_v	Specific heat at constant volume
d	Diameter, or characteristic length
E	Internal energy
F	Force
Fr	Froude number
g	Acceleration due to gravity
Gr	Grashof number
K	Bulk modulus
k	A constant, or thermal conductivity
L, l	Length, pipe length
m	Mass of fluid, or mass per unit length
M	Mass, or molecular weight
P, p	Pressure at a point

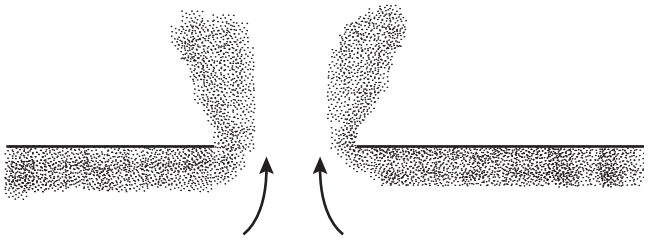

Figure 1-1.32. ***Operation of a roof vent.[12]***

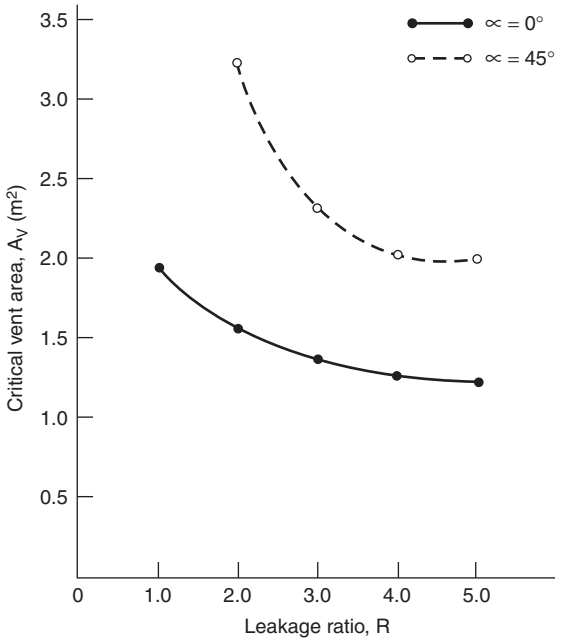

Figure 1-1.33. ***Variation of critical vent area (Av_{exit}) with leakage ratio R, for α = 0 degrees, 45 degrees.[11]***

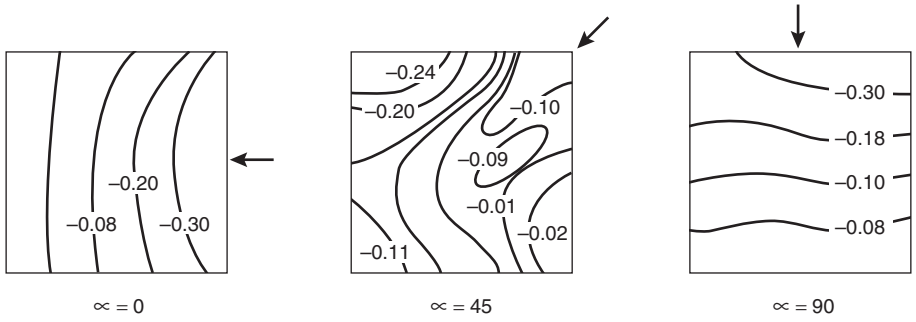

Figure 1-1.34. ***Pressure contours on the roof (C_{p0}) for wind directions α = 0 degrees, α = 45 degrees, and α = 90 degrees.[11]***

Pr	Prandtl number
q	Quantity of heat per unit mass
Q	Volume flow rate, or heat flux
R, r	Radius
R_L	Hydraulic radius
$\overline{R}$	Universal gas constant
Re	Reynold's number
T	Temperature
t, T	Time
u, v, w	Velocity components in the x, y, z direction, respectively
$\overline{u}, \overline{v}, \overline{w}$	Mean velocity components in the x, y, z direction, respectively
u', v', w'	Fluctuating velocity components in the x, y, z direction, respectively
U_∞	Free stream velocity
U_*	Friction velocity (Equation 89)
v	Volume of fluid
v_r, v_θ	Velocity components in the r and θ directions respectively
V	Volume of fluid (Equation 26), velocity (Equation 55)
V_H	Wind speed at building height
W	Work
x, y, z	Cartesian co-ordinates
$\overline{y}$	Position of centroid in the y direction
Z	Distance in the vertical direction
∇	Laplace's operator

Greek Symbols

α	Angle (Figure 1-1.2)
β	Coefficient of compressibility
β_1	Coefficient of thermal expansion
Γ	Circulation (Equation 53)
δ^*	Displacement thickness
δ_E	Energy thickness (Equation 79)
ε	Eddy viscosity
ϕ	Velocity potential
λ	Friction factor
μ	Coefficient of viscosity
ν	Kinematic viscosity
π	A constant (3.142)
θ	Angle (Figure 1-1.3)
ρ	Fluid density
σ	Surface tension coefficient
τ	Shear stress
ω	Angular velocity
ψ	Stream function
ζ	Vorticity

CHAPTER 2

Conduction of Heat in Solids

John A. Rockett and James A. Milke

Introduction

There are three mechanisms by which heat (thermal energy) is transferred from one object to another: (1) radiation, (2) convection, and (3) conduction. This chapter addresses both heat conduction and the historic development of heat conduction theory.[1–5]

Before discussing heat conduction, it is useful to consider the heat content of an object; that is, the property of the object subject to movement by conduction. The heat content of an object, Q, and its temperature are closely linked. When the heat content of one gram of water at 0°C is increased by one calorie, its temperature increases one degree Celsius. Heat content is associated with the kinetic energy of vibration of the atomic particles of which an object is composed. Since at absolute zero temperature all motion stops, heat content is zero at zero (absolute) temperature. In metals, where there are free electrons (those electrons not localized on a particular atom, but free to move through the crystal lattice), some of the heat content is associated with this electron ''gas.'' In all materials the atoms vibrate about their average position in the crystal lattice. Atomic vibration within the crystal lattice (standing acoustic waves called "phonons") accounts for the remainder of the heat content. The hotter the object, the more violent is the vibration of the electrons and atoms. Thus the transfer of heat from one body to another, or from one part of a body to another part of the same body, is equivalent to transferring the kinetic energy of vibration from particles in one location to those in another, adjacent location.

Dr. John A. Rockett, formerly senior scientist, U.S. National Bureau of Standards, is a consultant based in Washington, DC. His research has focused on the growth and spread of fire and the development of analytic models for describing fire in buildings.

James A. Milke is associate professor of fire protection engineering at the University of Maryland. His recent research activities have included the impact of fires on the structural response of steel and composite members, as well as the design of smoke management systems.

The heat content of an object is expressed as the integral of the material's specific heat with respect to temperature from absolute zero to the temperature in question, that is,

$$q''' = \int_o^T \rho c \, dT$$

The inability to correctly calculate specific heat was one of the singular failures of classical physics. The roots of modern quantum physics lie in the work of Planck, Lorentz, and Einstein to resolve this problem. Building on their work, Debye, and (independently) Born and von Karman, published a theory of specific heat in 1912, which is still accepted today with only refinements in detail. According to this theory, the specific heat rises from zero at zero temperature and approaches a constant at high temperature. A temperature characteristic of the material, or the "Debye temperature," determines the region where transition from rising to constant specific heat occurs. At a point well above the Debye temperature, the specific heat is given by the classical, constant value; below it, quantum effects must be included. For heavy atoms the Debye temperature is well below room temperature, but it is higher for light atoms. Beryllium, for example, is light enough that its specific heat varies noticeably near room temperature. For aluminum at room temperature the specific heat is 93 percent of the classical value; for copper, 95 percent. For some minerals, however, the Debye temperature is quite high and the assumption of constant specific heat may lead to significant errors. Nevertheless, constant specific heat is generally assumed, usually without discussion, in heat conduction studies.

Heat conduction is observed when a hot object is brought in physical contact with a cold one: the hot object cools and the cold one is heated. This process was studied by Newton but, in the modern sense, first quantified by Fourier in 1812. Fourier's equation states that the quantity of heat transferred per unit time across an area, A, is pro-

portional to the area and the temperature gradient, dT/dx. The heat flows from the hotter to the cooler material, so

$$\dot{q} = -kA\frac{dT}{dx}$$

where

A = surface area across which heat is transferred (m^2)
d = differential operator
k = thermal conductivity of the solid (W/m·K)
$\dot{q}$ = the rate of heat flow across the area A (W)
T = temperature (K)
x = distance normal to the surface A (m)

A more modern and more precise statement of Fourier's law is

$$\frac{dQ}{dt} = -\int_A (k_{ij}T_{,j})n_i\, dA$$

where

Q = heat content (Joules) of the material inside the closed surface A
n_i = outward directed vector normal to the surface element dA
t = time
$T_{,j}$ = vector gradient of the temperature of the object
k_{ij} = thermal conductivity (written here in its most general form as a tensor)
A = integral taken over the entire surface

The thermal conductivity of a material, k, will play a central role in what follows. Wiedemann and Franz observed in 1853 that electrical and thermal conductivity were proportional for metals. This observation suggests that the kinetic energy of free electrons is primarily responsible for heat transfer. This is a good first approximation for good electrical conductors, where free electrons are abundant. Sommerfeld, in 1928, calculated the Wiedemann-Franz ratio (ratio of thermal to electrical conductivity) based on a quantum mechanical model for the free electron gas. He found

$$\frac{k}{T}\sigma = 2.45 \times 10^{-8}$$

where σ is electrical conductivity, and T is absolute temperature. This relation is obeyed (error less than about 10 percent) by gold, silver, copper, copper-silver alloys, tungsten, and molybdenum for absolute temperatures from 50 to 360 K.

If this were all that was involved, electrical insulators would conduct virtually no heat. Actually, although heat is poorly conducted by electrical insulators, the amount of heat conducted is orders of magnitude too great to be accounted for solely by free electron conduction. Thus, the ratio of electrical conduction of glass to that of gold is 1.44×10^{-19}, but the ratio of their thermal conduction is 2.5×10^{-2}. Phonons are present in all solids heated above absolute zero. However, if the crystal lattice were perfect, and the material perfectly pure, the material would conduct no heat because these standing, acoustic waves would experience no attenuation. But imperfections within the solid (e.g., missing atoms-vacancies, extra atoms-interstitials, and lattice imperfections-dislocations) scatter the phonons and free electrons when they are present. It is this scattering that diffuses the phonon energy to produce heat conduction in electrical insulators.

Because cold-working a metal increases dislocations and heat treatment (e.g., precipitation hardening), lattice imperfections, thermal conductivity, as well as physical properties, can be significantly altered by these treatments. In general, treatments that increase hardness will decrease thermal (and electrical) conduction.

For some materials, for example, some laminates and fibrous materials such as wood and reinforced plastics, the thermal conductivity differs depending on whether the heat flow is parallel or across the grain. For these materials, the thermal conductivity, in general, differs with the direction of the heat flow. This pattern is the most general case, and will be addressed in this chapter. For these materials (orthotropic solids), the conductivity is a diagonal matrix (its only nonzero elements are the diagonals, k_{ii}). These are normally written simply k_1, k_2, k_3. In other materials, most notably some types of crystals, the off-diagonal elements of the k matrix are nonzero. For these materials the conductivity must be expressed as a general matrix (tensor).

From this brief discussion it is clear that the theoretical basis for thermal analysis is comparatively recent. The mathematical analysis of heat conduction used today was, however, well-established by the end of the last century.

Equation of Heat Conduction

Fourier's equation of heat conduction (as given in the introduction to this chapter) has been generalized to the basic, modern statement of conductive heat transfer. To reproduce this, consider a small rectangular block of material with density, ρ, specific heat, c, thermal conductivity, k, and average temperature, T. This small block is a segment of a much larger solid. Let the small block be oriented parallel to a Cartesian coordinate system, x, y, z, and let its dimensions be dx, dy, and dz measured along the respective axes. The center of the block is at location x, y, z.

If the temperature within the solid varies nonuniformly, the heat flux entering the small block across the face with area $dydz$ located at $x - dx/2$ may be different from the heat leaving across the parallel face at $x + dx/2$. According to Fourier's law and using a Taylor-series expansion for k and T, the difference in heat flux would be

$$\begin{aligned}\dot{q}_{x-\text{net}} &= \left[\dot{q}''\left(x+\frac{dx}{2}\right) - \dot{q}''\left(x-\frac{dx}{2}\right)\right]dy\,dz \\ &= \left\{\left[\left(k_1 + \frac{\partial k_1}{\partial x}\frac{dx}{2}\right)\left(\frac{\partial T}{\partial x} + \frac{\partial^2 T}{\partial x^2}\frac{dx}{2}\right)\right]\right. \\ &\quad \left. - \left[\left(k_1 + \frac{\partial k_1}{\partial x}\frac{dx}{2}\right)\left(\frac{\partial T}{\partial x} - \frac{\partial^2 T}{\partial x^2}\frac{dx}{2}\right)\right]\right\} dy\,dz \end{aligned} \quad (1)$$

Expanding this and neglecting terms containing (dx^2), the result is

$$\dot{q}_x = \frac{\partial}{\partial x}\left(k_1 \frac{\partial T}{\partial x}\right) dx\, dy\, dz$$

Similarly,

$$\dot{q}_y = \frac{\partial}{\partial y}\left(k_2 \frac{\partial T}{\partial y}\right) dx\, dy\, dz$$

$$\dot{q}_z = \frac{\partial}{\partial z}\left(k_3 \frac{\partial T}{\partial z}\right) dx\, dy\, dz$$

The sum of these three terms is the net rate of heat gain by the small block. Dividing by the volume of the block, the net gain per unit volume is

$$\dot{q}''' = \frac{\partial}{\partial x}\left(k_1 \frac{\partial T}{\partial x}\right) + \frac{\partial}{\partial y}\left(k_2 \frac{\partial T}{\partial y}\right) + \frac{\partial}{\partial z}\left(k_3 \frac{\partial T}{\partial z}\right) \qquad (2)$$

As stated, the energy stored in a material at temperature, T, is

$$q''' = \int_0^T \rho c\, dT \qquad (3)$$

For temperatures well above the Debye temperature, this can be written as

$$q''' = q_0''' + \rho c(T - T_0) \qquad (4)$$

where

$$q_0''' = \int_0^{T_0} \rho c\, dT \qquad (5)$$

is the heat stored in the material as a result of raising its temperature from absolute zero to T_0, a temperature high enough that c, in Equation 4, can be assumed constant. T_0 may be conveniently assumed to be zero Celsius, 273.16 K. Further, since changes in energy are the concern, the reference energy, q_0''', can be dropped from further consideration. Thus, the rate of change of thermal energy stored in the block per unit volume can be written as

$$\dot{q}''' = \rho c \frac{dT}{dt} \qquad (6)$$

Sometimes it is required to analyze materials that undergo an internal change of state. For example, in heating porous materials, such as wood or gypsum plaster, absorbed water may evaporate in one part of the solid, diffuse to a cooler part, and condense. The evaporation will remove heat from the locality where it occurs due to the latent heat of vaporization of the moisture, and the condensation will add heat locally where it occurs. Let the rate of such local heat addition be $\dot{q}_i'''$.

Combining Equations 2 and 6 and accounting for heat addition due to chemical or physical changes in the material results in

$$\rho c \frac{\partial T}{\partial t} = \frac{\partial}{\partial x}\left(k_1 \frac{\partial T}{\partial x}\right) + \frac{\partial}{\partial y}\left(k_2 \frac{\partial T}{\partial y}\right) + \frac{\partial}{\partial z}\left(k_3 \frac{\partial T}{\partial z}\right) + \dot{q}_i''' \qquad (7)$$

Equation 7 is the basic equation describing heat conduction in a solid.

To solve the heat conduction equation, initial and boundary conditions must be provided. These conditions distinguish one problem of interest from another. The conditions that must be specified are:

1. The initial temperature throughout the solid, and
2. The temperature or heat flux at the surface of the solid for all times. Note that along any part of the surface, either the temperature or the heat flux (but not both) should be specified; temperature may be specified for some areas, and heat flux for others. The temperature and flux need not be constant in space or time.

In formulating Equations 2 and 7, it was assumed that the thermal conductivity might be different in each of the three directions and further, that each of these values might vary with position. There are cases where these variations are important.[6,7] However, for the remainder of this chapter (unless specifically mentioned) the solid will be assumed isotropic (i.e., k the same in each direction) and independent of temperature. Also, for simplicity, the heat addition term, $\dot{q}_i'''$, will be assumed zero, except for a few specific examples.

If a dimensionless time ($\tau = t/t_0$) and a dimensionless distance ($\xi = x/b$) are substituted into Equation 7, and t_0 is chosen as

$$t_0 = \frac{\rho c b^2}{k}$$

the equation contains no parameters (for the case of an isotropic solid without local heat addition). Since t_0 and b are related, the choice of b is significant. Normally b would be a dimension of the object in question, with the most useful dimension being that along the principal direction of heat transfer. The quantity ($k/\rho c$) is called the "thermal diffusivity" of the solid; it has dimensions (m^2/s) and is often represented by the Greek letter α.

Steady-State Solutions

If the thermal environment of a solid has been constant for a sufficient time (i.e., the boundary conditions have not changed in value), it will achieve a steady temperature distribution. In this case, the time derivative of T will vanish and the left side of Equation 7 will be zero. Five examples of steady-state heat conduction will be considered.

EXAMPLE 1: Flat, Rectangular Plate, Insulated along Its Edges, Heat Flowing from One Face to the Other.

In this case Equation 7 reduces to

$$\frac{\partial}{\partial x}\left(k \frac{\partial T}{\partial x}\right) = 0 \qquad (7a)$$

The first integral with respect to x yields

$$k \frac{\partial T}{\partial x} = -\dot{q}'' \qquad (7b)$$

where $\dot{q}''$ is the constant of integration; it is the heat flux per unit area through the plate. Equation 7b is a variation of Fourier's law. The constant heat flux is characteristic of the one-dimensional, steady-state problem. Consequently, dT/dx is also a constant for cases of uniform conductivity, yielding a linear temperature profile through the solid. Equation 7b, in turn, integrates to

$$T = T_0 - x\frac{\dot{q}''}{k} \tag{8}$$

T_0 is the second integration constant. Two integration constants, $\dot{q}''$ and T_0, have been introduced, but no boundary conditions used. The boundary conditions selected will fix the values of these two constants. If the thickness of the plate is b, T_0 is the temperature of the left face, and the heat flux, $\dot{q}''$, is specified, the temperature on the right face must be

$$T_b = T_0 - b\frac{\dot{q}''}{k}$$

Or, if the two surface temperatures are known, the heat flux through the plate will be

$$\dot{q}'' = (T_0 - T_b)\frac{k}{b} \tag{8a}$$

Figure 1-2.1 illustrates this example.

EXAMPLE 2: Flat, Rectangular, Laminated Plate, Insulated along I ts Edges.

Here Equation 8 is appropriate to each layer separately, but there may be different constants for each layer. For a two-layer laminate with layers of thickness b_1 and b_2, and thermal conductivities k_1 and k_2, the temperature at the interface will be

$$T_1 = T_0 - b_1\frac{\dot{q}''}{k_1} \tag{8b}$$

A key principle in the solution of this problem is that the heat flux is a constant across any plane parallel to the surface of the plate. (See first integration of the steady-state heat conduction, i.e., Equation 7b.) Thus the temperature of the rear face will be

$$T_2 = T_0 - \dot{q}''\left(\frac{b_1}{k_1} + \frac{b_2}{k_2}\right) \tag{8c}$$

See Figure 1-2.2.

EXAMPLE 3: Radial Heat Flow between Two Concentric Cylindrical Surfaces (heat loss through the wall of a pipe with inside radius, r_0, and thickness, b).

Rewriting Equation 7 in cylindrical coordinates and assuming radial symmetry yields

$$\rho c\frac{\partial T}{\partial t} = \frac{1}{r}\frac{\partial}{\partial r}\left(kr\frac{\partial T}{\partial r}\right) + \frac{\partial}{\partial z}\left(k\frac{\partial T}{\partial z}\right) + \dot{q}''' \tag{9}$$

For the present problem assume no heat addition, $\dot{q}''' = 0$, and no variation of T along the length of the pipe (z direction); hence the last two terms on the right vanish. For steady-state the left side also vanishes. Thus, for purely radial heat flow, Equation 9 can be integrated to

$$r\frac{\partial T}{\partial r} = -\frac{\dot{q}'}{2\pi k} \tag{9a}$$

where $\dot{q}'$ is a constant of integration whose significance will be discussed. A second integration yields

$$T = T_0 - \frac{\dot{q}'}{2\pi k}\left[\ln\left(\frac{r}{r_0}\right)\right] \tag{9b}$$

The integration constant, $\dot{q}'$, can be understood by considering a very thin-walled pipe, thickness b much less than r_0. Then $r_1 = r_0 + b$ and

$$\ln\left(\frac{r_1}{r_0}\right) = \ln\left(1 + \frac{b}{r_0}\right) \approx \frac{b}{r_0} + \frac{1}{2}\left(\frac{b}{r_0}\right)^2 + \cdots$$
$$\approx \frac{b}{r_0}$$

or, with this approximation and rewriting Equation 9b,

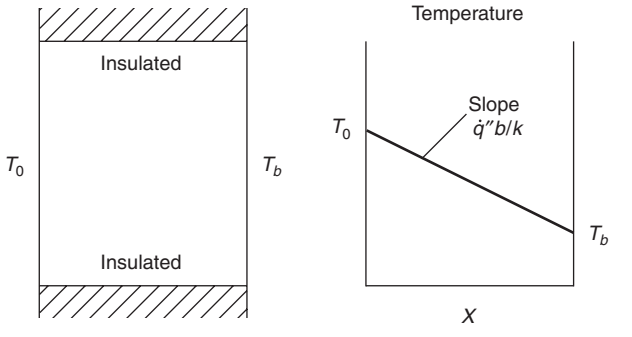

Figure 1-2.1. ***Flat plate of thickness b, insulated at its edges. Steady-state surface temperatures T_0 and T_b.***

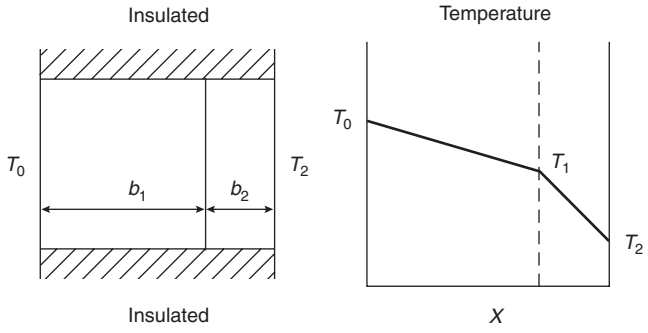

Figure 1-2.2. ***Two-layer, flat laminated plate insulated at its edges. Layer thickness b_1 and b_2. Layer 2 has the smaller thermal conductivity. Steady-state surface temperatures T_0 and T_2. Temperature of the interface between the plates, T_1.***

$$\frac{b}{r_0} = 2\pi k \frac{(T_0 - T_b)}{\dot{q}'}$$

$$\frac{\dot{q}'}{2\pi r_0} = k \frac{(T_0 - T_b)}{b}$$

Comparing this with Equation 8a it can be seen that

$$\dot{q}' = 2\pi r_0 \dot{q}''$$

or that $\dot{q}'$ equals the heat flux through the pipe per unit length. [See Figure 1-2.3(a).]

It can be verified that the heat flux per unit length of a pipe with conductivity k_1 and radii (r_0, r_1) surrounded by insulation, conductivity k_2, and radii (r_1, r_2) is

$$\dot{q}' = \frac{2\pi(T_0 - T_2)}{[(1/k_1)\ln(r_1/r_0) + (1/k_2)\ln(r_2/r_1)]} \qquad (9c)$$

where T_0 is the temperature at the inside of the pipe and T_2 the temperature of the outside of the insulation. [See Figure 1-2.3(b).] In this case integration of 9a gives the temperatures in the pipe and insulation. For the pipe, the integral 9b applies, but with $k = k_1$ and $\dot{q}'$ given by 9c, T_1, the temperature at the pipe-insulation interface, is given by this version of 9b with $r = r_1$. For the insulation, Equation 9b again applies with $\dot{q}'$ given by Equation 9c, and T_0 replaced by T_1, k by k_2, and r_0 by r_1.

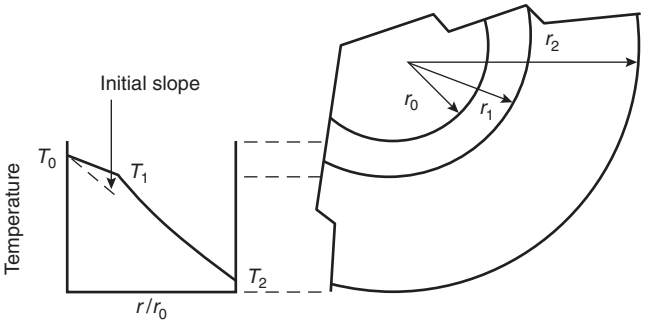

Figure 1-2.3(b). ***Steady-state radial heat flow through two concentric pipes or one pipe covered with insulation. The insulation has a lower conductivity than the pipe.***

EXAMPLE 4: Cavity Wall.

Many building walls consist of internal framing sheathed on both sides. For example, an interior wall of a residential building might be framed with wood 2″ × 4″ studs (41.3 × 92.1 mm), spaced 406 mm (16 in.) and sheathed with gypsum wallboard. An exterior wall might be similar except that the sheathing on the exterior side would be a weather-resistant material perhaps backed by insulation board. Between the two sheathing layers there will be a cavity unless the spaces between the studs are filled with insulation or other material.

For this example, assume that the two coverings are identical 15.9-mm ($^5/_8$ in.) gypsum board and the cavity is, for Case 1, filled with fiberglass insulation, and for Case 2, unfilled. The thermal conductivity of gypsum board is taken as 0.8 W/m·K, of wood 0.17 W/m·K, and of fiberglass 0.04 W/m·K.[8] Let the hot side wall surface temperature be 200°C and the cold side 20°C. [See Figure 1-2.4(a).]

Case 1: A correct calculation of this case requires solution of the two-dimensional steady-state heat flow equation (specialized from Equation 7). Either an analytical solution or numerical techniques (described later in this chapter) might be used. Here a small correction is anticipated for the studs. Equation 8 is used for the two layers of gypsum board and either the fiberglass insulation or the wood studs. An effective conductivity is calculated for the insulation or stud-filled cavity using an arithmetic average based on the space occupied by studs and insulation. The effective conductivity for the 92.1-mm deep by 406-mm wide cavity is

$$\frac{0.04 \cdot 0.3647 + 0.17 \cdot 0.0413}{0.406} = 0.0532 \text{ W/m·K}$$

Referring back to Example 2, the reader can verify that the heat conduction through the wall would be

$$\dot{q}'' = \frac{(200 - 20)}{(2 \times 0.0159/0.8 + 0.0921/0.0532)}$$

$$= \frac{180}{(0.0398 + 1.7312)}$$

$$= 0.1016 \text{ kW/m}^2$$

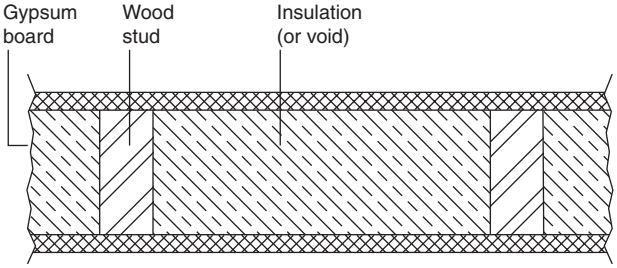

Figure 1-2.4(a). ***Geometry of the cavity wall.***

In spite of its low conductivity, the insulation in the cavity conducts the majority of the heat through the wall because of the large area occupied by it. The studs conduct about 30 percent of the heat for this particular case. Had the gypsum board not been present, the heat flow would have increased 2.3 percent for the same overall ΔT. Compared to the insulation, the gypsum board offers little resistance to the heat flow.

Had the steady-state, two-dimensional heat flow equation been solved for this case, the wood and insulation temperatures would reflect a small flow of heat from the insulation into the wood on the warm side of the cavity and an equal, reverse flow on the cool side. The temperature deviations (from one-dimensional heat flow) for the insulation are the larger, about 1.5°C, while those in the wood are less than 1°C. A small transverse heat flow in the gypsum board, toward the studs on the warm side of the cavity and away from the studs on the cool side, would be revealed. [See Figure 1-2.4(b).] In this figure, use has been made of symmetry about the center of the cavity.

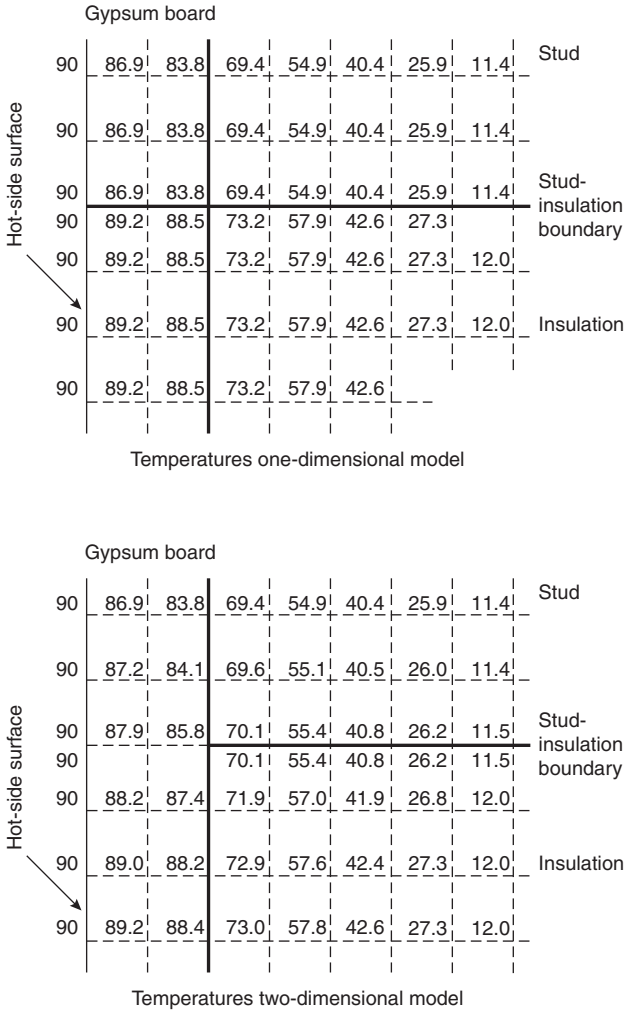

Figure 1-2.4(b). ***Comparison of wall and cavity temperatures—one- and two-dimensional models.***

The total 180°C temperature difference is divided in half: 90°C on the hot side and −90°C on the cool side. Only the area around the insulation-stud-gypsum board junction, on the hot side, is shown.

In the upper diagram in Figure 1-2.4(b), the stud and gypsum board opposite it are considered as one isolated unit, and the gypsum board and insulation as another. Each are separately analyzed using a one-dimensional model. There is a physically unrealistic temperature discontinuity within the gypsum board and between the stud and the insulation. The lower diagram is a two-dimensional treatment of the assembly. The temperatures at the interface between the insulation and the stud are now equal. There is a discontinuity in the slope of the temperature profile across the insulation-to-stud joint. This is expected, as the thermal conductivity of the stud and insulation are different. (See Example 2.)

Case 2: The two layers of gypsum board are treated as in Case 1. However, the cavity is empty and must be treated differently. With no insulation in the void, radiation across, and convection within it, will dominate the heat transfer. Again, conduction through the studs will yield a minor correction.

Radiation is addressed in Section 1, Chapter 4; the radiation exchange across the void is simple, but depends on the temperatures of the gypsum board on either side of the cavity, which must be approximated or found by an iterative calculation. Referring to Section 1, Chapter 4, the reader can verify that the effective conductivity of the cavity, if radiation alone were active and the emissivity of the gypsum board were 1.0, would be about 1.1723 W/m·K, more than 10 times that of the insulated cavity. (See Case 1.) If the wall were two sheets of gypsum board back to back (no cavity), about 4.5 kW/m^2 would be conducted. With the cavity present and only radiation active within it, this would be reduced to 1.52 kW/m^2.

Section 1, Chapter 3 addresses convection. In the absence of insulation to break up the buoyancy-induced flow in the cavity, air rises along the warmer side, crosses over, and descends along the cooler side. The calculation of the heat transferred by this circulation can be complex and is beyond the scope of this chapter. In a typical cavity, convective heat transfer is more than the heat transferred by radiation.

Is Case 2 consistent with what is known about vacuum bottles? The answer is yes. First, in the vacuum bottle, convective heat transfer is suppressed by removing the air. Second, the inner walls of the bottle are silvered and have a low emissivity. Had it been assumed that the cavity side of the gypsum board was aluminized and used an emissivity of 0.1 instead of 1.0, the radiative contribution to the heat transfer would have been comparable to that of the insulation.

EXAMPLE 5: Spherical Solid with Internal Heat Generation.

Rewriting Equation 7 in spherical polar coordinates and assuming spherical symmetry yields

$$\rho c \frac{\partial T}{\partial t} = \frac{1}{r^2} \frac{\partial}{\partial r} \left(k r^2 \frac{\partial T}{\partial r} \right) + \dot{q}''' \qquad (10)$$

For steady-state, purely radial heat flow, Equation 10 can be integrated to

$$-4\pi r^2 k \frac{\partial T}{\partial r} = \int_0^r \dot{q}''' \, 4\pi r^2 \, dr \tag{10a}$$

Here the term on the left is the outward heat flux across the spherical surface at r, while the term on the right is the total heat released inside the sphere bounded by this surface. A second integration yields

$$T = T_0 - \int_0^r \frac{1}{kr^2}\left(\int_0^r \dot{q}''' r^2 \, dr\right) dr$$

If $\dot{q}'''$ and k are constant and R is the outer radius of the sphere, the sphere's surface temperature will be

$$T_R = T_0 - \frac{\dot{q}''' R^2}{6k}$$

Conversely, the sphere is hottest at its center with temperature

$$T_0 = T_R + \frac{\dot{q}''' R^2}{6k} \tag{10b}$$

This analysis could be generalized to illustrate self-heating in a spherical object. However, it would involve a differential equation requiring more advanced mathematics than is desirable here. Instead, self-heating for a simpler, plane geometry is addressed later in this chapter.

One-Dimensional, Transient Equation

Thermally Thin Material

The simplest transient problem of interest is derived from the basic equation of heat conduction, Equation 7, in its one-dimensional form

$$\rho c \frac{\partial T}{\partial t} = \frac{\partial}{\partial x}\left(k \frac{\partial T}{\partial x}\right) \tag{11}$$

This is integrated once with respect to x. The result is

$$\rho c b \frac{\partial \overline{T}}{\partial t} = k \frac{\partial T}{\partial x}\bigg|_{x_1} - k \frac{\partial T}{\partial x}\bigg|_{x_0} \tag{12}$$

where $\overline{T}$ is the average plate temperature

$$\overline{T} = \frac{1}{b}\int_{x_0}^{x_1} T \, dx \tag{12a}$$

and $b = x_1 - x_0$.

The right side of Equation 12 is the net heat transferred into the plate; that is, the difference between the heat entering one side and that leaving by the other side. The left side of the equation is the rate of change of the average thermal energy stored in the plate.

For many problems it is sufficient to know only the average temperature (e.g., where thermal conduction within the plate is fast compared to the rate at which heat can be supplied to it). This will occur either for thin materials (small b) or ones of high thermal conductivity (large k).

As an example consider a plate with initial temperature of T_0, insulated on one face and suddenly exposed, at time $t = 0$, to a hot, moving air stream with temperature T_f. The heat transfer from such a hot stream is known, experimentally, to depend on the difference between the temperature of the air stream far from the plate (T_f) and the surface temperature of the plate ($\overline{T}$ in the present case, since it is assumed that the average temperature is a good approximation for the temperature anywhere in the plate). The constant of proportionality is the "convective heat transfer coefficient" and is usually designated with the letter h. (For more detail on convection, see Section 1, Chapter 3.) Thus, the heat transferred from the air to the plate is

$$h(T_f - \overline{T})$$

where h has units W/m²·K. Substituting this convective heating assumption for one term on the right of Equation 12 and zero (insulated rear face) for the other term yields the equation

$$\frac{\partial \overline{T}}{\partial t} = \frac{h}{\rho c b}(T_f - \overline{T})$$

This simple, first-order differential equation is easily integrated to give

$$\overline{T} = T_0 e^{-ht/\rho cb} + \frac{h}{\rho cb}\int_0^t T_f(\tau) e^{-(h/\rho cb)(t-\tau)} \, d\tau \tag{13}$$

The characteristic time for this solution is

$$t_c = \frac{\rho c b}{h} \text{ (seconds)}$$

It is noted that the transient heat flow equation, Equation 7, leads to the characteristic time

$$t_0 = \frac{\rho c b^2}{k}$$

Comparing these two characteristic times yields

$$\frac{t_0}{t_c} = \frac{hb}{k} = \text{Bi (Biot Number)}$$

When Bi is small (e.g., if thermal conductivity, k, is large or the sample thin) the material is thermally thin. Further, transient heat conduction within the solid is fast compared to heat transfer to its surface. Conversely, when Bi is large (e.g., if the surface heat transfer coefficient is large or the sample thick), it is not thermally thin and the above analysis would be inappropriate.

If T_f is a constant, the integral in Equation 13 can be evaluated. The result is

$$\overline{T} = T_0 e^{-t/t_e} + T_f(1 - e^{-t/t_c}) \tag{13a}$$

After a long time, $\overline{T} = T_f$.

The result, Equation 13a, can be recast in terms of the characteristic time mentioned above in the discussion of Equation 7. Recall that this time was

$$t_0 = \frac{\rho c b^2}{k}$$

Using this in Equation 13 gives

$$\frac{ht}{\rho cb} = \left(\frac{ht_0}{\rho cb}\right)\left(\frac{t}{t_0}\right)$$
$$= \left[\frac{h(\rho cb^2/k)}{\rho cb}\right]\left(\frac{t}{t_0}\right)$$
$$= \left(\frac{hb}{k_{\text{solid}}}\right)\left(\frac{t}{t_0}\right)$$
$$= \left(\frac{h\ell}{k_{\text{air}}}\right)\left(\frac{k_{\text{air}}}{k_{\text{solid}}}\right)\left(\frac{d}{\ell}\right)\left(\frac{t}{t_0}\right)$$

where ℓ is the length of the solid in the direction of the air flow. This length is needed to determine the value of h from published heat transfer data, such as McAdams.[9] The quantity, $\left(h\ell/k_{\text{air}}\right) = \text{Nu}$, is the Nusselt number, the ratio of the actual heat transferred under the given flow conditions to what would be conducted through still, stably stratified air, provided the temperature difference $(T_f - \overline{T})$ were applied over a distance ℓ. For natural convection, such as is often found in fire situations, the Nusselt number would be on the order of 100. For wood $(k_{\text{air}}/k_{\text{solid}})$ is about 0.1, and it may be supposed for the present that d/ℓ is also 0.1. Then the assumption that the sample is "thermally thin" would be true so long as t/t_0 were large compared to 1. For a metal, k_{solid} is 10^4 times that of wood, so the thermally thin assumption would hold for t/t_0 large compared to 10^{-3}.

A more interesting, but also more difficult problem arises if the hot air temperature is high enough that the plate begins to radiate significantly as it warms in response to the air's heating. This problem would arise if the heating were due to flames passing over the plate. For simplicity it can be assumed that the hot gas absorbs negligible radiant energy and all the radiation escapes to a distant, surrounding region, which is at the initial plate temperature, T_0. In this case, one must subtract the heat lost by radiation from the plate's surface from the heat transferred to the plate from the gas. (For more detail on radiation see Section 1, Chapter 4.) The re-radiation will be

$$\dot{q}_{RR} = \varepsilon\sigma(T^4 - T_0^4)$$

where σ = Boltzmann's constant = 5.6696×10^{-11} (kW/m²·K); ε = plate emissivity; and the equation to be integrated is

$$\rho cd\,\frac{\partial \overline{T}}{\partial t} = h(T_f - \overline{T}) - \varepsilon\sigma(\overline{T}^4 - T_0^4)$$

Because of the fourth power of $\overline{T}$ on the right side of the equation, this cannot be integrated in closed form. An approximate integral is obtained by linearizing the radiation term

$$(\overline{T}^4 - T_0^4) = \left(\frac{T_f^4 - T_0^4}{T_f - T_0}\right) \times (\overline{T} - T_0)$$

Linearized in this fashion, the equation can be integrated. After integration the result is

$$\overline{T} = T_0 + \left(\frac{h}{H}\right)(T_f - T_0)(1 - e^{-Ht/\rho cd})$$

where

$$H = h + \varepsilon\sigma\left(\frac{T_f^4 - T_0^4}{T_f - T_0}\right)$$

With significant effort, higher order analytic approximations can be obtained, or numerical methods used if a more accurate answer is needed. Note that, without the radiation loss, the plate temperature approaches the gas temperature, T_f (Equation 13a), but with the radiation loss, since $h/H < 1$, the final temperature is lower. (See Equation 14.) It also retains a dependence on the ambient temperature.

$$\overline{T} \rightarrow T_0 + \left(\frac{h}{H}\right)(T_f - T_0) \qquad (14)$$

Thick Plates

The theory of thick plates leads to much more involved analytic techniques than were needed for thermally thin plates. Only a brief outline of the theory will be given here; more complete treatments are available in such standard heat transfer texts as Carslaw and Jaeger.[10]

The most common approach to transient heating of thick plates uses the linearity of Equation 7. Equation 7 is linear only for the particular case where (1) the thermal diffusivity is either constant or a function of position, but not temperature, and (2) heat addition, if present, is a function of position and/or linear in temperature. These linearity restrictions can often be met while still giving useful results for practical problems. A linear equation can, of course, be solved by the linear superposition (sum) of primitive solutions. To use this technique, a suitable primitive solution is needed. Two ways to obtain and use primitive solutions will be discussed.

Separation of variables: A technique that may be used with Equation 7 for multidimensional problems is called "separation of variables."* Here the technique will be illustrated for only one dimension. The above linearity restrictions will be met by assuming constant density, specific heat, and thermal conductivity (more restrictive than just constant thermal diffusivity); and a heat addition term linear in temperature.

Consider a flat, rectangular plate of thickness $2b$, insulated along its edges, with heat generated within the plate at a rate that increases with temperature.

The following is a very simple example illustrating some aspects of self-heating. For an object to self-heat, it is necessary for an exothermic chemical reaction to occur within the solid. Further, the rate of this reaction should

*The method of separation of variables for solution of linear, partial differential equations is discussed in many graduate-level texts on mathematical methods of physics and chemistry. Recent texts tend to emphasize numerical methods to the exclusion of older, analytic ones. Texts predating the computer revolution may be more useful.

accelerate as the temperature rises. For a more complete discussion of self-heating see Thomas[11] or Section 2, Chapter 12 of this handbook.

The rate of chemical reactions typically increases exponentially with temperature, but to keep within the restrictions of the linear equation mathematics, it is assumed that the heat released per unit volume, $\dot{q}'''$, varies linearly with temperature

$$\dot{q}''' = C + DT$$

where C and D are presumably known and D is positive. For small temperature changes, this may be accepted as a valid linearization of an exponential increase. C may be eliminated by a suitable choice of reference temperature, $T_0 = -C/D$. It is assumed that the two surfaces of the plate are kept at the same temperature, T_s. The center of the plate is at $x = 0$. Because of the geometric symmetry, the boundary conditions are symmetric and T must be a symmetric function of x.

Using the separation of variables technique, assume that T can be written in the form

$$T = \theta(t)X(x)$$

Substituting this in the one-dimensional version of Equation 7, yields

$$\frac{X\partial\theta}{\partial t} = \frac{\alpha\theta\partial^2 X}{\partial x^2} + \left(\frac{D\alpha}{k}\right)\theta X$$

Dividing by θX yields

$$\frac{[\partial\theta(t)/\partial t]}{\theta(t)} = \alpha\frac{[\partial^2 X(x)/\partial x^2]}{X(x)} + \frac{D\alpha}{k} \tag{15}$$

The left side of the equation depends only on time while the right depends only on location, x. This can only be true if both sides are independently constant. Let this constant be λ and write two equations expressing the constancy of the two sides

$$\theta' + \lambda\theta = 0$$

$$X'' + \left(\frac{D}{k} + \frac{\lambda}{\alpha}\right)X = 0$$

If $\lambda = 0$ the first of these equations says θ = constant and the second that

$$\theta X = T = A\sin\left(\sqrt{\frac{D}{k}}\,x\right) + B\cos\left(\sqrt{\frac{D}{k}}\,x\right) \tag{15a}$$

Invoking the required symmetry and using the boundary condition $T = T_s$ at the surface, $x = b$, gives (remembering the reference temperature)

$$T = T_0 + (T_s - T_0)\frac{\cos\left(\sqrt{D/k}\,x\right)}{\cos\left(\sqrt{D/k}\,b\right)} \tag{15b}$$

This would be the steady-state (time-independent) solution, provided one exists.

If λ is not 0 the result is

$$T(x, t, \lambda) = e^{-\lambda t}\left[A(\lambda)\sin\left(\sqrt{\frac{D}{k} + \frac{\lambda}{\alpha}}\,x\right) + B(\lambda)\cos\left(\sqrt{\frac{D}{k} + \frac{\lambda}{\alpha}}\,x\right)\right] \tag{15c}$$

Equations 15a and 15c are the primitive solutions that are superimposed (summed). The separation parameter, λ, and the coefficients A and B are chosen to satisfy the initial and boundary conditions. The two major terms of Equation 15c decay exponentially with time (for positive λ), with those with the most rapid oscillation in x decaying most quickly. Clearly, this technique requires inclusion of many terms if the behavior for small time is needed. For hand calculations this is a serious drawback, but with the advent of very efficient "fast Fourier transform" numerical packages to evaluate the coefficients A_n and B_n, the separation of variables method has acquired some new appeal.

Combining Equation 15b (which is Equation 15a adjusted to satisfy the boundary conditions) with Equation 15c allows the evaluation of λ. Because the boundary conditions are already satisfied by Equation 15b, Equation 15c must be symmetric in X, and zero at $x = b$, hence $A_n = 0$ and

$$\sqrt{\frac{D}{k} + \frac{\lambda}{\alpha}} = \frac{(2n-1)\pi}{2b}$$

$$\lambda = \left\{\left[\frac{(2n-1)\pi}{2b}\right]^2 - \frac{D}{k}\right\}\alpha$$

and

$$T = T_0 + (T_s - T_0)\frac{\cos\left(\sqrt{D/k}\,x\right)}{\cos\left(\sqrt{D/k}\,b\right)} + \sum_{n=1}^{\infty} B_n\cos\left\{\left[\frac{(2n-1)\pi}{2}\right]\left(\frac{x}{b}\right)\right\} \times e - \left(\left\{\left[\frac{(2n-1)\pi}{2b}\right]^2 - \frac{D}{k}\right\}\alpha t\right) \tag{15d}$$

To satisfy the initial conditions, B_n are evaluated using the standard technique of multiplying both sides of Equation 15d, with $t = 0$, by the appropriate cosine and integrating with respect to x from 0 to b. To illustrate self-heating, however, this step is not necessary as long as it is realized that in general the B_n are nonzero. It will be assumed that the initial condition was almost the steady-state solution, Equation 15b (i.e., almost all the $B_n = 0$). But suppose that instead of the initial condition being exactly the steady-state distribution, a small perturbation away from the steady-state temperature distribution existed at $t = 0$. In other words, suppose that one of the B_n were a small, nonzero value. In this case Equation 15d

could show "thermal runaway"; that is, the temperature would grow exponentially with time, if D exceeded

$$D = k\left[\frac{(2n-1)\pi}{2b}\right]^2 \tag{15e}$$

In particular, if B_1 is nonzero, Equation 15e gives the critical value for D for which thermal runaway will occur. Where thermal runaway occurs, there is no steady-state solution. The use of Equation 15b is still valid, but its interpretation is altered—it describes a stable state if D is less than $k(\pi/2b)^2$; it is a metastable state if D is larger.

This example does not require evaluation of a large number of terms of the series. In fact, only one term is sufficient, since the lowest order term (smallest n) has the largest growth rate. Thus the separation of variables technique is particularly suited to this problem.

The analysis of self-heating involves many factors not considered in this simple calculation. One factor is determining the acceleration of the rate of chemical reaction as local temperature increases (i.e., determining the constant D for the material in question). Another factor is the effect of size. From the present simple example it is clear that for positive D, there is some thickness of material, $2b$, near which the potential for disastrous self-heating exists. The larger D, the smaller that b need be for self-heating runaway. Although the critical size is often large, materials, such as coal, wood chips, pelletized animal feeds, and so forth, are occasionally stored in piles large enough for self-heating to be important.

Integral (Duhammel's) method: Where a very large number of terms are needed to yield sufficient accuracy using the separation of variables technique, integral solutions may be more efficient. If an integral is considered as a special kind of sum, the technique is another type of superposition. Just as the separation of variables technique required a primitive solution, which could be summed, so the integral technique requires a suitable primitive solution. One such function is

$$f(x, t) = q_1'' 2\rho c\sqrt{\pi\alpha t}\,\exp\left(\frac{-x^2}{4\alpha t}\right) \tag{16}$$

where α is the thermal diffusivity referred to earlier. Also, $f(x, t)$ is the temperature response of the plate to an instantaneous heat addition per unit area of plate, q_1'' (units J/m^2) applied at time $t = 0$, and no heat is transferred to or from the plate at subsequent times. That f is a solution to the one-dimensional version of Equation 7 can be readily determined by differentiation. Note that at any time after the heat addition, the heat in the plate, assumed to extend to infinity in both directions from $x = 0$, will be

$$\begin{aligned}\rho c\int_{-\infty}^{\infty} f(x, t)\,dx &= q_1''\sqrt{\pi}\int_{-\infty}^{\infty}\exp\left(\frac{-x^2}{\sqrt{4\alpha t}}\right)d(x\sqrt{4\alpha t})\\ &= \frac{q_1''^2}{\sqrt{\pi}}\int_{-\infty}^{\infty}\exp(-\xi^2)\,d\xi\\ &= q_1''\end{aligned}$$

This equation shows that the quantity of heat added per unit area to the plate is just q'' which, with $q'' = 1$, gives 1 for the integral; that is, the total heat added to the plate is one Joule per unit area of plate.

Equation 16 yields a singular temperature at $x = 0$, $t = 0$. For all later times the temperature has a "Gaussian" profile with respect to x with a half width $\sqrt{4\alpha t}$. Thus the half width of the temperature distribution increases with time. The heat spreads out, so that, while the peak temperature drops, the heated part of the plate includes an ever thicker region adjacent to $x = 0$.

The principle of superposition, mentioned previously, is now used to construct a particular solution to the one-dimensional heat flow equation. Let

$$T(x, t) = T_0 + \int_{-\infty}^{\infty}\left[\frac{q'''(\xi)}{q_1''}\right] f_1(x - \xi, t)\,d\xi \tag{17}$$

where f_1 is used in place of the f of Equation 16 to emphasize the choice of $q_1'' = 1$ J per unit area. The quantity $q'''(\xi)d\xi/q_1''$ in Equation 17 is dimensionless. If q''' is chosen such that $q'''(-\xi) = q'''(\xi)$, the temperature at $x = 0$ will be T_0 and $[T(-x, t) - T_0] = -[T(x, t) - T_0]$, shifting from an infinite solid to a semi-infinite one. Further, writing $g = q'''/q_1''$ (g has dimension 1/m)

$$\begin{aligned}T(x, t) &= T_0 + \int_{-\infty}^{0} g(\xi) f_1(x - \xi, t)\,d\xi\\ &\quad + \int_{0}^{\infty} g(\xi) f_1(x - \xi, t)\,d\xi\\ &= T_0 - \int_{0}^{\infty} g(+\xi) f_1(x + \xi, t)\,d\xi\\ &\quad + \int_{0}^{\infty} g(\xi) f_1(x - \xi, t)\,d\xi\end{aligned}$$

Recalling the definition of f_1, substitute in the first integral

$$\xi = -x + 2\eta\sqrt{\alpha t}$$

and in the second

$$\xi = x + 2\eta\sqrt{\alpha t}$$

The result is

$$\begin{aligned}T(x, t) = T_0 + \frac{q_1''}{\rho c\sqrt{\pi}}\Bigg[&\int_{-x/2\sqrt{\alpha t}}^{\infty} g(x + 2\eta\sqrt{\alpha t})\exp(-\eta^2)\,d\eta\\ &-\int_{x/2\sqrt{\alpha t}}^{\infty} g(-x + 2\eta\sqrt{\alpha t})\exp(-\eta^2)\,d\eta\Bigg]\end{aligned} \tag{17a}$$

Finally, if g is constant,

$$T(x, t) = T_0 + \frac{q_1'' g}{\rho c}\left[2\sqrt{\pi}\int_0^{x/2\sqrt{\alpha t}}\exp(-\eta^2)\,d\eta\right] \tag{17b}$$

$T(x, t)$ is the temperature in a semi-infinite plate with initial temperature $T_0 + T_{c(x)}$ whose surface is brought to T_0 at

time zero and held there for all subsequent time.* If $x = 0$ the integral is zero and thus $T(0, t) = T_0$. The surface temperature of the plate is a constant for all time. Also, because of the t in the denominator of the limit of integration of the integral, it is clear that, for very small time, for any finite x, the integral tends to 1 and the result is $T_0 + q''\sqrt{\rho c} = T_0 + T_c$ (for simplicity). Thus Equation 17 is the temperature distribution in a solid, initially at temperature $(T_0 + T_c)$ which, at time 0, has its surface brought to temperature T_0 and held there for all future time. Figures 1-2.5(a) and (b) show the temperature in the plate according to Equation 17b.

What heat input to the material must be supplied in order to achieve this; that is, to bring the surface instantly from $(T_0 + T_c)$ to T_0 and hold it there? The heat input to the surface is just

$$-k\left.\frac{\partial T}{\partial x}\right|_{x=0} = kT_c\left(\frac{1}{\sqrt{\pi\alpha t}}\right)\exp\left(\frac{-x^2}{4\alpha t}\right)\Big|_{x=0} = kT_c\left(\frac{1}{\sqrt{\pi\alpha t}}\right) = T_c\left(\frac{k^2}{\pi\alpha t}\right)^{1/2} \tag{18}$$

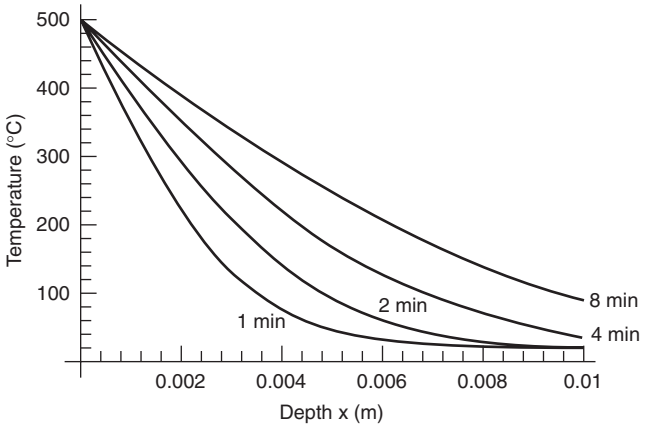

Figure 1-2.5(a). ***Equation 17b temperature vs. depth into the plate for four times.***

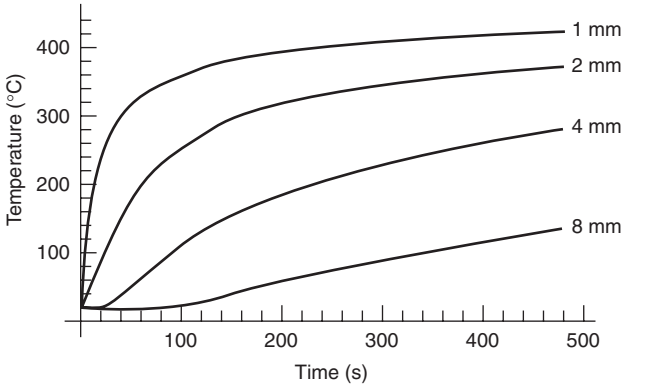

Figure 1-2.5(b). ***Equation 17b temperature vs. time for four depths into the plate.***

*The quantity within the square brackets is the "error function." Its value may be found in mathematical tables just as for the sine or cosine functions.

Thus the necessary heat flux to be applied at the surface is initially infinite (at $t = 0$) and for finite times, decreases as $1\sqrt{t}$.

This is a useful approximation for fire studies as many materials may be rapidly heated to a high temperature and their surface temperature stabilized there.

The quantity $k^2/\alpha = k\rho c$, which appears in Equation 18, is an important parameter of a material and is often referred to as the "thermal inertia." The ratio of the thermal inertia to the square of the convective heat transfer coefficient, h, has the units of time

$$\frac{k\rho c}{h^2}$$

$$(\text{W/m·K})(\text{gm/m}^3)(\text{J/gm·K})(\text{W/m}^2\text{·K})^2 = (\text{sec})$$

It is the characteristic time for the surface of a solid to respond to heating on exposure to a hot gas with film resistance h. With other modes of heating, an analogous ratio would be appropriate, and would have the same significance—the characteristic time for the solid to respond to the heating.

The next example of heat conduction in a solid is from thermal flame spread theory. The problem is to determine the temperature of the surface of a thick fuel as a function of time, as the fuel is heated from ambient conditions to its ignition temperature. This example of the thermally thick solid is analogous to the thermally thin case discussed earlier.

If heat is applied uniformly to the surface of a flat material (fuel), only one-dimensional heat conduction needs to be considered in calculating the surface temperature of the material. If the heat is applied nonuniformly, but in such a way that temperature gradients along the surface are small compared to those normal to the surface, lateral heat conduction in the fuel will be small compared to conduction normal to its surface, and a one-dimensional heat transfer model may still be adequate. For many cases this approach is indeed suitable. The principal exception is near extinction (very slow flame spread), where the flame spread rate is comparable to or less than the thermal penetration rate. Assuming that extinction is not a present concern, the one-dimensional approach may be adopted.

The analysis is complicated, but available in many standard heat transfer references, such as Carslaw and Jaeger.[10] It will not be repeated here. If the solid is exposed to a constant external heat flux, $\dot{q}''$, and loses heat by radiation and convection, its temperature will be given by

$$T(t) = T_0 + \frac{\dot{q}''}{H}\left[erfc\left(\frac{x}{2\sqrt{\alpha t}}\right) - e^{-\left(Hx/k + H^2t/\beta\right)}erfc\left(\frac{x}{2\sqrt{\alpha t}} + \sqrt{\frac{H^2t}{\beta}}\right)\right] \tag{19}$$

where *erfc* is the complementary error function $(1 - erf)$ and has a value of 1 for an argument of 0.

Figure 1-2.6 shows the temperature of the solid as given by Equation 19 for $x = 0$ (surface) and a depth of 1 mm below the surface $(x > 0)$. In preparing this plot, properties for oak were used.[8] The applied external flux

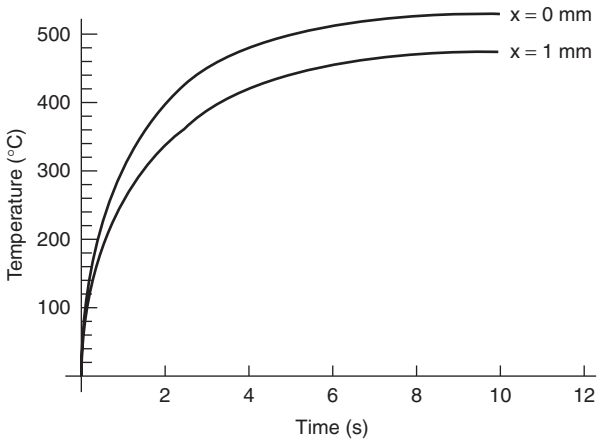

Figure 1-2.6. ***Transient heating of a solid exposed to a constant incident heat flux. The material loses heat to its surroundings by convection and a linearized approximation of radiation.***

was 30 kW/m^2. Ambient temperature was 20°C. When the surface of the sample reached the approximate ignition temperature of wood (420°C), the temperature 1 mm below the surface was 60°C cooler. The heat was diffusing into the sample, but was far from equilibrium conditions. [See Figure 1-2.5(a).] If pyrolysis products from the sample were exposed to a nonimpinging pilot flame, Equation 19 suggests that ignition would occur after about 3 sec exposure to the applied flux. If the applied flux were abruptly switched off as soon as ignition occurred, the sample would probably self-extinguish because of the heat loss to its interior. This would rapidly cool the surface to below its piloted ignition temperature. Conversely, Figure 1-2.6 illustrates that, to achieve sustained ignition, the surface must be: (1) heated to ignition temperature, but heating must continue until the bulk of the sample has been sufficiently heated and (2) that quenching will not occur due to heat conduction into the bulk material.

Many other integral solutions based on Equation 16, but satisfying other initial and boundary conditions, can be found in the heat conduction literature.[10] However, the solutions involve special mathematical functions and use more advanced analytic techniques than are appropriate to this text. The reader is urged to become acquainted with these powerful tools.

The above analysis is qualitatively correct, but, for fire problems, may not yield satisfactory quantitative results. The assumptions of constant material thermal properties and linearization of the convective/radiative heat transfer coefficient may not be valid for the temperature range encountered. In addition, for porous materials containing absorbed moisture (e.g., wood), thermal effects associated with migration of the moisture within the solid may lead to significant deviation from temperatures calculated on the assumption that heat conduction alone is occurring.

Considerable algebraic manipulation is required to get analytic solutions to heat conduction problems. The advantage of an analytic solution includes the insight that it gives about thermal behavior. However, even when this labor is completed, the solution may be limited by the necessity to linearize it. In many cases, numerical techniques, discussed next, may be the simplest route. A limitation of numerical methods is that, to understand the full thermal behavior, many solutions may be needed before a reasonable understanding of the behavior is attained.

Numerical Techniques

The heat conduction literature contains many analytic solutions to transient heat transfer problems for various geometries. However, rather than use the complex analytic forms, it is often easier to obtain solutions numerically, capitalizing on the recent increase in the availability of powerful, inexpensive microcomputers. Further, for solutions in which material properties vary significantly with direction or temperature, or heat addition within the solid is important, numerical methods are likely to be the most efficient approach. Two numerical formulations are available for solving heat conduction problems: (1) finite difference method and (2) finite element method. A comprehensive overview of numerical methods for heat transfer is available in Minkowycz.[12] An extensive review of the finite difference method is available in most introductory heat transfer texts. The finite element method is reviewed by Zienkiewicz.[13]

Both numerical formulations involve the *discretization* of the object being analyzed. *Discretization* divides the section into small segments using a set of nodes connected by lines referred to as grid or mesh. (See Figure 1-2.7.) Consequently, both methods approximate the geometry of the section being modeled.

Smaller grids provide increased accuracy, though extra nodes result in an increase in computation time. Grid spacing may vary through the assembly, being smallest where the temperature gradient is expected to be the greatest (e.g., near the heated boundary or in insulating materials). A variable grid spacing requires an additional amount of effort to formulate the governing equations for each node.

Generally, the finite difference method uses a "Taylor series" expansion to reformulate the partial differential equation, resulting in a set of algebraic equations. The finite difference form of Equation 7 for the case of transient

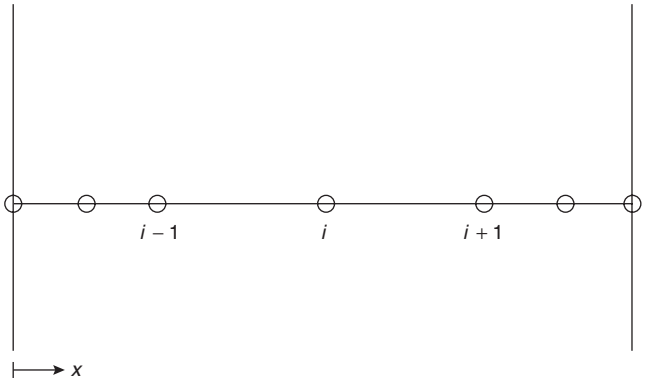

Figure 1-2.7. ***Nomenclature of finite difference grid.***

one-dimensional heat conduction with no internal heat addition is

$$C_i \frac{(T_i' - T_i)}{\Delta t} = \frac{k_m(T_{i+1} - T_i)/\Delta x - k_n(T_i - T_{i-1})/\Delta x}{\Delta x} \quad (20)$$

Equation 20 is applicable to cases where the grid spacing is the same on each side of node *i*. Alternative expressions can be readily developed for nonuniform grids. A version of Equation 20 must be developed for each node. Conditions at each node are assumed to represent the conditions in a small region around each node. In particular

T_i = temperature at node i at time t (at beginning of time step)

T_i' = temperature at node i after time step, Δt

where points $i + 1$, i, and $i - 1$ are all in the interior of the section, and

$$k_m = \frac{1}{2}(k_{i+1} + k_i)$$

$$k_n = \frac{1}{2}(k_i + k_{i-1})$$

$$C_i = \rho_i c_p \Delta x$$

Alternatively, for points on a surface, a heat balance needs to be formulated to develop the finite difference equation. Introductory heat transfer texts include finite difference equations for surface nodes exposed to a variety of conditions.

Equation 20 is expressed as an explicit formulation, that is, T_i', can be solved directly, as long as the nodal temperatures are known at the beginning of the time step. Consequently, the equations are uncoupled and can be readily solved. However, this formulation can provide numerically unstable results (computed temperatures may become greater than the exposure temperature or may decrease within an object even though it is being heated). Stability limits are based on the time step and grid size. For constant material properties, the stability limit for one-dimensional problems is expressed as

$$\frac{\alpha \Delta t}{(\Delta x)^2} < 0.5 \quad (21)$$

In order to satisfy the stability limit, a sufficiently small time step must be selected for a given grid spacing. As the grid spacing is decreased, the time step also needs to be decreased. The stability criterion is applied at each node, with the resulting time step for the analysis being less than the smallest time step required for stability.

Another formulation for the finite difference equation, referred to as the implicit formulation, is presented as

$$C_i \frac{(T_i' - T_i)}{\Delta t} = \frac{k_m(T_{i+1}' - T_i')/\Delta x - k_n(T_i' - T_{i+1}')/\Delta x}{\Delta x} \quad (22)$$

The implicit formulation has the characteristic of being numerically stable for any time step or grid size. In this formulation, the time step and grid size are selected solely based on concerns for accuracy. However, the disadvantage of the implicit formulation is that all of the equations are coupled as the right-hand side of the equation includes nodal temperatures at the end of the time step. Thus, all of the equations must be solved simultaneously.

EXAMPLE 6:

A 10-cm-thick wall is initially at a uniform temperature of 20°C. The properties of the wall are: conductivity = 25 W/m·K, density = 6000 kg/m^3, and the specific heat = 500 J/kg·K. Assume that the material properties are independent of temperature. The right side is suddenly exposed to a convective environment, with a coefficient of 10 W/m^2·K and a temperature of 500°C. The left side of the wall is maintained at 20°C. A grid size of 2.5 cm is selected. Determine the temperature within the wall after 5 min. (See Figure 1-2.8.)

Node 1 has a known temperature due to the maintained surface temperature. Thus, only the temperatures at the other nodes need to be determined.

The finite difference equation for the interior nodes (nodes 2 through 4), based on the formulation of Equation 20, is

$$6000 \cdot 500 \frac{(T_i' - T_i)}{\Delta t} = \frac{25(T_{i+1} - 2T_i + T_{i-1})}{(0.025)^2}$$

For node 5, the following equation is applicable

$$6000 \cdot 500 \frac{(T_i' - T_i)}{\Delta t} = \frac{10(500 - T_i) - 25(T_i - T_{i-1})/0.025}{0.025}$$

The stability criterion for nodes 2 through 4 is given as

$$\frac{[25/(6000 \cdot 500)]\Delta t}{0.025^2} < 0.5$$

According to this criterion, the time step must be less than 37 s. For node 5, the stability criterion is expressed as

$$\frac{(25/0.025 + 10)\Delta t}{(6000 \cdot 500 \cdot 0.025)} < 1.0$$

The maximum time step according to this criterion is 2970 s. Consequently, a time step of 30 s is selected, less than the smallest time step of 37 s determined for the wall. The resulting calculations are presented in Table 1-2.1.

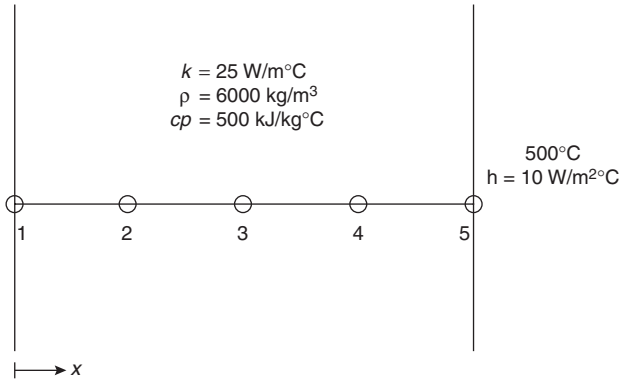

Figure 1-2.8. ***Finite difference grid, Example 6.***

Table 1-2.1 ***Temperatures within Wall Assembly (°C)***

Time (s)	Node 1	Node 2	Node 3	Node 4	Node 5
0	20.0	20.0	20.0	20.0	20.0
30	20.0	20.0	20.0	20.0	21.9
60	20.0	20.0	20.0	20.8	23.1
90	20.0	20.0	20.3	21.4	24.1
120	20.0	20.1	20.6	22.0	24.9
150	20.0	20.3	21.0	22.6	25.6
180	20.0	20.5	21.3	23.2	26.3
210	20.0	20.6	21.7	23.7	27.0
240	20.0	20.8	22.1	24.2	27.6
270	20.0	21.0	22.4	24.7	28.1
300	20.0	21.2	22.8	25.2	28.6

The finite element method also starts with a discretized object. However, one of the principal differences from the finite difference method is the use of the exact governing equation. Most finite element formulations use a polynomial fit of the temperature profile within an element to solve the equation. The partial differential equation is reformulated as an ordinary differential equation often using principles of variational calculus. Because an exact equation is used, and only the geometry is being approximated, the finite element method typically provides a more accurate analysis for course grids than the finite difference method. The equation is applied for each element, with the resulting set of equations assembled into a matrix.

$$[C]\{\dot{T}\} + [K]\{T\} = \{Q\}$$

where

C = capacitance matrix, accounting for ρc product associated with each element

K = conductivity matrix, accounting for conductivity of element

T = vector (column matrix), which represents temperature at each node

Q = vector (column matrix), which represents heat generation at each node

Determination of the temperature profile within the wall requires solving the matrix-based equations. Several typical matrix solutions can be used, such as Gaussian elimination, though such methods are not efficient due to the K matrix being sparsely populated. Consequently, advancements in finite element modeling are related to more efficient solution techniques.

As with finite difference models, explicit and implicit formulations can be developed. However, an elementary expression for the stability criterion for the explicit formulation is not available.

Numerous finite difference and finite element algorithms are available to analyze the heat conduction within a fire-exposed assembly. Even though recent publications refer more frequently to the application of finite element analyses, some recent applications of finite difference models have been described. Lie and Harmathy formulated a finite difference model to analyze the heating of circular reinforced concrete columns exposed to the standard fire.[14] In addition, finite difference models have been developed to examine the heating of fire-exposed concrete floor slabs, square reinforced concrete columns, and concrete-filled tubular steel columns.[15–17] Ahmed and Hurst have applied a one-dimensional, finite difference analysis of the coupled heat and mass transfer through carbonate and siliceous aggregate concrete slabs and multi-layered gypsum wallboard-and-stud assemblies.[18] Dehydration and evaporation phenomena and changes in porosity were considered in Ahmed and Hurst's model. Mehaffey and Takeda formulated a finite difference model to analyze the heating of wood stud walls exposed to the standard fire.[19] In Mehaffey and Takeda's model, dehydration and porosity of gypsum wallboard is accounted for through the use of effective properties. Milke and Vizzini developed a finite difference model to investigate the thermal response of fire-exposed anisotropic slabs, such as graphite-reinforced epoxy composites and glass-reinforced thermoplastic composites.[7,20] PATHOS-2 is a one-dimensional finite difference model developed principally for the evaluation of fire-exposed structures on offshore platforms.[21] In a recent review of thermal analysis programs by Sullivan et al.,[22] FIRETRANS and CEFICOSS were identified as contemporary finite difference models.[23,24] FIRETRANS can be used to address one-dimensional problems involving slabs exposed to fire. CEFICOSS is capable of addressing two-dimensional problems with one axis of symmetry perpendicular to the heating direction.

Several recently-documented examples can be found where finite element analyses have been applied to analyze the thermal response of fire-exposed building assemblies including steel beams, partially- and fully-protected steel columns, wall assemblies, and floor systems. Finite element models which have been specifically developed to address the thermal response of fire-exposed building assemblies include FIRES-T3, TASEF-2, SUPER-TEMPCALC, STABA-F, and a model by Terro.[25–29] All of the models can address two-dimensional problems except for FIRES-T3, which can address three-dimensional problems. FIRES-T3, TASEF-2, and SUPER-TEMPCALC can be used to evaluate the thermal response of assemblies with voids.

Some of the applications can only simulate conditions associated with the standard fire exposure associated with fire resistance tests, while others can address any specified exposure condition. Milke and Sullivan et al. provide reviews of five finite element models to evaluate thermal response from fire.[22,30]

FIRES-T3 and TASEF are of particular interest due to their capability to account for time-varying exposure conditions and temperature-dependent material properties.[25,26] Both codes were formulated to predict the temperature distribution in structural members resulting from exposure to a fire. Both models are based on the same principles and have virtually the same explicit formulation. They differ primarily in their input requirements. Some additional information on FIRES-T3 and TASEF is available in Section 4, Chapter 9 of this handbook. A comparison of FIRES-T3 and TASEF was provided elsewhere by Milke.[30] TASEF is available from Sterner and Wickström at

the Swedish National Testing Institute.[25] FIRES-T3 is available from Milke at the University of Maryland.

A typical diagram of a finite element mesh for a steel column with spray-applied, contour protection is presented in Figure 1–2.9. Element numbers are included within the circles, nodal numbers are encircled. Elements representing the steel are 1, 5, 9, and 13. As a result of symmetry, only one quadrant of the column needs to be modeled.

Limitations

This short summary of heat conduction has included only a few of the better known solutions of the heat conduction equation. It is very difficult to obtain analytic solutions for objects with complex geometric contours. Published analytic solutions all relate to simple geometric forms. Numerical methods can be used for more complex shapes, but coding the boundary conditions for complex shapes is awkward and tedious. It is seldom done unless there is strong economic motivation to do so.

For the temperature ranges found in fire studies, there are often significant changes in k, the thermal conductivity.[8] Where k is a function of T, the heat conduction equation becomes nonlinear and numerical methods are required. Using a variable k produces a quantitatively superior result, but usually not one that is qualitatively different than would be found with constant k.

Some materials, such as wood, are not isotropic and in these cases k is a tensor quantity. Although results calculated assuming a constant, scalar k may not differ qualitatively from more accurate calculations using a tensor k, in some cases (for example, flame spread), the difference may be important.[31]

Specific heat may also vary, though this is less often a problem than changes in k. When the specific heat appears to vary, it is well to suspect chemical changes, as they are more likely to occur than the Debye temperature being too high.

Transmission of heat in gases or liquids often plays a major role in fire analysis. Occasionally, conduction is important for these materials, but in making calculations, care must be taken that thermally induced convection or radiation does not dominate the heat transfer. If the hotter material is above the cooler it will be stable against convective motions, while in the reverse case, it will be unstable and convection will surely dominate. Radiation may be more important than conduction even in the thermally stable case because for many gases (e.g., air), conduction is low (since gases are electrical insulators), but they absorb radiation only weakly. The radiant energy passes directly through these gases. For example, near room temperature a layer of air 1 cm thick transmits about as much heat by radiation as by conduction.

Where liquids are involved, changes in surface tension with temperature have been shown to induce subsurface

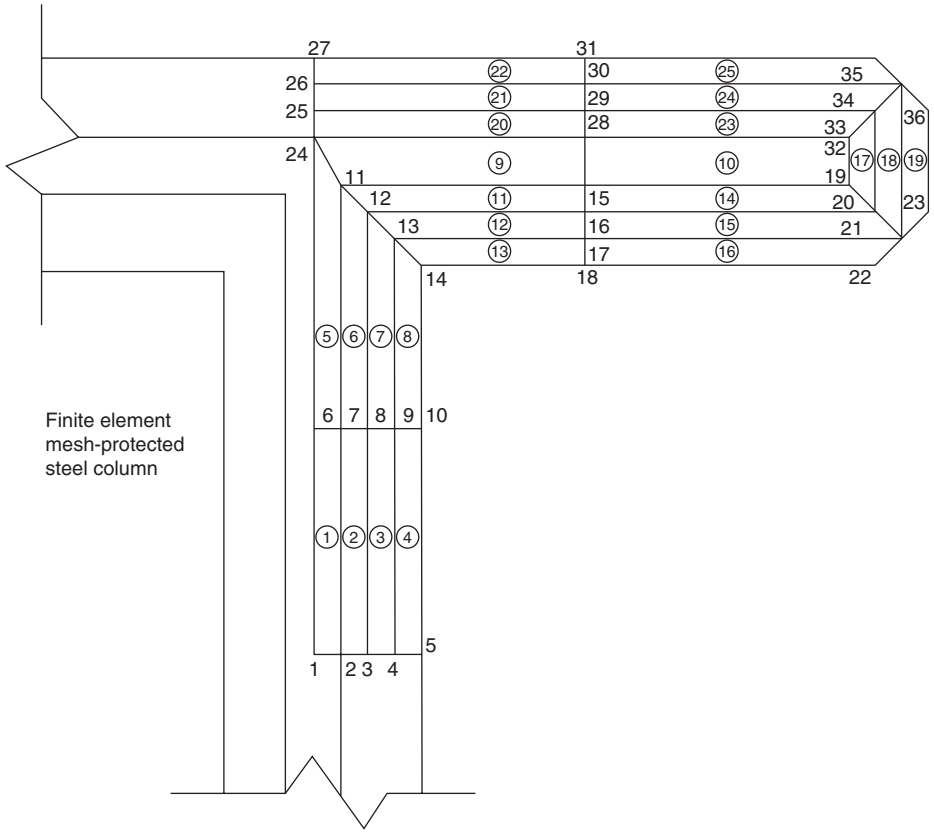

Figure 1-2.9. ***Finite element mesh—protected steel column.***

convective flows that dominate the heat transfer process. In this case, heat transfer calculations including only conduction (based on the assumption of a quiescent liquid) may be incorrect.[32]

An example where heat transmission in a "solid" may be influenced by convection is a large-pore, closed-cell cellular foam. When a temperature difference is imposed across the sides of a vertical slab, a small temperature difference is imposed across each cell. This results in small density differences in the gas in each cell. In the presence of gravity these differences will induce a convective circulation of the gas in each cell, which may transfer more heat across the cell than can be conducted through its thin walls.

Radiation may also be important in these materials. An example where radiation is an important mode of heat transfer within a "solid" is in a low-density porous, smoldering material or in porous char. The forward transmission of heat, which is necessary for the spread of smoldering combustion, against a thermally induced airflow through the porous material occurs almost entirely by radiation across the pores, not by conduction through the solid pore walls.[33]

One of the most serious problems in heat conduction calculations occurs when the material is not thermally stable. Changes in thermal conductivity may be important; but often more important, there may be the release or absorption of heat within the solid. This release or absorption is often accompanied by the release of material, which then migrates (diffuses) through the (porous) solid. The heat conduction equation allows for this release of heat, but the accompanying physical/chemical processes must be treated by separate, coupled, simultaneous equations. The total computation becomes complex (e.g., in the theoretical treatment of smoldering or the pyrolysis of wood). Theoretical studies of the fire performance of reinforced concrete require that the effect of adsorbed and chemically bound water be included, and today this is regularly done.[34,35] Similarly, the effect of moisture should be included in the analysis of the fire performance of gypsum wallboard. Unfortunately, this is not often done, although the same techniques that are used successfully with concrete apply.

There are two drawbacks to the applicability of numerical models to predict the thermal response of any building assembly to fire. One difficult aspect of applying a numerical model is associated with acquiring accurate input data. "Boundary conditions" associated with the exposure must be stipulated. Material properties need to be available as a function of temperature for all components of the object or assembly being analyzed.

The other difficult aspect involves material behavior. The existing heat transfer analysis algorithms are applicable primarily to inert materials. Where assemblies experience moisture migration, phase changes, dehydration, decomposition or changes in geometry, specific algorithms will need to be identified or developed to model the thermal response of such assemblies. Results for the available models often deviate appreciably from measured temperatures in the area of 100 to 200°C where concrete, gypsum, wood, and other moisture containing materials are included despite the use of effective properties to account for the change in enthalpy.[22] Ahmed and Hurst's model has much better predictive capabilities within this range of temperatures.[18]

Nomenclature

A	surface area across which heat is transferred (m^2)
A	constant
B	constant
b	plate thickness (m)
C	capacitance matrix
C_i	volumetric thermal capacitance of node i($J/m^3 \cdot K$)
c	specific heat ($J/gm \cdot K$)
D	rate of heat release parameter
H	convective heat transfer coefficient plus linearized radiation term ($W/m^2 \cdot K$) $h_c + \varepsilon\sigma[(T_s + T_a)^4 - (T_0 + T_a)^4]/[(T_s + T_a) - (T_0 + T_a)]$
h	convective film coefficient ($W/m^2 \cdot K$)
h_c	convective film coefficient ($W/m^2 \cdot K$)
K	conductivity matrix
k	thermal conductivity of the solid ($W/m \cdot K$)
k_i	thermal conductivity evaluated at temperature of node i($W/m \cdot K$)
$k_{m,n}$	average thermal conductivity ($W/m \cdot K$)
ℓ	length of plate in direction of airflow across its surface
Q	heat content (J)
$\dot{Q}$	heat generation vector
$\dot{q}''$	radiative heat flux per unit area to the surface (W/m^2)
T_a	ambient temperature (K)
T_i	temperature at node i(°C)
T_i'	temperature at node i at end of next time step (°C)
T_s	temperature of the material surface (K)
T	temperature (K)
T	temperature of the solid in Eq 19 (K)
T	temperature vector
T_0	reference temperature, T_0 (K)
t	time (s)
Δt	time step
x	distance normal to the surface (m)
x	coordinate normal to the fuel surface
Δx	grid spacing

Greek Letters

α	the material thermal diffusivity, $k/\rho c$ (m^2/s)
β	thermal inertia, $k\rho c$ ($W^2 s/m^4 \cdot K^2$)
ε	material surface emissivity
ξ	dimensionless distance
τ	dimensionless time
θ	temperature (K)
ρ	density (kg/m^3)
ρ_i	density evaluated at temperature of node i(kg/m^3)
σ	electrical conductivity (ohm)

σ Boltzmann's constant, $\sigma = 5.67 \times 10^{-11}$ (kW/m^2·K^4)
η dummy integration variable
μ dummy integration variable
∂ differential operator

CHAPTER 3

Convection Heat Transfer

Arvind Atreya

Introduction

There are only two fundamental physical modes of energy transfer, conduction and radiation. In conduction, energy slowly diffuses through a *medium* from a point of higher temperature to a point of lower temperature, whereas in radiation, energy is transmitted with the speed of light by electromagnetic waves (or photons), and a transmitting medium is not required. Thus from a conceptual viewpoint, convection is not a basic mode of heat transfer. Instead, it occurs by a combined effect of conduction (and/or radiation) and the motion of the transmitting medium.

Nevertheless, convection plays a very important role in fires. It transports the enormous amount of chemical energy released during a fire to the surrounding environment by the motion of hot gases. This motion may be induced naturally by the fire itself (hot gases rise and cold air rushes to replace them) or by a source external to the fire, such as a prevailing wind. Based on this distinction, the subject of convective heat transfer is usually subdivided into *natural* (free) and *forced* convection. Obviously, both natural and forced convection may occur simultaneously, resulting in a mixed mode of convective heat transfer. A further subdivision based on whether the flow occurs inside (e.g., in a pipe) or outside the body under consideration is also often made. For application of convective heat transfer to fire science, natural convection around objects is clearly far more important than forced convection inside a pipe. Thus greater attention is devoted here to natural convective heat transfer and external flows.

The objective of this chapter is to provide a firm understanding of the physical mechanisms that underlie convective heat transfer, as well as to develop the means to perform convection heat transfer calculations. In the first section of the chapter, basic concepts and relations are developed, while calculation methods are illustrated with the help of examples in the second section. Tables of empirical and theoretical results (including their range of applicability) are also provided for quick reference.

Concepts and Basic Relations

A simple, everyday problem of drying a wet body in a stream of warm dry air is shown in Figure 1-3.1. From our knowledge of fluid mechanics, we expect the flow of air to slow down next to the surface of the wet body, thus transferring some of its momentum to the body. Conversely, the body will experience a drag force if it moves through stationary air. In addition to this exchange of momentum, the body also losses some of its moisture; that is, transfer of mass takes place from the wet surface to the warm air. Furthermore, for moisture to evaporate at the wet surface the necessary heat must also be transferred from the warm air to the wet body. Hence, the body experiences a simultaneous transfer of momentum, mass, and energy.

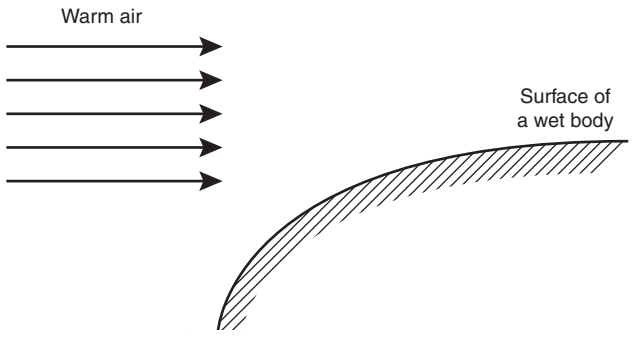

Figure 1-3.1. ***Drying of a wet body in a stream of warm air.***

Dr. Arvind Atreya is a professor of mechanical engineering at the University of Michigan. He has been actively involved in fire research since 1979. This chapter is respectfully dedicated to the author's father, Dr. Dharam Dev Atreya.

To obtain a quantitative description of the above process, note first that all the quantities (mass, momentum, and energy) being transported in the example are conserved, so conservation laws govern their rate of transfer.

These conservation laws need to be supplemented by basic or constitutive relations that relate the rate of transfer to the driving forces and fluid properties. These basic laws are: (1) Newton's law of viscosity, which relates the rate of change of momentum to velocity gradients; (2) Fourier's law of heat conduction, which relates the rate of heat transfer to temperature gradients; and (3) Fick's law of mass diffusion, which relates the rate of mass transfer to concentration gradients. With this framework of conservation and basic laws a majority of laminar convective heat transfer problems can be analyzed, at least in principle. For the turbulent case this framework provides guidance for developing useful empirical correlations.

This section covers the basic laws in the context of laminar flows and their relationships to the more familiar heat transfer coefficients. Later, we see how these heat transfer coefficients can be determined by the application of conservation laws. The effect of turbulence is also discussed and empirical correlations presented.

Basic Laws of Molecular Transfer

Newton's law of viscosity: An isothermal system is shown in Figure 1-3.2. It consists of a fluid trapped between two impervious flat plates that are infinite in extent and separated by a distance, δ. Experiments show that if the lower plate is fixed and the upper plate is moved at a constant velocity, u_∞, then the velocity of the fluid between the two plates varies from u_∞ near the top plate to zero at the fixed plate. Under steady laminar conditions, a linear velocity profile is established as shown in Figure 1-3.2. The fluid thus exerts a shear force on the stationary plate. Experiments also show that τ, the shear force exerted on the bottom plate per unit area, is directly proportional to u_∞ and inversely proportional to the separation distance, δ; that is,

$$\tau \alpha \frac{u_\infty}{\delta} \quad \text{or} \quad \tau = \mu \frac{u_\infty}{\delta}$$

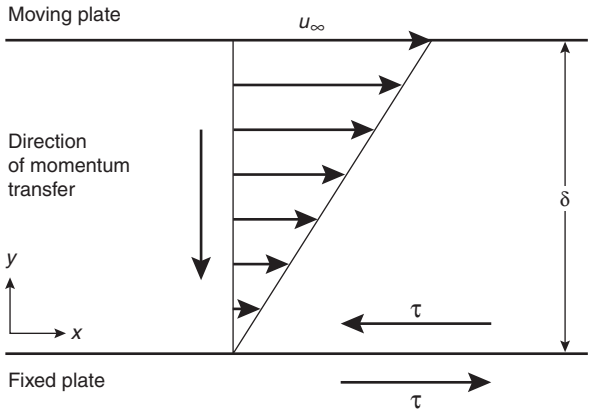

Figure 1-3.2. ***Steady-state velocity distribution in a Newtonian fluid.***

The constant of proportionality, μ, is called the dynamic viscosity of the fluid (units: $N \cdot s/m^2$) and the force per unit area, τ, is called the shear stress. (In some texts a negative sign is introduced to emphasize the direction of net momentum transfer, i.e., from the fluid at higher velocity to the fluid at lower velocity.) Note that the shear stress τ exerted by the fluid on the fixed plate is in the positive x-direction and that exerted by the fixed plate on the fluid is equal and opposite in direction.) In differential form this relationship expresses the shear stress at any location, y, in the fluid as

$$\tau = \mu \frac{du}{dy} \tag{1}$$

This is Newton's law of viscosity. Equation 1 states that the shear stress experienced by a fluid layer is directly proportional to the velocity gradient inside the fluid at that location.

Fluids that behave according to Equation 1 (i.e., τ is linearly related to the velocity gradient, du/dy, and μ is not a function of the velocity gradient) are called Newtonian fluids. Fortunately, all gases and most simple liquids such as water obey this simple law. For gases, μ roughly increases as the square root of temperature as predicted by the kinetic theory of dilute gases. Liquids, on the other hand, become "thinner" (less viscous), that is, μ decreases with increase in temperature. For non-Newtonian fluids (e.g., pastes, slurries, blood, etc.) the dynamic viscosity μ also depends on the velocity gradient or the rate of shear.

Fourier's law of heat conduction: Two stationary parallel plates separated by a distance, δ_t, are shown in Figure 1-3.3. Let the temperature of the upper plate be T_∞ and that of the lower plate be T_s. Under steady conditions and for temperature independent properties of the trapped fluid, a linear temperature distribution as shown in Figure 1-3.3 is obtained. Thus, as expected, heat is transferred by the stationary fluid from the hot to the cold plate. The heat flow per unit area per unit time through the fluid ($\dot{q}''$ J/m^2s) is found to be directly proportional to the temperature difference, $T_\infty - T_s$, and inversely proportional to the separation distance, δ_t; that is,

$$\dot{q}'' \alpha \frac{T_\infty - T_s}{\delta_t} = -k \frac{T_\infty - T_s}{\delta_t}$$

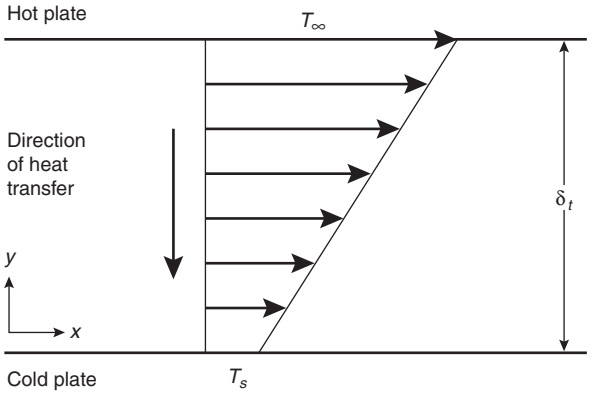

Figure 1-3.3. ***Steady-state temperature distribution.***

The constant of proportionality, k, is called the thermal conductivity (units: J/mKs). The minus sign is a consequence of the second law of thermodynamics, which requires the heat to flow in the direction of decreasing temperature. In differential form the heat across any fluid layer is given by

$$\dot{q}'' = -k\frac{dT}{dy} \tag{2}$$

This is known as Fourier's law of heat conduction, which states that the heat flux is directly proportional to the temperature gradient and the heat flux vector is oriented in the direction of decreasing temperature. The thermal conductivity, k, like viscosity, μ, is a physical property of the fluid. The thermal conductivity of gases at low densities increases with increasing temperature (roughly as $\sqrt{T}$ according to the kinetic theory of dilute gases) whereas the thermal conductivity of most liquids decreases with increasing temperature.

Fick's law of mass diffusion: Once again, consider the parallel plate example. This time, there are no temperature gradients and no directed motion of the plates. Instead, the top plate is maintained at a higher concentration of species A ($C_{A\infty}$, kg of A/m^3), assuming that it is wet, and the bottom plate is maintained at a fixed but lower concentration of species A (C_{AW}, kg of A/m^3). Then, under steady conditions a concentration profile, as shown in Figure 1-3.4, is established. This nonuniform concentration field is the driving force for species A to diffuse from the top to the bottom plate. The mass flux of species A, $\dot{m}''$ (units: kg/m^2s), leaving the top plate and arriving at the bottom plate through the fluid, B, is found to be directly proportional to the concentration difference and inversely proportional to the separation distance δ_d, that is,

$$\dot{m}''_A \alpha \frac{C_{A\infty} - C_{AW}}{\delta_d} = -D_{AB}\frac{C_{A\infty} - C_{AW}}{\delta_d}$$

The constant of proportionality, D_{AB}, is called diffusivity of species A through species B and has units of m^2/s. The negative sign once again indicates that the net mass transfer of species A occurs in the direction of decreasing concentration. In the differential form, the mass flux of species A across any layer of fluid B is given by

$$\dot{m}'' = -D_{AB}\frac{dC_A}{dy} \tag{3}$$

This is known as Fick's law of mass diffusion, which states that the mass flux across a fluid layer is directly proportional to the local concentration gradient. For binary gas mixtures, D_{AB} increases with increasing temperature roughly as three-halves power, as predicted by the kinetic theory of dilute gases.

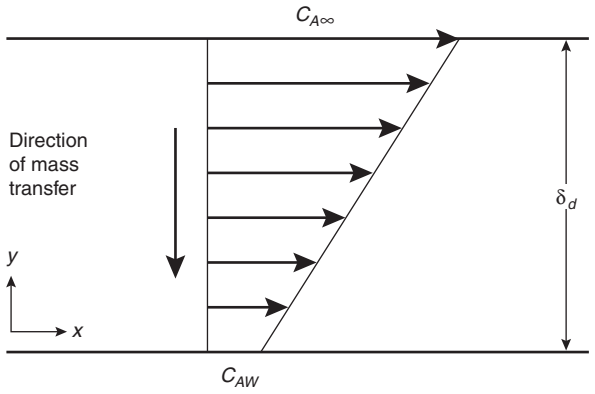

Figure 1-3.4. ***Steady-state concentration distribution.***

Discussion: Equations 1, 2, and 3 look very similar—they all relate the flux of the transported quantity to their respective local gradients. Actually, these equations may be considered definitions of the three macroscopic physical properties, μ, k, and D_{AB} of the fluid. In general, these properties are functions of temperature, pressure, and composition. As noted earlier, for low pressure binary gas mixtures (<10 atm) the pressure, temperature, and composition dependence of these properties can be approximately predicted by the kinetic theory of gases. In fact, the physical mechanism of all three transport processes is easily understood by considering the random motion of molecules in an ideal gas.

Molecules of a gas, even in the absence of bulk fluid motion, move around randomly at high speeds and bump into each other. Thus, a given molecule may be found anywhere between the two parallel plates. The problem, however, is how to distinguish one molecule from another. When the upper plate is moving relative to the bottom plate, the molecules adjacent to the upper plate attain a directed velocity over and above their random motion. Consequently, as the molecules near the upper plate find themselves in lower fluid layers (and vice versa) they exchange directed motion (or momentum) by bumping into each other. Similarly, the gas molecules near the hot upper plate are distinguished from those adjacent to the cold lower plate because they possess a higher kinetic energy. Once again, by virtue of random motion, these higher kinetic energy molecules find themselves near the cold plate and collide with low kinetic energy molecules (or vice versa), thus transporting energy. In the case of mass diffusion, the molecules are chemically labeled and their random motion results in mass transfer. Since increasing the gas temperature increases the random molecular motion, the transport processes become more efficient at higher gas temperatures. For gases, the macroscopic physical properties (viscosity, thermal conductivity, and diffusivity) that characterize momentum, heat, and mass transport must also increase with temperature.

Assuming constant properties, Equations 1 and 2 can be rewritten in the following forms:

$$\tau = \left(\frac{\mu}{\rho}\right)\frac{d(\rho u)}{dy} \tag{1a}$$

$$\dot{q}'' = -\left(\frac{k}{\rho c_p}\right)\frac{d(\rho c_p T)}{dy} \tag{1b}$$

Here, μ/p is known as the kinematic viscosity, ν, and has units of m^2/s. The product, ρu, has units of $(kg\ m/s)/m^3$; that is, momentum per unit volume. The quantity, $k/\rho c_p$, is known as the thermal diffusivity, α, and it too has units of m^2/s. The product, $\rho c_p T$, then becomes enthalpy per unit volume and has units of J/m^3. Comparing these with Equation 3, where the mass diffusivity, D_{AB}, also has units of m^2/s and C_A is expressed in kg of species A/m^3, we find that the fluxes are related to their corresponding gradients of volumetric concentration. Furthermore, the ratios of various physical constants yield the familiar nondimensional numbers. These are

$$\text{Prandtl number, Pr} = \nu/\alpha$$
$$\text{Schmidt number, Sc} = \nu/D_{AB}$$
$$\text{Lewis number, Le} = \alpha/D_{AB}$$

Here, the Prandtl number compares the relative magnitude of momentum transfer to heat transfer, the Schmidt number compares momentum transfer to mass transfer, and the Lewis number compares heat transfer to mass transfer. The significance of these nondimensional numbers will become obvious when we discuss boundary layer transfer processes. The balance of this section will discuss primarily heat transfer. The treatment of mass transfer is similar and will not be discussed. However, since fluid motion is central to convective heat transfer, it is necessary to understand momentum transport to solve convective heat transfer problems.

Relationship of Basic Laws to Transfer Coefficients

A flow condition is shown in Figure 1-3.5. A fluid of velocity, u_∞, and temperature, T_∞, flows over an arbitrarily shaped stationary surface of area, A_s. If the surface conditions are such that $T_s \neq T_\infty$, we know that convection heat transfer will occur. The convection heat transfer problem is to relate the local heat flux, $\dot{q}''$, to its driving force, $T_s - T_\infty$. By expressing the heat flux as

$$\dot{q}'' = h(T_s - T_\infty) \tag{4}$$

the problem is reduced to determining h, which is called the heat transfer coefficient. From Equation 2 it is clear that the heat transfer coefficient may be expressed as

$$h = \frac{-k(\partial T/\partial y)\Big|_{y=0}}{(T_s - T_\infty)} \left(\frac{\text{J}}{\text{m}^2\text{s K}}\right) \tag{5}$$

In Equation 5 the partial derivative is used because, in general, temperature is a function of x, y, z, and time. Thus, if the thermal conductivity of the fluid is known, the problem of determining the local heat transfer coefficient is reduced to that of determining the local temperature gradient in the fluid adjacent to the surface. This local temperature gradient can be experimentally measured or obtained theoretically from the solution of the conservation laws. Obviously, the temperature gradient will vary from point to point along the surface of the body. Often, such detail is not required and it may only be necessary to determine an average heat transfer coefficient, $\bar{h}$. This is obtained by integrating over the entire surface area, A_s. The total rate of heat transfer from the body to the fluid is given by

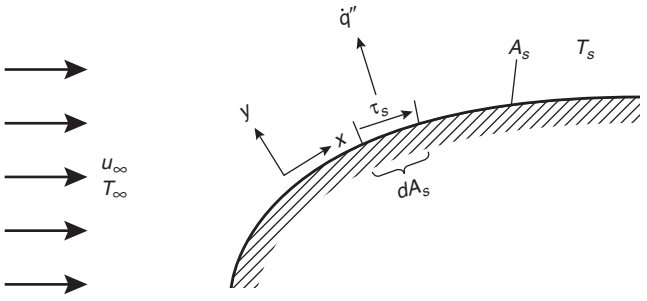

Figure 1-3.5. ***Example of the convection heat transfer problem.***

$$\dot{q}(\text{J/s}) = \int_{A_s} \dot{q}''(\text{J/m}^2\text{s}) \cdot dA_s(\text{m}^2) \tag{6}$$

Defining an average heat transfer coefficient, $\bar{h}$, as

$$\dot{q} = \bar{h} A_s (T_s - T_\infty) \tag{7}$$

The following is obtained from the use of Equations 4, 6, and 7

$$\bar{h} = \frac{1}{A_s(T_s - T_\infty)} \int_{A_s} h(T_s - T_\infty) dA_s \tag{8}$$

If the surface temperature, T_s, is held constant, then

$$\bar{h} = \frac{1}{A_s} \int_{A_s} h dA_s \left(\frac{\text{J}}{\text{m}^2\text{s K}}\right) \tag{9}$$

Similarly, the local shear stress at the surface, τ_s, can be related to its cause, the fluid velocity, u_∞. This relation is derived by defining a local nondimensional friction coefficient, C_f, according to the equation

$$\tau_s \equiv C_f \left(\frac{1}{2}\rho u_\infty^2\right) \tag{10}$$

Once again, the problem is reduced to the determination of C_f. Using Equation 1 we obtain

$$C_f = \frac{\mu(\partial u/\partial y)\Big|_{y=0}}{(1/2)\rho u_\infty^2} \tag{11}$$

Thus, the local friction coefficient can be evaluated from the knowledge of the local velocity gradient in the fluid adjacent to the surface. The average friction coefficient can easily be obtained by integrating the local shear stress, τ_s, over the entire surface area, A_s. The total drag force, D, experienced by the body is given by the product of average shear stress, $\bar{\tau}_s$, and the surface area, A_s. In other words,

$$D \equiv \bar{\tau}_s A_s = \int_{A_S} \tau_S dA_S \tag{12}$$

Assuming u_∞ to be the same at all locations

$$\bar{\tau}_s = \frac{(1/2\rho u_\infty^2)}{A_s} \int_{A_s} C_f A_s \tag{13}$$

Defining the average friction coefficient, $\overline{C}_f$, as

$$\overline{C}_f \equiv \frac{\bar{\tau}_s}{(1/2\rho u_\infty^2)} \tag{14}$$

we get

$$\overline{C}_f = \frac{1}{A_s} \int_{A_s} C_f \, dA_s \tag{15}$$

To obtain h, $\overline{h}$, C_f, and $\overline{C}_f$ a knowledge of fluid properties and temperature and velocity gradients in the fluid adjacent to the surface is required. To obtain these gradients it is necessary to be more specific about the surface geometry and the flow conditions. The governing conservation equations for an arbitrary surface geometry will be first derived and then applied to a flat plate to illustrate the methodology.

Conservation Equations for Convection Heat Transfer

It has been shown that to determine the heat transfer and friction coefficients, the temperature and velocity distributions in the flow are needed. In principle, these may be obtained from the solution of the conservation equations with appropriate boundary conditions. Although in practice it is difficult, the very knowledge of conservation equations and their solutions for simple cases (such as a flat plate) provide considerable insight about the parameters influencing the heat transfer and friction coefficients. Thus, the necessary equations will be first developed and then applied to a flat plate.

Consider the flow over the surface shown in Figure 1-3.6. To simplify the development assume two-dimensional flow conditions, for which x is the direction along the surface and y is normal to the surface. Extension of this to three-dimensional flows is available in the literature.[1–5]

Conservation of mass (continuity equation): The first conservation law that is pertinent to the problem is that matter is neither created nor destroyed. When applied to the differential control volume shown in Figures 1-3.6 and 1-3.7 it states that the net rate of mass flow entering the elemental control volume in the x-direction, plus the net rate of mass flow entering the elemental control volume in the y-direction equals the net rate of increase of mass stored in the control volume. Mass enters and leaves the control volume exclusively through gross fluid motions. Such a transport is often referred to as convective transport.

For a control volume of unit depth in the z-direction, mass entering the left face per unit time, $\dot{M}_x$, is given by

$$\dot{M}_x = \rho(\text{kg/m}^3) u(\text{m/s})\, dy(\text{m}) \cdot 1(\text{m})$$

Similarly, mass entering the bottom face per unit time, $\dot{M}_y$, is given by

$$\dot{M}_y = \rho \cdot v \cdot dx \cdot 1$$

where v is the fluid velocity in the y-direction.

Since ρu and ρv are continuous functions of x, y, and time, in general they will be different at different locations. To determine ρu at $(x + dx)$, expand ρu about the point x in the Taylor series as

$$\rho u(x + dx, y) = \rho u(x, y) + \left[\frac{\partial(\rho u)}{\partial x}\right]_{x,y} dx \tag{16}$$

Similarly,

$$\rho v(x, y + dy) = \rho v(x, y) + \left[\frac{\partial(\rho v)}{\partial y}\right]_{x,y} dy$$

Thus, mass leaving the right face per unit time, $\dot{M}_{x+dx}$, is given by

$$\dot{M}_{x+dx} = \left[\rho u + \frac{\partial(pu)}{\partial x} dx\right] \cdot dy \cdot 1 \tag{17}$$

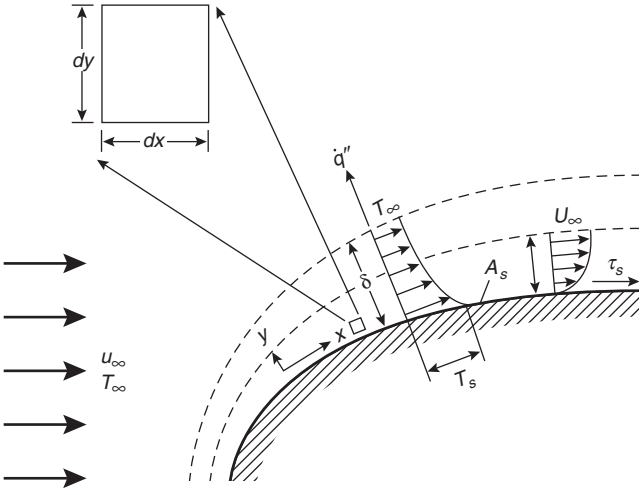

Figure 1-3.6. ***Velocity and temperature distributions inside the fluid for flow over a hot surface.***

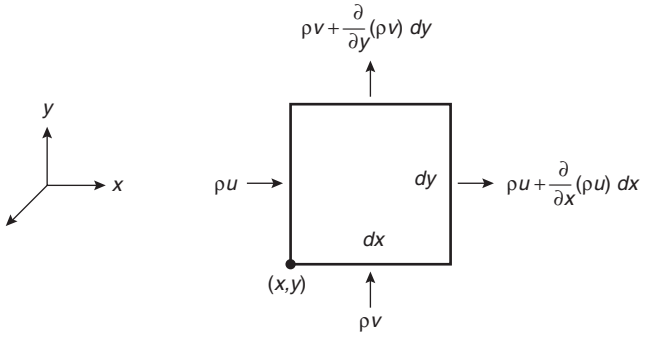

Figure 1-3.7. ***Differential control volume for mass conservation in a two-dimensional flow.***

and mass leaving the top face per unit time, $\dot{M}_{y+dy}$, is

$$\dot{M}_{y+dy} = \left[\rho v + \frac{\partial(\rho v)}{\partial y}\,dy\right] \cdot dx \cdot 1 \tag{18}$$

Finally, the rate of increase (or decrease) of mass stored in the control volume, $\dot{M}_s$, is of the form

$$\dot{M}_s = \frac{\partial}{\partial t}(\rho \cdot dx \cdot dy \cdot 1) = \frac{\partial \rho}{\partial t}\,dx\,dy \tag{19}$$

Thus, conservation of mass requirement may now be expressed as

$$\begin{aligned}(\rho u)\,dy + (\rho v)\,dx - \left[\rho u + \frac{\partial(\rho u)}{\partial x}\,dx\right]dy \\ - \left[\rho v + \frac{\partial(\rho v)}{\partial y}\,dy\right]dx = \frac{\partial \rho}{\partial t}\,dx\,dy\end{aligned} \tag{20}$$

After canceling terms and dividing by $dx\,dy$

$$\frac{\partial \rho}{\partial t} + \frac{\partial(\rho u)}{\partial x} + \frac{\partial(\rho v)}{\partial y} = 0 \tag{21}$$

This is the *continuity equation,* which is an expression of the overall mass conservation requirement and must be satisfied at every point in the flow. This equation applies for a single species fluid, as well as for mixtures in which species diffusion and chemical reactions may be occurring.

Conservation of momentum: The second conservation law pertinent to the convection heat transfer problem is Newton's second law of motion. For a differential control volume in a flow field, this requirement states that the sum of all forces acting on the control volume must equal the rate of increase of the fluid momentum within the control volume, plus the net rate at which momentum leaves the control volume (outflow-inflow).

The forces acting on the fluid may be categorized into *body forces* that are proportional to the volume, and *surface forces,* which are proportional to the area. Gravitational, centrifugal, magnetic, and electric fields are familiar examples of body forces. Of these, gravitational body force is the most important from the fire science point of view. The x- and y-components of this body force per unit volume of the fluid will be designated as F_{Bx} and F_{By}, respectively.

The surface forces, F_s, acting on the fluid are called stresses (force/area). These are due to fluid static pressure, p, and viscous stresses. Since pressure is always normal to the surface, the viscous stresses are also resolved into normal stresses, σ_{ii}, which act normal to the surface, and shear stresses, τ_{ij}, which act along or parallel to the surface. Figure 1-3.8 shows the various viscous stresses acting on the surface of a differential control volume. A double subscript notation is used to specify the stress components. The first subscript indicates the direction of the outward normal to the surface, and the second subscript indicates the direction of the force component. Accordingly, the stress τ_{xy}, acting on the left face, corresponds to the viscous shear force per unit area in the negative y-direction on a face whose normal is in the negative x-direction—resulting in a positive shear stress. All the viscous stresses shown in Figure 1-3.8 are positive according to the adopted convention. It should be noted that

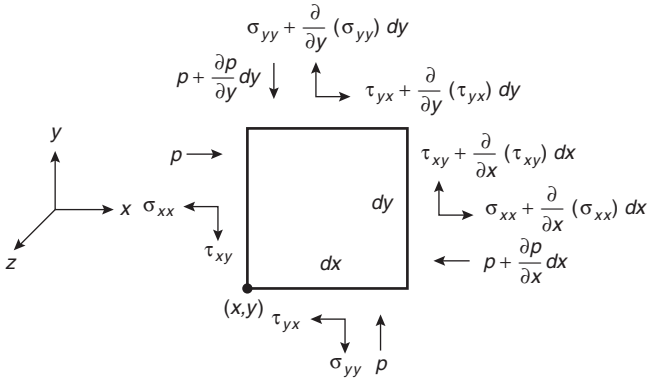

Figure 1-3.8. ***Static pressure, p, and normal and shear viscous stresses acting on a differential control volume in a two-dimensional flow.***

these forces act on the fluid inside the control volume and are caused by its interaction with the surrounding fluid. Thus, these viscous stresses will vanish if the fluid velocity, or more specifically the velocity gradient in the fluid, becomes zero. The normal viscous stresses shown in Figure 1-3.8 must not be confused with static pressure, p, which does not vanish for zero velocity. Since these stresses are continuous functions of x, y, and time, the customary Taylor's expansion is used to express the stresses on the top and right faces of the control volume shown in Figure 1-3.8. Thus, the net surface force in the x- and y-directions may be expressed as

$$F_{sx} = \left(\frac{\partial \sigma_{xx}}{\partial x} - \frac{\partial p}{\partial x} + \frac{\partial \tau_{yx}}{\partial y}\right)dx\,dy \tag{22}$$

$$F_{sy} = \left(\frac{\partial \sigma_{yy}}{\partial y} - \frac{\partial p}{\partial y} + \frac{\partial \tau_{xy}}{\partial x}\right)dx\,dy \tag{23}$$

To use Newton's second law, the time rate of change of momentum and the momentum influx and outflux must also be evaluated. To focus on the x-direction, the relevant momentum fluxes are shown in Figure 1-3.9. The mass flux through the left face is ρu and hence the corresponding momentum flux is $(\rho u)u$. Similarly, the x-momentum flux due to mass flow in the y-direction through the bottom face is $(\rho v)u$. Thus the net rate at which momentum leaves the control volume is given by (x-momentum outflow – inflow)

$$\frac{\partial}{\partial x}[(\rho u)u]\,dx\,dy + \frac{\partial[(\rho v)u]}{\partial y}\,dy\,dx$$

In addition, the time rate of change of x-momentum of the fluid within the control volume is given by

$$\frac{\partial}{\partial t}(\rho u)\,dx\,dy$$

Equating the total rate of change in the x-direction to the sum of forces in the x-direction, we obtain

$$\frac{\partial(\rho u)}{\partial t} + \frac{\partial[(\rho u)u]}{\partial x} + \frac{\partial[(\rho v)u]}{\partial y} = \frac{\partial \sigma_{xx}}{\partial x} - \frac{\partial p}{\partial x} + \frac{\partial \tau_{yx}}{\partial y} + F_{Bx} \tag{24}$$

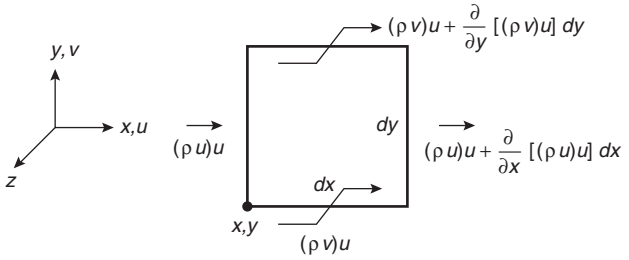

Figure 1-3.9. ***Influx and outflux of x-momentum in the control volume.***

By using Equation 21, Equation 24 may be expressed in a more convenient form as

$$\rho\left(\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y}\right) = \frac{\partial}{\partial x}(\sigma_{xx} - p) + \frac{\partial \tau_{yx}}{\partial y} + F_{Bx} \qquad (25)$$

A similar expression is obtained for the y-direction. This is

$$\rho\left(\frac{\partial v}{\partial t} + u\frac{\partial v}{\partial x} + v\frac{\partial v}{\partial y}\right) = \frac{\partial}{\partial y}(\sigma_{yy} - p) + \frac{\partial \tau_{xy}}{\partial x} + F_{By} \qquad (26)$$

In Equations 25 and 26, the first term on the left side represents the increase in momentum of the fluid inside the control volume, and the remaining terms represent the net rate of momentum efflux from the control volume. The terms on the right side of the equations account for the net viscous, pressure, and body forces acting on the control volume. These equations must be satisfied at every point in the fluid. A solution of Equations 21, 25, and 26 along with appropriate boundary conditions yields the velocity field needed to determine the friction coefficient.

Before a solution to the above equations can be obtained, it is necessary to relate the viscous stresses to the velocity gradients. For a one-dimensional flow of a Newtonian fluid, Equation 1 relates the shear stress to the velocity gradient in the fluid. For a two-dimensional flow of Newtonian fluid,[2] the required stress-velocity gradient expressions are

$$\sigma_{xx} = 2\mu\frac{\partial u}{\partial x} - \frac{2}{3}\mu\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}\right) \qquad (27)$$

$$\sigma_{yy} = 2\mu\frac{\partial v}{\partial y} - \frac{2}{3}\mu\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}\right) \qquad (28)$$

$$\tau_{xy} = \tau_{yx} = \mu\left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right) \qquad (29)$$

On substituting Equations 27, 28, and 29 into Equations 25 and 26, the desired form of the x- and y-momentum equations is obtained. These are

x-momentum equation

$$\rho\left(\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y}\right) = -\frac{\partial p}{\partial x} + \mu\left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2}\right) + \frac{1}{3}\mu\frac{\partial}{\partial x}\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}\right) + F_{Bx} \qquad (30)$$

y-momentum equation

$$\rho\left(\frac{\partial v}{\partial t} + u\frac{\partial v}{\partial x} + v\frac{\partial v}{\partial y}\right) = -\frac{\partial p}{\partial y} + \mu\left(\frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2}\right) + \frac{1}{3}\mu\frac{\partial}{\partial y}\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}\right) + F_{By} \qquad (31)$$

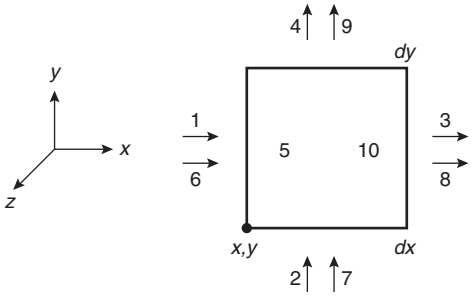
For an isothermal system, Equations 21, 30, and 31 along with the equation of state ($p = \rho RT$ for an ideal gas) provide a complete set for determining the four dependent variables (u, v, p, and ρ) as a function of the three independent variables x, y, and t. However, for a non-isothermal system such as a fire, energy balance must also be considered.

Conservation of energy: The temperature field inside the fluid, $T(x, y, t)$, needed to determine the heat transfer coefficient is obtained by applying the first law of thermodynamics to the differential control volume shown in Figure 1-3.6. Before writing the energy balance for this control volume, it is necessary to identify the items that must be included in the energy budget. These are:

1. The stored energy. This includes the specific internal or thermal energy, e; J/kg, and the kinetic energy of the fluid per unit mass, $V^2/2 = (u^2 + v^2)/2$. Potential energy is neglected because for most problems in convective heat transfer it is substantially smaller than thermal and kinetic energy. Hence, the total energy content per unit volume is given by: $\rho(e + V^2/2)$.
2. Conduction of thermal energy across the surfaces of the control volume. Here, the rate of energy transported per unit area per unit time across the control surface is given by Equation 2 as $\dot{q}''_x = -k\partial T/\partial x$ for the x-direction, and $\dot{q}''_y = -k\partial T/\partial y$ for the y-direction.
3. Energy generated per unit volume per unit time inside the control volume (Q watts/m^3). This may be due to chemical reactions (endothermic or exothermic) or may be caused by the radiative loss of heat. Although the specific form of Q will depend upon the nature of the physical process, here we will treat it only as a rate of heat loss or gain per unit volume.
4. The rate of work done by surface or body forces. For surface forces, $\vec{F}_S$, it is given by: [$\vec{F}_S \cdot$ (velocity vector)] (surface area): and for the body forces, $\vec{F}_B$, it is given by: [$\vec{F}_B \cdot$ (velocity vector)](volume). Both these expressions have units of 'watts' or work done per unit time.

With these definitions, consider the control volume shown in Figures 1-3.6 and 1-3.10. The conservation of energy for this control volume can be simply stated as

$$\begin{pmatrix}\text{rate of increase}\\ \text{of energy inside}\\ \text{the control volume}\end{pmatrix} = \begin{pmatrix}\text{net rate of energy flow}\\ \text{into the control volume}\\ \text{by bulk fluid motion}\end{pmatrix} + \begin{pmatrix}\text{flow of heat through}\\ \text{the control surface}\\ \text{by conduction}\end{pmatrix} + \begin{pmatrix}\text{rate of work done by body}\\ \text{and surface forces}\end{pmatrix} + \begin{pmatrix}\text{energy generated inside}\\ \text{the control volume}\end{pmatrix} \qquad (32)$$



1. $\rho\left(e + \frac{V^2}{2}\right)u \cdot dy \cdot 1$
2. $\rho\left(e + \frac{V^2}{2}\right)v \cdot dx \cdot 1$
3. $\left\{\rho\left(e + \frac{V^2}{2}\right)u + \frac{\partial}{\partial x}\left[\rho u\left(e + \frac{V^2}{2}\right)\right]dx\right\} dy \cdot 1$
4. $\left\{\rho\left(e + \frac{V^2}{2}\right)v + \frac{\partial}{\partial x}\left[\rho v\left(e + \frac{V^2}{2}\right)\right]dy\right\} dx \cdot 1$
5. $\frac{\partial}{\partial t}\left[\rho\left(e + \frac{V^2}{2}\right)\right]dx \cdot dy \cdot 1$
6. $\dot{q}''_x \cdot dy \cdot 1$
7. $\dot{q}''_y \cdot dx \cdot 1$
8. $\left(\dot{q}''_x + \frac{\partial \dot{q}''_x}{\partial x}dx\right) dy \cdot 1$
9. $\left(\dot{q}''_y + \frac{\partial \dot{q}''_y}{\partial y}dy\right) dx \cdot 1$
10. Energy generated $\quad Q\,dx\,dy \cdot 1$

Figure 1.3-10. ***A control volume showing the energy conducted and convected through its control surfaces.***

In Equation 32 the rate of increase of energy inside the control volume is given by

$$\frac{\partial}{\partial t}\left[\rho\left(e + \frac{V^2}{2}\right)\right]dx\,dy$$

The net rate at which the energy enters the control volume by convection or bulk fluid motion is obtained by subtracting the energy going out from that coming in, to yield

$$-\frac{\partial}{\partial x}\left[\rho u\left(e + \frac{V^2}{2}\right)\right]dx\,dy - \frac{\partial}{\partial y}\left[\rho v\left(e + \frac{V^2}{2}\right)\right]dx\,dy$$

Similarly, the heat flowing into the control volume by conduction is given by

$$-\left(\frac{\partial \dot{q}''_x}{\partial x} + \frac{\partial \dot{q}''_y}{\partial y}\right)dx\,dy = \left[\frac{\partial}{\partial x}\left(k\frac{\partial T}{\partial x}\right) + \frac{\partial}{\partial y}\left(k\frac{\partial T}{\partial y}\right)\right]dx\,dy$$

Finally, the net rate at which work is done on the fluid inside the control volume (Figure 1-3.11) is given by the expression

$$(uF_{Bx} + vF_{By})\,dx\,dy - \left[\frac{\partial(pu)}{\partial x} + \frac{\partial(pv)}{\partial y}\right]dx\,dy + \left[\frac{\partial}{\partial x}(u\sigma_{xx}) + \frac{\partial}{\partial y}(v\sigma_{yy}) + \frac{\partial}{\partial y}(u\tau_{yx}) + \frac{\partial}{\partial x}(v\tau_{xy})\right]dx\,dy$$

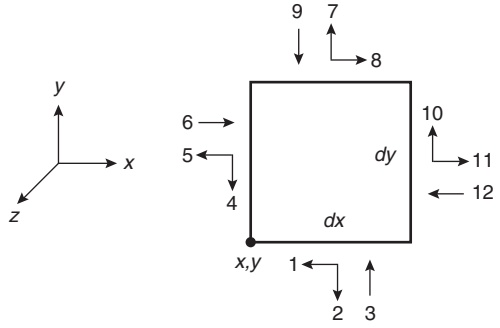
On substituting these expressions into Equation 32, simplifying and using Equations 27 through 31, we obtain

$$\rho C_p\frac{\partial T}{\partial t} + \rho u C_p\frac{\partial T}{\partial x} + \rho v C_p\frac{\partial T}{\partial y} = \frac{\partial}{\partial x}\left(k\frac{\partial T}{\partial x}\right) + \frac{\partial}{\partial y}\left(k\frac{\partial T}{\partial y}\right) + \left(\frac{\partial p}{\partial t} + u\frac{\partial p}{\partial x} + v\frac{\partial p}{\partial y}\right) + \mu\Phi \tag{33}$$

In Equation 33, the thermodynamic definition of enthalpy ($i = e + p/\rho$ and $di = C_p dT$) has been used. Also, the term $u\Phi$ is called the viscous dissipation and is given by

$$u\Phi = 2\mu\left[\left(\frac{\partial u}{\partial x}\right)^2 + \left(\frac{\partial v}{\partial y}\right)^2\right] + \left(\frac{\partial u}{\partial y} + \frac{\partial v}{\partial x}\right)^2 - \frac{2}{3}\left(\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y}\right)^2 \tag{34}$$

Equations 21, 30, 31, and 33, along with the equation of state ($p = \rho RT$, for an ideal gas), provide a complete set for determining the temperature and velocity field [$T(x, y, t)$,



1. $-u\tau_{yx}\,dx$
2. $-v\sigma_{yy}\,dx$
3. $pv\,dx$
4. $-v\tau_{zy}\,dy$
5. $-u\sigma_{xx}\,dy$
6. $pu\,dy$
7. $\left[v\sigma_{yy} + \frac{\partial}{\partial y}(v\sigma_{yy})\,dy\right]dx$
8. $\left[u\tau_{yx} + \frac{\partial}{\partial y}(u\tau_{yx})\,dy\right]dx$
9. $\left[-pv - \frac{\partial}{\partial y}(pv)\,dy\right]dx$
10. $\left[v\tau_{xy} + \frac{\partial}{\partial x}(v\tau_{xy})\,dx\right]dy$
11. $\left[u\sigma_{xx} + \frac{\partial}{\partial x}(u\sigma_{xx})\,dx\right]dy$
12. $\left[-pu - \frac{\partial}{\partial x}(pu)\,dx\right]dy$

Figure 1-3.11. ***Control volume showing the rate of work done by various surface forces. All units are in watts.***

$u(x, y, t)$, $v(x, y, t)$] inside the fluid. However, it is not possible to solve the above set of coupled nonlinear partial differential equations. Therefore, several simplifying approximations are made. These are discussed below.

Simplifications:

1. *Low velocity:* For most problems encountered in convective heat transfer, the flow velocity is low enough (Mach number $< 1/3$) to ignore the contribution of viscous work in the energy equation. This allows the term $\mu\Phi$ in Equation 33 to be dropped.
2. *Incompressible flow:* Fluid density is assumed to be constant except in the buoyancy terms (F_{Bx}, F_{By}) of Equations 30 and 31. This is called the Boussinesq approximation and will be discussed later in greater detail.
3. *Steady flow:* This approximation allows all the time derivative terms in the above equations to be dropped.
4. *Constant properties:* Specific heat, thermal conductivity, and viscosity are all assumed to be constant; that is, independent of temperature and pressure.

With these simplifications and assuming that the body force is only due to gravity (i.e., $F_{Bx} = -\rho g_x$ and $F_{By} = -\rho g_y$), Equations 21, 30, 31, and 33 become

Continuity

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \tag{35}$$

x-momentum

$$u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = -\frac{1}{\rho}\frac{\partial p}{\partial x} + \nu\left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2}\right) - g_x \tag{36}$$

y-momentum

$$u\frac{\partial v}{\partial x} + v\frac{\partial v}{\partial y} = -\frac{1}{\rho}\frac{\partial p}{\partial y} + \nu\left(\frac{\partial^2 v}{\partial x^2} + \frac{\partial^2 v}{\partial y^2}\right) - g_y \tag{37}$$

Energy equation

$$u\frac{\partial T}{\partial x} + v\frac{\partial T}{\partial y} = \alpha\left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2}\right) + \frac{1}{\rho C_p}\left(u\frac{\partial p}{\partial x} + v\frac{\partial p}{\partial y}\right) \tag{38}$$

Often, the energy equation is further simplified by assuming that the terms ($u\,\partial p/\partial x$) and ($v\,\partial p/\partial y$) are negligible. This assumption is justified since most processes of interest are nearly isobaric. Thus the energy equation becomes

$$u\frac{\partial T}{\partial x} + v\frac{\partial T}{\partial y} = \alpha\left(\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2}\right) \tag{39}$$

Equations 35, 36, 37, and 39, along with the equation of state ($p = \rho RT$, for an ideal gas), provide a complete set for determining $u(x, y)$, $v(x, y)$, $T(x, y)$, $\rho(x, y)$, and $p(x, y)$. Once these dependent variables are known, the desired heat transfer coefficient and friction factor are obtained from Equations 5 and 11, respectively. However, the above equations are still too difficult to solve and a further simplification, known as the boundary layer approximation, is often made.

The Boundary Layer Concept

In 1904, Prandtl proposed that all the viscous effects are concentrated in a thin layer near the boundary and that outside this layer the fluid behaves as though it is inviscid. Thus, the flow over a body, such as the one shown in Figure 1-3.6, can be divided into two zones: (1) a thin viscous layer near the surface, called the boundary layer, and (2) inviscid external flow, which can be closely approximated by the potential flow theory. As will be seen later, the fact that the boundary layer is thin compared to the characteristic dimensions of the object is exploited to simplify the governing equations and obtain a useful solution. This boundary layer approximation plays an important role in convective heat transfer, since the gradients of velocity and temperature at the surface of the body are required to determine the heat transfer coefficient and the friction factor.

To illustrate these ideas, consider fluid flow over a flat plate as shown in Figure 1-3.12. The fluid particles in contact with the plate surface must assume zero velocity because of no slip at the wall, whereas the fluid particles far away from the wall continue to move at the free stream velocity, u_∞. The transition of fluid velocity from zero to u_∞ takes place in a small distance, δ, which is known as the boundary layer thickness and is defined as

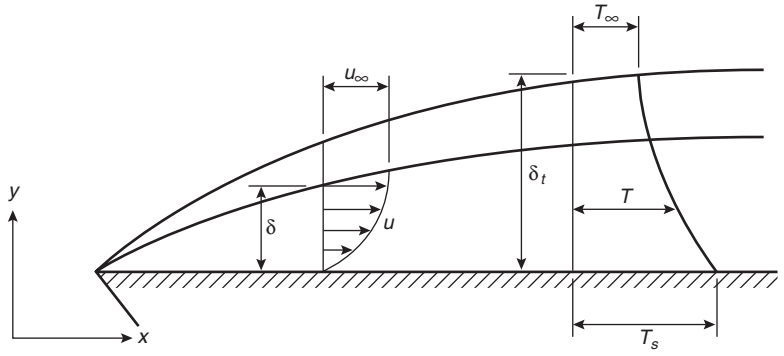


Figure 1-3.12. ***Velocity and thermal boundary layers on a flat plate.***

the value of y for which $u = 0.99\ u_\infty$. As is intuitively obvious, the thickness of the boundary layer increases with fluid viscosity and decreases with increasing free-stream velocity. By defining the Reynolds number, Re, as $\text{Re} = u_\infty L/\nu$, where L is the characteristic length of the plate, the boundary layer thickness decreases with increasing Re. For most flows of practical interest, the Reynolds number is large enough such that δ is much less than the characteristic length, L ($\delta \ll L$).

Just as a velocity boundary layer develops because of viscous effects near the surface, a thermal boundary layer develops due to heat transfer between the free stream and the surface if their temperatures are different. The fluid particles that come into contact with the plate surface achieve thermal equilibrium at the plate's surface temperature. In turn, these particles exchange energy with those in the adjoining fluid layer, and temperature gradients develop in the fluid. As shown in Figure 1-3.12, the region of the fluid in which these temperature gradients exist is the thermal boundary layer, and its thickness, δ_t, is defined as the value of y for which the ratio $[(T - T_S)/(T_\infty - T_S)] = 0.99$. The thermal boundary layer thickness increases with the thermal diffusivity, α, of the fluid and decreases with increasing free stream velocity. In other words, δ_t is inversely proportional to the product of Reynolds number and Prandtl number [$\text{Re Pr} = (u_\infty L/\nu)(\nu/\alpha) = u_\infty L/\alpha$]. For air, $\text{Pr} \approx 0.7$ and the Reynolds number is sufficiently large for flows of practical interest, consequently $\delta_t \ll L$.

Boundary layer approximation: The governing Equations 35 through 37 and 39 can be further simplified for the case when the Reynolds number is reasonably large [$\text{Re} \sim (L/\delta)^2$; that is, Re is of the order $(L/\delta)^2$] such that $\delta \ll L$. To compare the various terms in the governing equations, first normalize all the variables so that they are of the order of magnitude unity. By defining

$$x^* = \frac{x}{L} \quad y^* = \frac{y}{\delta} \quad u^* = \frac{u}{u_\infty}$$

and

$$T^* = \frac{T - T_S}{T_\infty - T_S} \tag{40}$$

variables that change from 0 to 1 inside the boundary layer are obtained. Substituting these into Equation 35 we find that

$$-\frac{\partial u^*}{\partial x^*} = \left(\frac{L}{\delta u_\infty}\right)\frac{\partial v}{\partial y^*}$$

This suggests that

$$v^* = \frac{Lv}{\delta u_\infty}$$

so that

$$\frac{\partial u^*}{\partial x^*} + \frac{\partial v^*}{\partial y^*} = 0 \tag{41}$$

Substituting x^*, y^*, u^*, and v^* into Equation 36 and simplifying

$$u^*\frac{\partial u^*}{\partial x^*} + v^*\frac{\partial u^*}{\partial y^*} = -\frac{\partial p^*}{\partial x^*} - g_x^* + \left(\frac{\nu}{Lu_\infty}\right)\left[\frac{\partial^2 u^*}{\partial x^{*2}} + \left(\frac{L}{\delta}\right)^2\frac{\partial^2 u^*}{\partial y^{*2}}\right] \tag{42}$$

where $p^* \equiv p/\rho u_\infty^2$ and $g_x^* \equiv g_x L/u_\infty^2$.

In Equation 42, the quantity ν/Lu_∞ is recognized as $1/\text{Re}$ which is of the order (δ/L^2). Thus all terms in Equation 42 are of order of magnitude unity except the term $[(\nu/Lu_\infty)\partial^2 u^*/\partial x^{*2}]$, which is much less than 1 and can be ignored. Thus, Equation 36 is simplified to

$$u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = -\frac{1}{\rho}\frac{\partial p}{\partial x} - g_x + \nu\frac{\partial^2 u}{\partial y^2} \tag{43}$$

Similarly, Equations 37 and 39 reduce to

$$\frac{\partial p}{\partial y} \approx 0 \tag{44}$$

and

$$u\frac{\partial T}{\partial x} + v\frac{\partial T}{\partial y} = \alpha\frac{\partial^2 T}{\partial y^2} \tag{45}$$

Equation 44 simply implies that $p = p(x)$, that is, the pressure at any plane where x = constant does not vary with y inside the boundary layer and hence is equal to the free stream pressure. To summarize, the boundary layer approximation yields a simpler set of governing equations that are valid inside the boundary layer. These equations for steady flow of an incompressible fluid with constant properties are

Continuity

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \tag{35}$$

x-momentum

$$u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = -\frac{1}{\rho}\frac{\partial p}{\partial x} - g_x + \nu\frac{\partial^2 u}{\partial y^2} \tag{43}$$

Energy

$$u\frac{\partial T}{\partial x} + v\frac{\partial T}{\partial y} = \alpha\frac{\partial^2 T}{\partial y^2} \tag{45}$$

To illustrate the use of these equations in determining the heat transfer coefficient, consider two classical examples: (1) laminar forced convection over a flat surface, and (2) laminar free convection on a vertical flat surface. Forced convection is chosen as a precursor to free convection because it is simpler and also allows us to illustrate the difference between them. A flat geometry is also chosen in both cases for simplicity.

Laminar forced convection over a flat surface: A schematic of this problem is presented in Figure 1-3.12, and the objective here is to obtain the gradients of temperature and velocity profile at $y = 0$. By applying the Bernoulli

Equation in the potential flow region outside the boundary layer we obtain

$$\frac{u_\infty^2}{2} + \frac{p}{\rho} + gh = \text{constant} \tag{46}$$

Since the free stream velocity, u_∞, is constant, for a given height $y = h$ above the flat surface we obtain that p = constant, that is, $p \neq p(x)$ outside the boundary layer in the potential flow region. From Equation 44 note that $p \neq p(y)$ inside the boundary layer. Hence, p = constant both inside and outside the boundary layer over a flat surface. This implies that the term $\partial p/\partial x$ equals zero in Equation 43. Also, since the flow is forced (i.e., generated by an external agent such as a fan, rather than by buoyancy) the gravitational force, g_x, in Equation 43 does not contribute to the increase in momentum represented by the left side of the equation, and $g_x = 0$. Thus Equation 43 becomes

$$u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = \nu\frac{\partial^2 u}{\partial y^2} \tag{47}$$

Equations 35, 45, and 47 govern the temperature and velocity distributions inside the boundary layer shown in Figure 1-3.12. The associated boundary conditions are

no-slip

$$u = v = 0 \quad \text{at} \quad y = 0$$

and

$$T = T_S \quad \text{at} \quad y = 0 \tag{48}$$

also

$$u = u_\infty \quad \text{and} \quad T = T_\infty \quad \text{as} \quad y \to \infty$$

Nondimensionalizing Equations 35, 45, 47, and 48 according to Equation 40* we obtain

$$\frac{\partial u^*}{\partial x^*} + \frac{\partial v^*}{\partial y^*} = 0 \tag{49}$$

$$u^*\frac{\partial u^*}{\partial x^*} + v^*\frac{\partial u^*}{\partial y^*} = \frac{1}{\text{Re}_L}\frac{\partial^2 u^*}{\partial y^{*2}} \tag{50}$$

$$u^*\frac{\partial T^*}{\partial x^*} + v^*\frac{\partial T^*}{\partial y^*} = \frac{1}{\text{Re}_L \text{Pr}}\frac{\partial^2 T^*}{\partial y^{*2}} \tag{51}$$

*A more convenient definition of $y^* = y/L$ and $v^* = v/u_\infty$ has been used since we are no longer interested in quantities of order of magnitude unity; instead we are simply interested in eliminating units.

along with the boundary conditions

$$u^* = v^* = T^* = 0 \quad \text{at} \quad y^* = 0$$

and

$$u^* = T^* = 1 \quad \text{as} \quad y^* \to \infty \tag{52}$$

where

$$\text{Re}_L \equiv \frac{u_\infty L}{\nu}$$

is the Reynolds number based on length, L, and $\text{Pr} \equiv \nu/\alpha$ is the Prandtl number. Note that Equations 49 and 50 are sufficient for determining $u^*(x^*, y^*)$ and $v^*(x^*, y^*)$ and that once these are known, Equation 51 can be independently solved for $T^*(x^*, y^*)$. Also note that for Pr = 1, Equations 50 and 51 as well as their corresponding boundary conditions are identical. Thus for Pr = 1 only Equations 49 and 50 need to be solved.

A similarity solution of Equations 49 and 50 along with the boundary conditions (Equation 52) was obtained by Blasius.[2] Blasius observed that since the system under consideration has no preferred length, it is reasonable to suppose that the velocity profiles at different values of x have similar shapes; that is, if u and y are suitably scaled then the velocity profile may be expressed by a single function for all values of x. (See Figure 1-3.13.) An obvious choice is

$$\frac{u}{u_\infty} = \phi\left[\frac{y}{\delta(x)}\right]\phi \tag{53}$$

This choice, as it stands, is not very useful because $\delta(x)$ is not known. However, in accordance with the boundary layer approximation, $\text{Re}_x \equiv u_\infty x/\nu \sim (x/\delta)^2$. Therefore,

$$\delta \sim \sqrt{\frac{\nu x}{u_\infty}}$$

can be expected. Substituting into Equation 53 we obtain

$$u^* = \frac{u}{u_\infty} = \phi\left[\frac{y}{x}\sqrt{\text{Re}_x}\right] = \phi(\eta) \tag{54}$$

where

$$\eta \equiv \frac{y}{x}\sqrt{\text{Re}_x} = \left[\left(\frac{y^*}{\sqrt{x^*}}\right)\sqrt{\text{Re}_L}\right]$$

is the similarity variable. By introducing a stream function, ψ, such that

$$u^* = \frac{\partial \psi}{\partial y^*} \quad \text{and} \quad v^* = -\frac{\partial \psi}{\partial x^*} \tag{55}$$

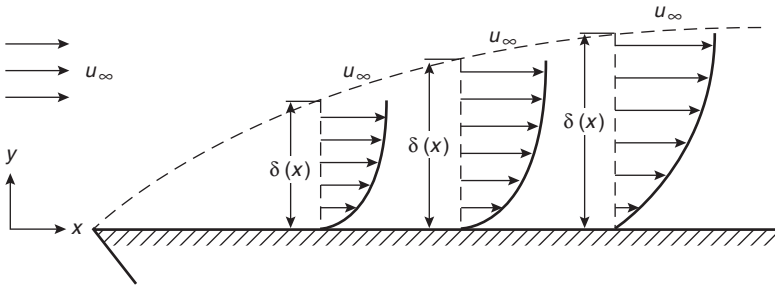

Figure 1-3.13. ***Observed velocity profiles at different values of x.***

Equation 49 is identically satisfied. Substituting Equation 54 into Equation 55 and integrating, we get

$$\psi = \int \phi(\eta)\, dy^* + f_1(x^*)$$
$$= \frac{\sqrt{x^*}}{\sqrt{\mathrm{Re}_L}} \int \phi(\eta)\, d\eta + f_1(x^*)$$

Since $v^* = 0$ at $y^* = 0, f_1(x^*)$ is at best an arbitrary constant which is taken as zero. Also, defining a new function $f(\eta) \equiv \int \phi(\eta)\, d\eta$, we obtain

$$\psi = \sqrt{x^*}\frac{f(\eta)}{\sqrt{\mathrm{Re}_L}} \tag{56}$$

therefore,

$$u^* = \left(\frac{\partial \psi}{\partial y^*}\right)_{x^*} = \left(\frac{\partial \psi}{\partial \eta}\right)_{x^*}\left(\frac{\partial \eta}{\partial y^*}\right)_{x^*} = f'(\eta) = \frac{df}{d\eta} \tag{57}$$

and

$$-v^* = \left(\frac{\partial \psi}{\partial x^*}\right)_{y^*} = \left(\frac{\partial \psi}{\partial x^*}\right)_{\eta} + \left(\frac{\partial \psi}{\partial \eta}\right)_{x^*}\left(\frac{\partial \eta}{\partial x^*}\right)_{y^*}$$
$$= \frac{1}{2}(f - \eta f')\sqrt{x^* \mathrm{Re}_L} \tag{58}$$

On substituting u^*, v^* into Equation 50 and simplifying we obtain

$$2f''' + ff'' = 0 \tag{59}$$

where primes represent differentiation with respect to η. Equation 59 is a third-order nonlinear ordinary differential equation. Recall that η was a combination of two independent variables, x^* and y^*, and it was assumed that $u^* = \phi(\eta)$. If this similarity assumption was incorrect, then the partial differential Equation 50 would not have reduced to an ordinary differential Equation 59—that is, x^* would not have completely disappeared from the governing equation. Note also that even though Equation 59 is nonlinear and has to be solved numerically, there are no parameters and therefore it needs to be solved only once. Boundary conditions corresponding to Equation 59 become

$$f = f' = 0 \quad \text{at} \quad \eta = 0, \quad \text{and} \quad f' = 1 \quad \text{as} \quad \eta \to \infty \tag{60}$$

A numerical solution of Equation 59 along with the boundary conditions, Equation 60 is shown in Figure 1-3.14. Note that for Pr = 1, the solution for T^* is the same as that for u^*. Also, once $T^*(x^*, y^*)$ and $u^*(x^*, y^*)$ are known the heat transfer coefficient and friction factor can easily be obtained from Equations 5 and 11. Furthermore, from the definition of thermal and velocity boundary layer thickness ($T^* = u^* = 0.99$), we find that $\eta = 5$.

Therefore,

$$\eta = \frac{y}{x}\sqrt{\frac{u_\infty x}{\nu}} = 5 \quad \text{for} \quad y = \delta = \delta_t$$

or for Pr = 1,

$$\delta = \delta_t = \frac{5x}{\sqrt{\mathrm{Re}_x}} \tag{61}$$

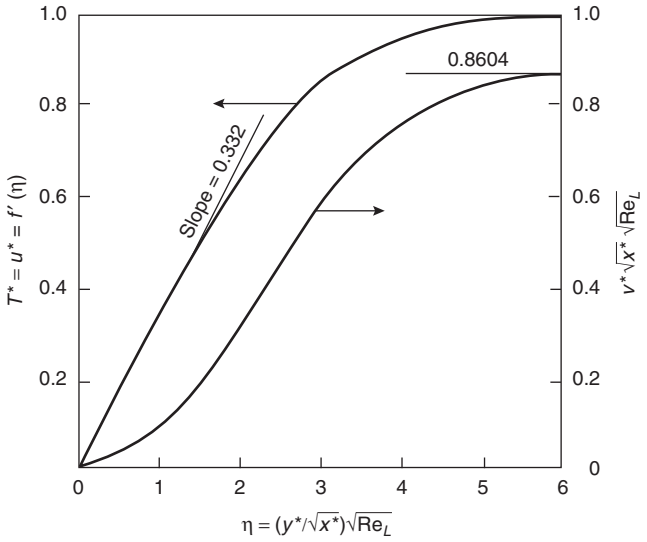

Figure 1-3.14. ***Nondimensional velocity profiles in laminar boundary layer over a flat plate.***

From Equation 61 it is clear that δ and δ_t increase with x but decrease with increasing u_∞ (the larger the free stream velocity, the thinner the boundary layer). Now, to determine the heat transfer coefficient and the friction factor we need $\partial T/\partial y\big|_{y=0}$ and $\partial u/\partial y\big|_{y=0}$. From Figure 1-3.14, we have

$$\left.\frac{\partial T^*}{\partial \eta}\right|_{\eta=0} = \left.\frac{\partial u^*}{\partial \eta}\right|_{\eta=0} = 0.332$$

Thus,

$$\tau_s = \mu \left.\frac{\partial u}{\partial y}\right|_{y=0} = 0.332 u_\infty \sqrt{\rho \mu u_\infty / x} \tag{62}$$

and

$$\dot{q}_s'' = -k \left.\frac{\partial T}{\partial y}\right|_{y=0} = 0.332(T_s - T_\infty)k\sqrt{\rho u_\infty / \mu x} \tag{63}$$

Hence the *local* friction and heat transfer coefficients are

$$C_f = \frac{0.664}{\sqrt{\mathrm{Re}_x}} \tag{64}$$

and

$$h = 0.332\frac{k}{x}\sqrt{\mathrm{Re}_x} \tag{65}$$

Equation 65 is often rewritten in terms of a nondimensional heat transfer coefficient called the Nusselt number, Nu, as

$$\mathrm{Nu} = \frac{hx}{k} = 0.332\sqrt{\mathrm{Re}_x} \tag{66}$$

All the above results are for the case when Pr = 1. When Pr $\neq$ 1, Equation 51 must also be solved with the help of the

solution just obtained for Equations 49 and 50. This solution does not change the expressions for δ and C_f given by Equations 61 and 64. However δ_t and Nu become[2]

$$\delta_t = \frac{5x}{\sqrt{\mathrm{Re}_x}}\,\mathrm{Pr}^{-1/3} = \delta \mathrm{Pr}^{-1/3} \tag{67}$$

and

$$\mathrm{Nu} = 0.332\sqrt{\mathrm{Re}_x}\mathrm{Pr}^{1/3} (\mathrm{Pr} \gtrsim 0.6) \tag{68}$$

Note that for $\mathrm{Pr} < 1$ (usually true for gases) $\delta_t > \delta$, that is, the thermal boundary layer is thicker than the momentum boundary layer. This is to be expected since $\mathrm{Pr} < 1$ implies that $\nu < \alpha$.

The results for the friction factor, C_f, and the Nusselt number, Nu, given by Equations 64 and 68 are for local values; that is, C_f and Nu change with x. This variation is shown in Figure 1-3.15. At $x = 0$, both C_f and h tend to infinity. This is physically incorrect and happens because near $x = 0$ the boundary layer approximation breaks down since δ is no longer much less than x.

For many applications, only average values of the heat transfer coefficient, $\overline{h}$, and friction factor, $\overline{C}_f$, are required. These are obtained by using Equations 9 and 15. In these equations $dA_s = dx \cdot$ (the unit width of the flat plate), and the average can be obtained from $x = 0$ to any length, L (which may be the total length of the plate). Simple integration leads to the following results:

$$\overline{C}_{fL} = 1.328\,\mathrm{Re}_L^{-1/2} = 2C_f\left(\begin{matrix}\text{evaluated}\\ \text{at } x = L\end{matrix}\right) \tag{69}$$

and

$$\overline{\mathrm{Nu}}_L \equiv \frac{\overline{h}_L L}{k} = 0.664\,\mathrm{Re}_L^{1/2}\mathrm{Pr}^{1/3} = 2\mathrm{Nu}\left(\begin{matrix}\text{evaluated}\\ \text{at } x = L\end{matrix}\right) \tag{70}$$

It is interesting to note that C_f and Nu are closely related. For example, from Equations 69 and 70 one can easily obtain

$$\overline{\mathrm{Nu}}_L = \frac{C_{fL}\,\mathrm{Re}_L\mathrm{Pr}^{1/3}}{2}$$

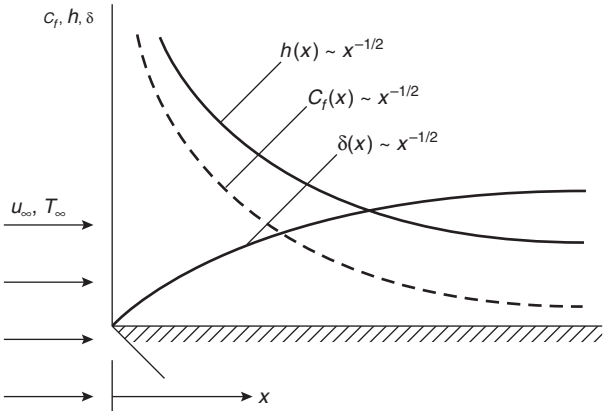

Figure 1-3.15. ***Variation of C_f, h, and δ with x for flow over a flat plate.***

or

$$\mathrm{St} \equiv \frac{\overline{\mathrm{Nu}}_L}{\mathrm{Re}_L\mathrm{Pr}} = \frac{\overline{C}_{fL}}{2}\,\mathrm{Pr}^{-2/3} \tag{71}$$

where St is known as the Stanton number.

This analogy between heat and momentum transfer is called the *Reynolds analogy* which is significant because the heat transfer coefficient can be determined from the knowledge of the friction factor. This analogy is especially useful for cases where mathematical solutions are not available.

Laminar free convection: In contrast with forced convection, where the fluid motion is externally imposed, for free convection the fluid motion is caused by the buoyancy forces. Buoyancy is due to the combined effect of *density gradients* within the fluid and a *body force* that is proportional to the fluid density. In practice the relevant body force is usually gravitational, although it may be centrifugal, magnetic, or electric. Of the several ways in which a density gradient may arise in a fluid, the two most common situations are due to (1) the presence of temperature gradients, and (2) the presence of concentration gradients in a multicomponent system such as a fire. Here, the focus will be on free convection problems in which the density gradient is due to temperature and the body force is gravitational. Note, however, that the presence of density gradients in a gravitational field does not ensure the existence of free convection currents. For example, the high temperature lighter fluid may be on top of a low temperature, denser fluid, resulting in a stable situation. It is only when the condition is unstable that convection currents are generated. An example of an unstable situation would be a denser fluid on top of a lighter fluid. In a stable situation there is no fluid motion and, therefore, heat transfer occurs purely by conduction. Here we will only consider the unstable situation that results in convection currents.

Free convection flow may be further classified according to whether or not the flow is bounded by a surface. In the absence of an adjoining surface, free boundary flows may occur in the form of a plume or a buoyant jet. A buoyant plume above a fire is a familiar example. However, here we will focus on free convection flows that are bounded by a surface. A classical example of boundary layer development on a heated vertical flat plate is discussed below.

Heated, vertical flat plate: Consider the flat plate shown in Figure 1-3.16. The plate is immersed in an extensive, quiescent fluid, with $T_s > T_\infty$. The density of the fluid close to the plate is less than that of the fluid that is farther from the plate. Buoyancy forces therefore induce a free convection boundary layer in which the heated fluid rises vertically, entraining fluid from the quiescent region.

Under steady-state laminar flow conditions, Equations 35, 43, and 45 describe the mass, momentum, and energy balances for the two-dimensional boundary layer shown in Figure 1-3.16. Assume that the temperature differences are moderate, such that the fluid may be treated as having constant properties. Also, with the exception of the buoyancy force term (g_x in Equation 43), the fluid can

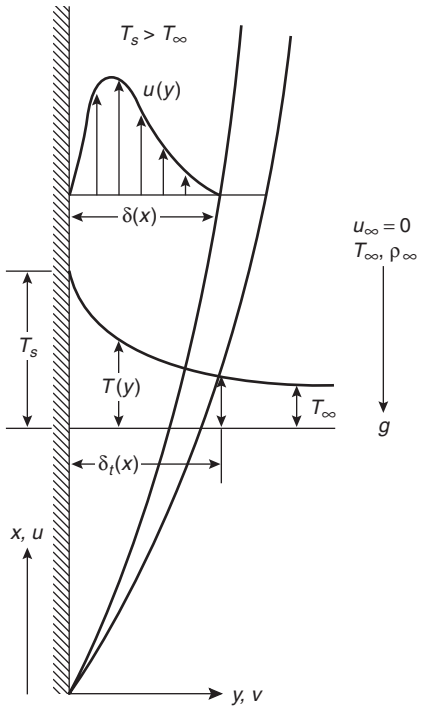

Figure 1-3.16. ***Boundary layer development on a heated vertical plate.***

be assumed to be incompressible. Outside the boundary layer, Equation 36 is valid, and since $u = v = 0$ outside the boundary layer we obtain: $\partial p/\partial x = -\rho_\infty g_x$. Since $\partial p/\partial y = 0$ because of the boundary layer approximation [i.e., $p \neq p(y)$ inside the boundary layer; Equation 44], $\partial p/\partial x$ inside the boundary layer must be equal to its corresponding value outside, that is, $\partial p/\partial x = -\rho_\infty g_x$.

Substituting this into Equation 43

$$u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = g_x\frac{(\rho_\infty - \rho)}{\rho} + \nu\frac{\partial^2 u}{\partial y^2} \tag{72}$$

The first term on the right side of Equation 72 is the buoyancy force, and the flow originates because the density ρ is variable. By introducing the coefficient of volumetric thermal expansion, β,

$$\beta = -\frac{1}{\rho}\left(\frac{\partial \rho}{\partial T}\right)_\rho \approx -\frac{1}{\rho}\frac{(\rho_\infty - \rho)}{(T_\infty - T)} \tag{73}$$

it follows that

$$\frac{(\rho_\infty - \rho)}{\rho} = \beta(T - T_\infty) \tag{74}$$

Substituting Equation 74 into Equation 72 a useful form of the x-momentum is obtained as

$$u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = g_x\beta(T - T_\infty) + \nu\frac{\partial^2 u}{\partial y^2} \tag{75}$$

From Equation 75 it is now apparent how buoyancy force is related to temperature difference. Note that the appearance of the buoyancy term in the momentum equation mathematically complicates the situation. The decoupling between the hydrodynamic and the thermal problems achieved in forced convection is no longer possible, since T appears in both Equations 45 and 75. The boundary conditions associated with the governing equations, Equations 35, 45, and 75, are

$$u = v = 0 \quad T = T_\infty \quad \text{as} \quad y \to \infty \tag{76}$$

Nondimensionalizing Equations 35, 45, 75, and 76 with $x^* = x/L$, $y^* \equiv y/L$, $u = u/u_0$, $v^* \equiv v/u_0$ and $T^* \equiv (T - T_\infty)/(T_s - T_\infty)$, we obtain

$$\frac{\partial u^*}{\partial x^*} + \frac{\partial v^*}{\partial y^*} = 0 \tag{77}$$

$$u^*\frac{\partial u^*}{\partial x^*} + v^*\frac{\partial u^*}{\partial y^*} = \frac{g\beta T^*(T_s - T_\infty)L}{u_0^2} + \frac{1}{\mathrm{Re}_L}\frac{\partial^2 u^*}{\partial y^{*2}} \tag{78}$$

and

$$u^*\frac{\partial T^*}{\partial x^*} + v^*\frac{\partial T^*}{\partial y^*} = \frac{1}{\mathrm{Re}_L\mathrm{Pr}}\frac{\partial^2 T^*}{\partial y^{*2}} \tag{79}$$

Note that u_0 in Equation 78 is an unknown reference velocity and not the free stream velocity as in the case of forced convection. Also, the dimensionless parameter

$$\frac{g\beta(T_s - T_\infty)L}{u_0^2}$$

is a direct result of buoyancy forces. To eliminate the unknown reference velocity, u_0 from the dimensionless parameter, we define

$$\text{Grashof Number, } \mathrm{Gr}_L \equiv \frac{g\beta(T_s - T_\infty)L}{u_0^2}\left(\frac{Lu_0}{\nu}\right)^2 = \frac{g\beta(T_s - T_\infty)L^3}{\nu^2}$$

Thus, the first term on the right side of Equation 78 becomes $\mathrm{Gr}_L/(\mathrm{Re}_L)^2$. The Grashof number plays the same role in free convection as the Reynolds number does in forced convection. Gr is the ratio of buoyancy and viscous forces. The governing equations now contain three parameters—the Grashof number, Reynolds number, and Prandtl number. For the forced convection case it is seen (Equation 68) that Nu = Nu (Re, Pr); thus for the free convection case, we expect Nu = Nu (Re, Gr, Pr). If the buoyancy term in Equation 79 is $\mathrm{Gr}/(\mathrm{Re})^2 \gg 1$, then we primarily have free convection; that is, Nu = Nu(Gr, Pr). For $\mathrm{Gr}/(\mathrm{Re})^2 \ll 1$, the forced convective case exists, where as has already been seen, Nu = Nu (Re, Pr). However, when $\mathrm{Gr}/(\mathrm{Re})^2 \sim 1$ a mixed (free and forced) convection case is obtained. For the present problem we will assume that $\mathrm{Gr} \gg (\mathrm{Re})^2$, thus, Nu must be a function of only Gr and Pr.

Since $\mathrm{Gr} \gg \mathrm{Re}^2$, it follows that buoyancy forces are much larger than inertia forces; in other words, the primary balance is between the buoyancy and viscous forces. Since the left side of Equation 78 represents the inertia forces, the primary balance is between the two terms on the right side, that is,

$$-\frac{g\beta T^*(T_s - T_\infty)L}{u_0^2} \approx \left(\frac{\nu}{u_0 L}\right)\frac{\partial^2 u^*}{\partial y^{*2}}$$

Crudely approximating the various terms, we have in dimensional variables

$$g\beta(T_\infty - T) \approx \nu \frac{u}{\delta^2} \tag{a}$$

Similarly approximating Equations 77 and 79 and expressing the result in dimensional form (it is more convenient to use Equations 35 and 45), we get from Equation 35 or 77

$$\frac{u}{x} \approx \frac{v}{\delta} \quad \text{or} \quad v \approx \frac{\delta u}{x} \tag{b}$$

and from Equation 79 or 45 along with relation (b)

$$u\frac{(T_\infty - T)}{x} \approx \alpha \frac{(T_\infty - T)}{\delta^2} \quad \text{or} \quad u \approx \frac{\alpha x}{\delta^2} \tag{c}$$

Combining (a) and (c) we obtain an expression for the boundary layer thickness, δ,

$$\delta \approx \left(\frac{\nu\alpha x}{g\beta(T_\infty - T)}\right)^{1/4}$$

Thus, we expect δ to scale with $x^{1/4}$ and u to scale with $x^{1/2}$. (Note that in the forced convective case we found that $\delta \sim x^{1/2}$; Figure 1-3.15.) Following a reasoning similar to the forced convective case, a similarity variable $\xi \approx y/\delta(x)$ or $\xi = Ay/x^{1/4}$ may be found, where A is an arbitrary constant. Also, motivated by Equation 57 for forced convection, it is hoped that $u = Bx^{1/2}f'(\xi)$, where B is an arbitrary constant. Expressing these in nondimensional variables, we get

$$\xi = Ay^*/x^{*1/4} \tag{80}$$

and

$$u^* = Bx^{*1/2}f'(\xi)$$

where $f'(\xi) = df/d\xi$. Note that the definitions of the arbitrary constants A and B have been changed during nondimensionalization. By introducing a stream function, ψ, as in Equation 55, Equation 77 is identically satisfied.

Thus,

$$\begin{aligned}\psi &= \int Bx^{*1/2}f'(\xi)\,dy^* + f_1(x^*) \\ &= \int \frac{B}{A}x^{*3/4}f'(\xi)\,d\xi + f_1(x^*) \\ &= \frac{B}{A}x^{*3/4}f(\xi) + f_1(x^*)\end{aligned} \tag{81}$$

Since $v^* = 0$ at $y^* = 0$ (or $\xi = 0$), $f_1(x^*)$ is at best an arbitrary constant which is taken to be zero without any loss of generality. From Equations 55 and 81 we get

$$v^* = -\frac{B}{4Ax^{*1/4}}[3f(\xi) - \xi f'(\xi)] \tag{82}$$

By using Equations 80 and 82, Equations 78 and 79 can be reduced to

$$f''' + 3ff'' - 2(f')^2 + T^* = 0 \tag{83}$$

and

$$T^{*\prime\prime} + 3\mathrm{Pr}fT^{*\prime} = 0 \tag{84}$$

where the following definitions of the arbitrary constants A and B have been used:

$$\begin{aligned}B &= \left[\frac{4g\beta(T_s - T_\infty)L}{u_\infty^2}\right]^{1/2} \\ A &= \left[\frac{g\beta(T_s - T_\infty)L^3}{4\nu^2}\right]^{1/4}\end{aligned} \tag{85}$$

Note that in Equation 84 it has been assumed that T^* is a function of ξ only. From Equation 85 it follows that

$$\xi = \frac{y^*}{x^{*1/4}}\left[\frac{g\beta(T_s - T_\infty)L^3}{4\nu^2}\right]^{1/4} = \frac{y^*}{x^{*1/4}}\left(\frac{\mathrm{Gr}_L}{4}\right)^{1/4} \tag{86}$$

The associated boundary conditions given by Equation 76 become

$$\begin{aligned} &f = f' = 0 \quad \text{and} \quad T^* = 1 \quad \text{when} \quad \xi = 0 \\ &\text{and} \quad f' = 0 \qquad\quad T^* = 0 \quad \text{at} \quad\ \xi = \infty\end{aligned} \tag{87}$$

A numerical solution of Equations 83 and 84 along with the boundary conditions given by Equation 87 is shown in Figure 1-3.17. Note that the nondimensional x-velocity component, u^*, may be readily obtained from Figure 1-3.17 part (a) through the use of Equations 80 and 85. Note also that, through the definition of the similarity variable, ξ, Figure 1-3.17 may be used to obtain values of u^* and T^* for any value of x^* and y^*. Once $u^*(x^*, y^*)$ and $T^*(x^*, y^*)$ are known, the heat transfer coefficient can easily be obtained from Equation 5. Thus, the temperature gradient at $y = 0$ after using Equation 86, becomes

$$\left.\frac{\partial T}{\partial y}\right|_{y=0} = \frac{(T_s - T_\infty)}{L}\left.\frac{\partial T^*}{\partial y^*}\right|_{y^*=0} = \frac{(T_s - T_\infty)}{Lx^{*1/4}}\left(\frac{\mathrm{Gr}_L}{4}\right)^{1/4}\left.\frac{dT^*}{d\xi}\right|_{\xi=0}$$

The *local* heat transfer coefficient is

$$h = \frac{-k}{Lx^{*1/4}}\left(\frac{\mathrm{Gr}_L}{4}\right)^{1/4}\left.\frac{dT^*}{d\xi}\right|_{\xi=0} \tag{88}$$

or

$$\mathrm{Nu} = \frac{hx}{k} = -x^{*3/4}\left(\frac{\mathrm{Gr}_L}{4}\right)^{1/4}\left.\frac{dT^*}{d\xi}\right|_{\xi=0} = \left(\frac{\mathrm{Gr}_x}{4}\right)^{1/4} g(\mathrm{Pr}) \tag{89}$$

As is evident from Figure 1-3.17, the dimensionless temperature gradient at $\xi = 0$ is a function of the Prandtl number. In Equation 89 this function is expressed as $-g(\mathrm{Pr})$. Values of $g(\mathrm{Pr})$ obtained from the numerical solution are listed in Table 1-3.1.

From Equation 88 for the local heat transfer coefficient the average heat transfer coefficient for a surface of length L is obtained by using Equation 9 as follows

$$\begin{aligned}\overline{h}_L &= \frac{1}{L}\int_0^L h(dx \cdot 1) = \frac{k}{L^{7/4}}\left(\frac{\mathrm{Gr}_L}{4}\right)^{1/4} g(\mathrm{Pr}) \times \int_0^L \frac{dx}{x^{1/4}} \\ &= \frac{4}{3}\frac{k}{L}\left(\frac{\mathrm{Gr}_L}{4}\right)^{1/4} g(\mathrm{Pr})\end{aligned} \tag{90}$$

Thus,

$$\overline{\mathrm{Nu}}_L = \frac{\overline{h}_L L}{k} = \frac{4}{3}\left(\frac{\mathrm{Gr}_L}{4}\right)^{1/4} g(\mathrm{Pr}) \tag{91}$$

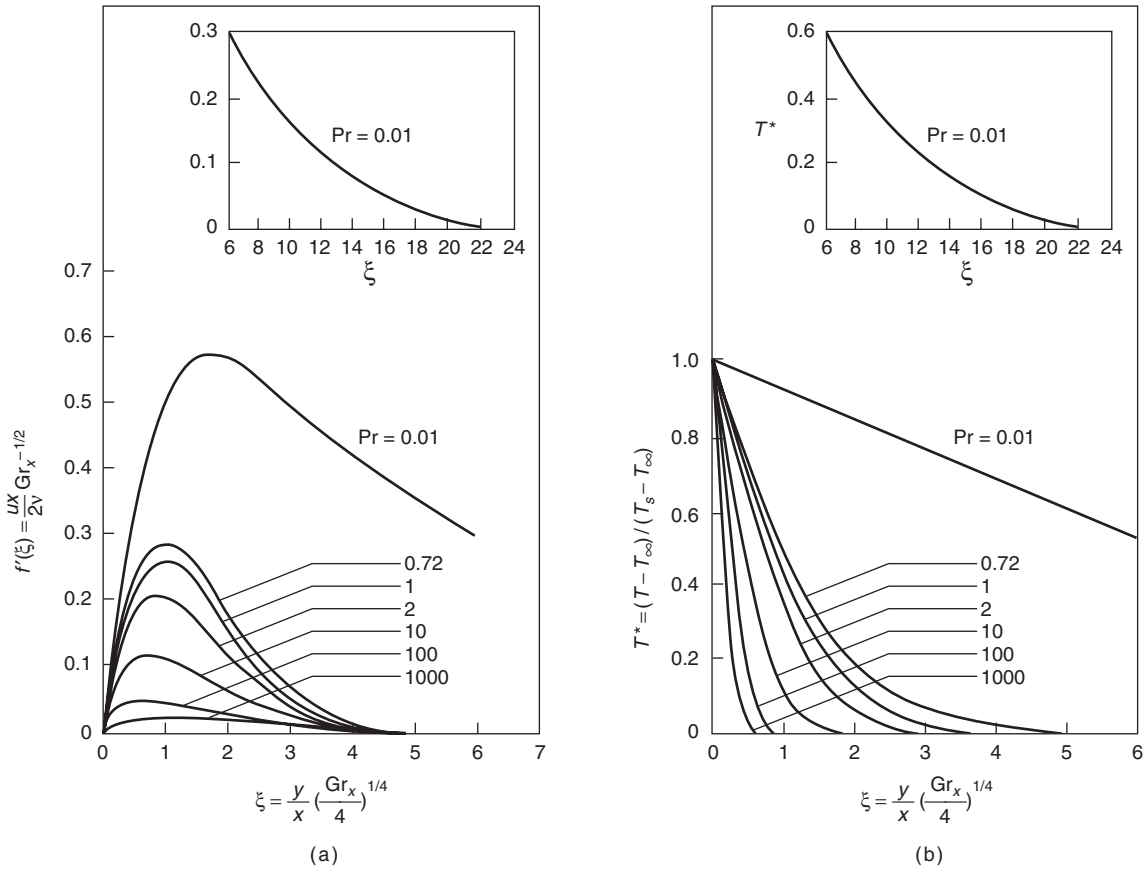

Figure 1-3.17. ***Laminar free convection boundary layer on an isothermal, vertical surface.***

or from Equation 89, with $x = L$ we get

$$\overline{\mathrm{Nu}}_L = \frac{4}{3}\mathrm{Nu}\left(\begin{matrix}\text{evaluated}\\ \text{at } x = L\end{matrix}\right) \tag{92}$$

It should be noted that the foregoing results apply irrespective of whether $T_s > T_\infty$ or $T_s < T_\infty$. If $T_s < T_\infty$, the conditions are inverted from those shown in Figure 1-3.16. The loading edge is on the top of the plate, and positive x is defined in the direction of the gravity force.

Complications in Practical Problems

In the previous section two relatively simple problems of laminar forced and free convection on a flat surface were solved. These solutions illustrate the methodology for determining the heat transfer coefficient and provide the necessary insight regarding the relationship between the various dimensionless parameters. Most practical situations are often more complex, and mathematical solutions, such as those presented in the previous section, are not always possible. Complexities arise due to more complex geometry, onset of turbulence, changes in fluid properties with temperature, and because of simultaneous mass transfer from the surface as illustrated in Figure 1-3.17. For such cases, empirical correlations are obtained. These correlations are discussed in the next section and the various complications are individually discussed below.

Table 1-3.1 ***Dimensionless Temperature Gradient for Free Convection on a Vertical Flat Plate***

Pr	0.01	0.72	1	2	10	100	1000
g(Pr)	0.081	0.505	0.567	0.716	1.169	2.191	3.966

Effect of turbulence: In both forced and free convective flows, small disturbances may be amplified downstream, leading to transition from laminar to turbulent flow conditions. These disturbances may originate from the free stream or be induced by surface roughness. Whether these disturbances are amplified or attenuated depends upon the ratio of inertia to viscous forces for forced flows (the Reynolds number), and the ratio of buoyancy to viscous forces for free convective flows (the Grashof number). Note that in both Reynolds and Grashof numbers, viscosity appears in the denominator. Thus for relatively large viscous forces or small Reynolds and Grashof numbers, the naturally occurring disturbances are dissipated, and the flow remains laminar. However, for sufficiently large Reynolds and Grashof numbers ($\mathrm{Re} > 5 \times 10^5$ and $\mathrm{Gr} > 4 \times 10^8$, for flow over a flat plate) disturbances are amplified, and a transition to turbulence occurs.

The onset of turbulence is associated with the existence of *random fluctuations* in the fluid, and on a small scale the flow is *unsteady*. As shown in Figure 1-3.18, there are sharp differences between laminar and turbulent flows. In the laminar boundary layer, fluid motion is highly ordered and it is possible to identify streamlines

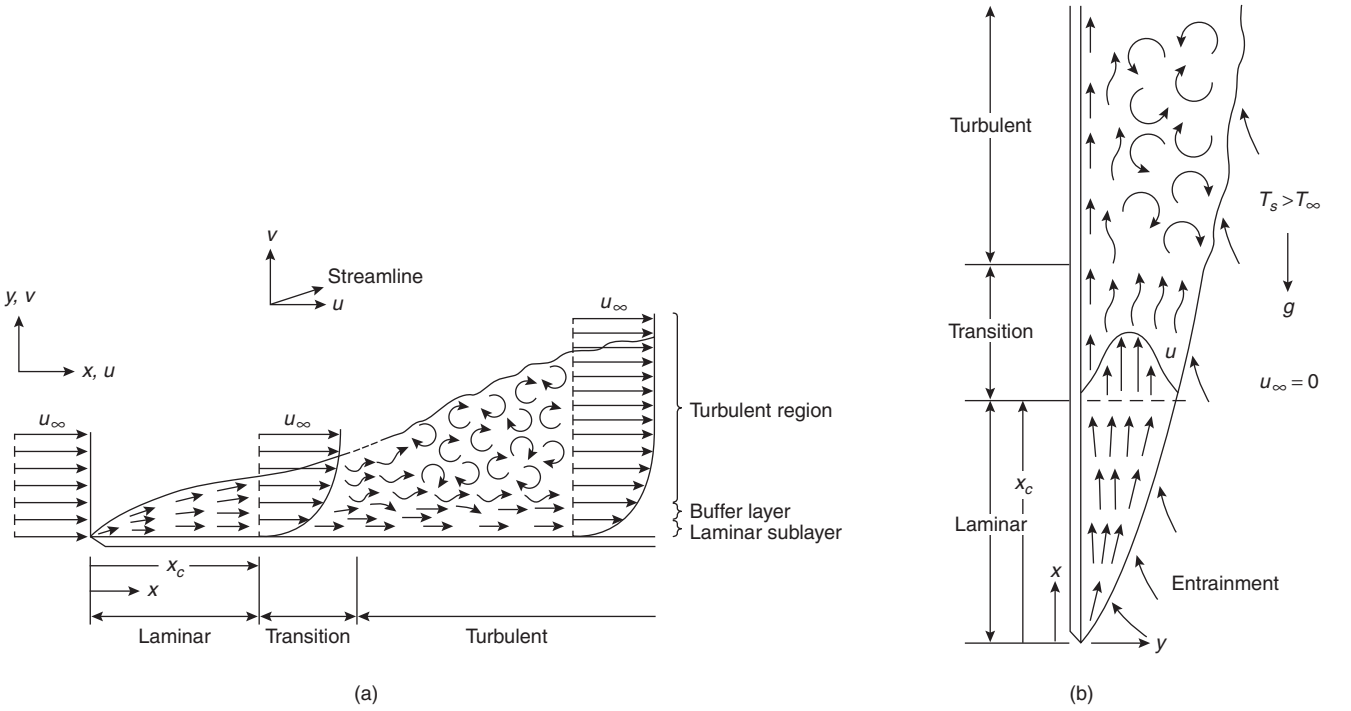

Figure 1-3.18. ***(a) Velocity boundary layer development on a flat plate for forced flow; (b) velocity boundary layer development on a vertical flat plate for free convective flow.***

along which fluid particles move. In contrast, fluid motion in the turbulent boundary layer is highly irregular and is characterized by velocity fluctuations. These fluctuations enhance the momentum and energy transfers and hence increase the surface friction and convection heat transfer rate. Also, due to the mixing of fluid resulting from the turbulent fluctuations, the turbulent boundary layer is thicker and the boundary layer profiles (of velocity, temperature, and concentration) are flatter than in laminar flow.

In a fully turbulent flow, the primary mechanism of momentum and heat transfer involves macroscopic lumps of fluid randomly moving about in the flow. Turbulent flow contrasts with the random molecular motion resulting in molecular properties discussed at the beginning of this chapter. In the turbulent region *eddy viscosity* and *eddy thermal conductivity* are important. These eddy properties may be ten times as large as their molecular counterparts.

If one measures the variation of an arbitrary flow variable, *P,* as a function of time at some location in a turbulent boundary layer, then the typical behavior observed is shown in Figure 1-3.19. The variable *P,* which may be a velocity component, fluid temperature, pressure, or species concentration, can be represented as the sum of a time-mean value, $\overline{P}$, and a fluctuating component, P'. The average is taken over a time interval that is large compared with the period of a typical fluctuation, and if $\overline{P}$ is time independent then the mean flow is steady. Thus, the instantaneous values of each of the velocity components, pressure, and temperature are given by

$$u = \overline{u} + u', \quad v = \overline{v} + v', \quad p = \overline{p} + p'$$
$$T = \overline{T} + T' \quad \text{and} \quad \rho = \overline{\rho} + \rho' \tag{93}$$

Substituting these expressions for each of the flow variables into the boundary layer equations (Equations 35, 43, and 45) and assuming the mean flow to be steady, incompressible (ρ = constant) with constant properties, and using the well established time averaging procedures,[1–4] the following governing equations are obtained:

Continuity

$$\frac{\partial \overline{u}}{\partial x} + \frac{\partial \overline{v}}{\partial y} = 0 \tag{94}$$

x-momentum

$$\rho\left(\overline{u}\,\frac{\partial \overline{u}}{\partial z} + \overline{v}\,\frac{\partial \overline{u}}{\partial y}\right) = \frac{\partial}{\partial y}\left(\mu\,\frac{\partial \overline{u}}{\partial y} - \rho\overline{u}'\overline{v}'\right) - \frac{\partial \overline{p}}{\partial x} - \rho g_x \tag{95}$$

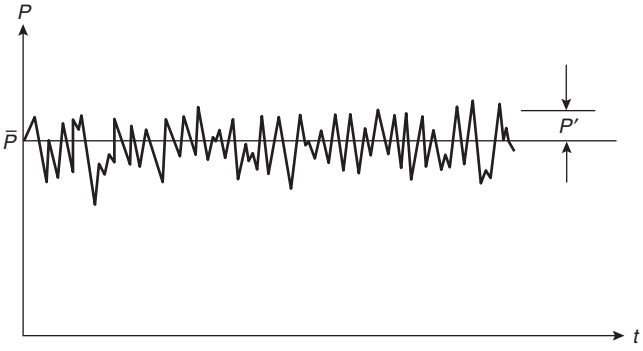

Figure 1-3.19. ***Variation in the variable P with time at some point in a turbulent boundary layer.***

Energy

$$\rho C_p\left(\overline{u}\frac{\partial \overline{T}}{\partial x}+\overline{v}\frac{\partial \overline{T}}{\partial y}\right)=\frac{\partial \overline{T}}{\partial y}\left(k\frac{\partial \overline{T}}{\partial y}-\rho C_p\overline{v}'\overline{T}'\right) \quad (96)$$

Equations 94 through 96 are similar to the laminar boundary layer equations expressed in mean flow variables, except for the presence of additional terms $\rho\overline{u}'\overline{v}'$ and $\rho C_p\overline{v}'\overline{T}'$. Physical arguments[2] show that these terms result from the motion of macroscopic fluid lumps and account for the effect of the turbulent fluctuations on momentum and energy transport.

On the basis of the foregoing result it is customary to speak of total shear stress and total heat flux, which are defined as

$$\tau_{\text{tot}} \equiv \left(\mu\frac{\partial \overline{u}}{\partial y}-\rho\overline{u}'\overline{v}'\right)$$

and

$$\dot{q}_{\text{tot}} \equiv -\left(k\frac{\partial \overline{T}}{\partial y}-\rho C_p\overline{v}'\overline{T}'\right) \quad (97)$$

The terms $\rho\overline{u}'\overline{v}'$ and $\rho C_p\overline{v}'\overline{T}'$ are always negative and so result in a positive contribution to total shear stress and heat flux. The term $\rho\overline{u}'\overline{v}'$ represents the transport of momentum flux due to turbulent fluctuations (or eddies), and it is known as the Reynolds stress. The notion of transport of heat and momentum by turbulent eddies has prompted the introduction of transport coefficients, which are defined as the eddy diffusivity for momentum transfer, ε_M, and eddy diffusivity for heat transfer, ε_H, and have the form

$$\begin{aligned}\varepsilon_M\frac{\partial \overline{u}}{\partial y} &\equiv -\overline{u}'\overline{v}'\\ \varepsilon_H\frac{\partial \overline{T}}{\partial y} &\equiv -\overline{v}'\overline{T}'\end{aligned} \quad (98)$$

Thus Equation 97 becomes

$$\tau_{\text{tot}} \equiv \rho(\upsilon+\varepsilon_M)\frac{\partial \overline{u}}{\partial y}$$

and

$$\dot{q}''_{\text{tot}} \equiv -\rho C_p(\alpha+\varepsilon_H)\frac{\partial \overline{T}}{\partial y} \quad (99)$$

As noted earlier, eddy diffusivities are much larger than molecular diffusivities, therefore the heat and momentum transfer rates are much larger for turbulent flow than for laminar flow. A fundamental problem in performing turbulent boundary layer analysis involves determining the eddy diffusivities as a function of the mean properties of the flow. Unlike the molecular diffusivities, which are strictly fluid properties, the eddy diffusivities depend strongly on the nature of the flow. They vary across the boundary layer and the variation can only be determined from experimental data. This is an important point, because all analyses of turbulent flow must eventually rely on experimental data. To date, there is no adequate theory for predicting turbulent flow behavior.

Complex geometry: In a previous section on the boundary layer concept, analysis was limited to the simplest possible geometry, that is, a flat plate. This provided considerable simplification because $dp/dx = 0$ in Equation 43 for the forced flow case. However, the situation is not as simple for fluid flow over bodies with a finite radius of curvature.

Consider a common example of flow across a circular cylinder shown in Figure 1-3.20. Boundary layer formation is initiated at the forward stagnation point, where the fluid is brought to rest with an accompanying rise in pressure. The pressure is a maximum at this point and decreases with increasing x, the streamline coordinate, and θ, the angular coordinate. (Note: In the boundary layer approximation, the pressure is the same inside and outside the boundary layer. This can be seen from Equation 44.) The boundary layer then develops under the influence of a favorable pressure gradient ($dp/dx < 0$). At the top of the cylinder (i.e., at $\theta = 90°$) the pressure eventually reaches a minimum and then begins to increase toward the rear of the cylinder. Thus, for $90° < \theta < 180°$, the boundary layer development occurs in the presence of an adverse pressure gradient ($dp/dx > 0$).

Unlike parallel flow over a flat plate, for curved surfaces the free stream velocity, u_∞, varies with x. [Note that in Figure 1-3.20 a distinction has been made between the fluid velocity upstream of the cylinder, V, and the velocity outside the boundary layer, $u_\infty(x)$.] At the stagnation point, $\theta = 0°$, $u_\infty = 0$. As the pressure decreases for $\theta > 0°$, u_∞ increases according to the Bernoulli equation, Equation 46, and becomes maximum at $\theta = 90°$. For $\theta > 90°$, the adverse pressure gradient decelerates the fluid, and conversion of kinetic energy to pressure occurs in accordance with Equation 46, which applies only to the inviscid flow outside the boundary layer. The fluid inside the boundary layer has considerably slowed down because of viscous friction and does not have enough momentum to overcome the adverse pressure gradient, eventually leading to boundary layer separation, which is illustrated more clearly in Figure 1-3.21. At some location in the fluid, the velocity gradient at the surface becomes zero and the boundary layer detaches or separates from the surface. Farther downstream of the separation point, flow reversal occurs and a wake is formed behind the solid. Flow in this region is characterized by vortex formation and is highly irregular. The separation point is defined as the location at which $(\partial u/\partial y)_{y=0} = 0$. If the boundary layer transition

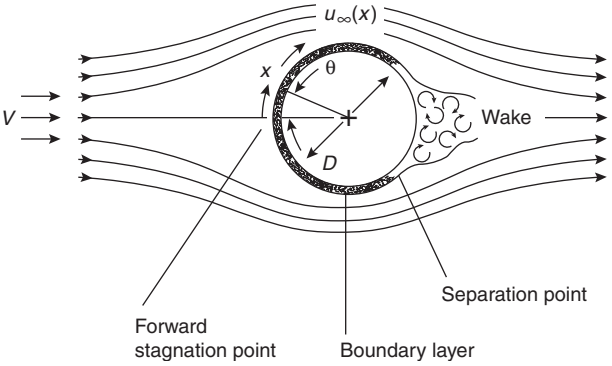

Figure 1-3.20. ***Boundary layer formation and separation on a circular cylinder in cross flow.***

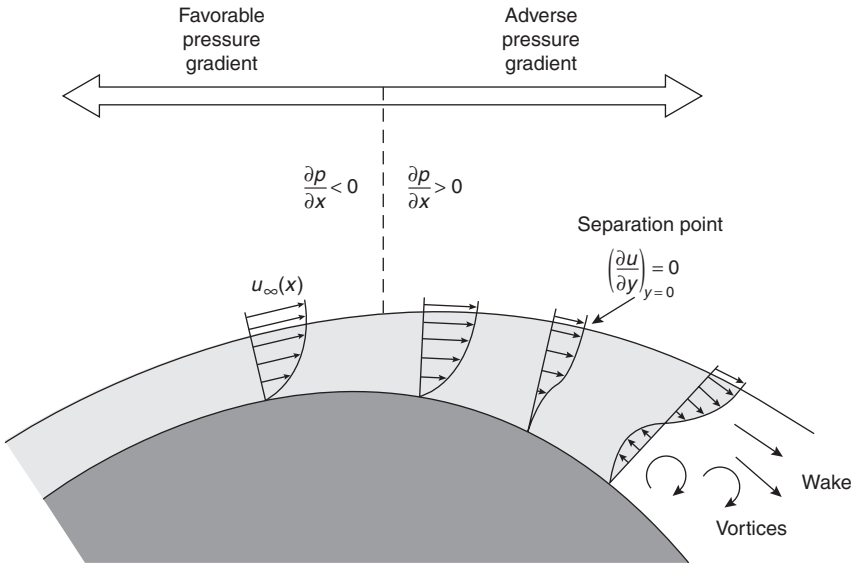

Figure 1-3.21. ***Velocity profiles associated with separation on a circular cylinder in cross flow.***

to turbulence occurs prior to separation, the separation is delayed and the separation point moves farther downstream. This happens because the turbulent boundary layer has more momentum than the laminar boundary layer to overcome the adverse pressure gradient.

The foregoing processes strongly influence both the rate of heat transfer from the cylinder surface and the drag force acting on the cylinder. Because of the complexities associated with flow over a cylinder, experimental methods are used to determine the heat transfer coefficient. Such experimental results for the variation of the local Nusselt number with θ are shown in Figure 1-3.22 for a cylinder in a cross flow of air. Consider the results for $Re_D \leq 10^5$ (note: Re_D is defined as VD/ν). Starting at the stagnation point, Nu_θ decreases with increasing θ due to the development of the laminar boundary layer. However, a minimum is reached at $\theta \approx 80°$. At this point separation occurs, and Nu_θ increases with θ due to the mixing associated with vortex formation in the wake. For $Re_D \geq 10^5$, the variation of Nu_θ with θ is characterized by two minima. The decline in Nu_θ from the value at the stagnation point is again due to laminar boundary layer development, but the sharp increase that occurs between 80° and 100° is now due to boundary layer transition to turbulence. With further development of the turbulent boundary layer, Nu_θ must again begin to decline. However, separation eventually occurs ($\theta \approx 140°$), and Nu_θ increases due to considerable mixing associated with the wake region.

The foregoing example clearly illustrates the complications introduced by nonplanar geometry. Heat transfer correlations for these cases are often based on experimental data. Fortunately, for most engineering calculations the local variation in the heat transfer coefficient such as that presented in Figure 1-3.22 is not required; only the overall average conditions are needed. Empirical correlations for

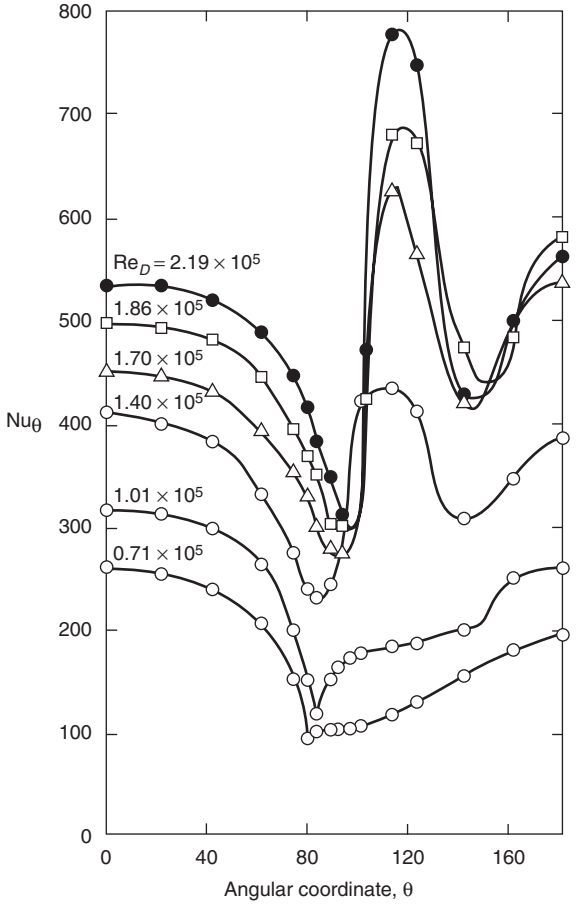

Figure 1-3.22. ***Local Nusselt number for airflow normal to a circular cylinder.***

average heat transfer coefficients will be presented in the next section.

Changes in fluid properties: In the analysis and discussion presented thus far, fluid properties were assumed to be constant. However, fluid properties vary with temperature across the boundary layer and this variation will have a significant impact on the heat transfer rate. In the empirical heat transfer correlations this influence is accounted for in one of two ways: (1) in correlating the experimental data all properties are evaluated at the mean boundary layer temperature, $T_f = (T_s + T_\infty)/2$, called the film temperature, and (2) alternatively, all properties are evaluated at T_∞ and an additional parameter is used to account for the property variation. This parameter is commonly of the form $(\mathrm{Pr}_\infty/\mathrm{Pr}_s)^r$ or $(\mu_\infty/\mu_s)^r$, where the subscripts ∞ and s designate evaluation of properties at the free stream and surface temperatures, respectively, and r is an empirically determined constant.

It is important to note that in the empirical correlations to be presented in the next section, the same method that is employed in deriving the correlation should be used when applying the correlation.

Effect of mass transfer: Special attention needs to be given to the effect that species mass transfer from the surface of the solid has on the velocity and thermal boundary layers. Recall that the velocity boundary layer development is generally characterized by the existence of zero fluid velocity at the surface. This condition applies to the velocity component v normal to the surface, as well as to the velocity component u parallel to the surface. However, if there is simultaneous mass transfer to or from the surface, it is evident that v can no longer be zero at the surface. Nevertheless, for the problems discussed in this chapter, mass transfer is assumed to have a negligible effect, that is, $v \approx 0$. This assumption is reasonable for problems involving some evaporation from gas-liquid or sublimation from gas-solid interfaces. For larger surface mass transfer rates a correction factor (often called the blowing correction) is utilized. This correction factor is simply stated here, and discussed in greater detail by Bird et al.[1] The correction factor is defined as $E(\phi) \equiv h^*/h$, where h^* is the corrected heat transfer coefficient and h is the heat transfer coefficient in the absence of mass transfer. According to film theory, $E(\phi)$ is given by

$$E(\phi) = \frac{\phi}{(e^{\phi} - 1)} \tag{100}$$

where

$$\phi = \frac{\dot{m}'' C_{pg}}{h}$$

$\dot{m}'' = \rho_s v_s$ is the mass flux coming out of the surface and C_{pg} is the specific heat of the gas.

Empirical Relations of Convection Heat Transfer

The analysis and discussion presented in the section on the boundary layer concept have shown that for simple cases the convection heat transfer coefficient may be determined directly from the conservation equations. In the previous section it was noted that the complications inherent to most practical problems do not always permit analytical solutions, and that it is necessary to resort to experimental methods. Experimental results are usually expressed in the form of either empirical formulas or graphical charts so that they may be utilized with maximum generality. Difficulties are encountered in the process of trying to generalize the experimental results in the form of empirical correlations. The availability of an analytical solution for a simpler but similar problem greatly assists in guessing the functional form of the results. Experimental data is then used to obtain values of constants or exponents for certain significant parameters, such as the Reynolds or Prandtl numbers. If an analytical solution for a similar problem is not available, it is necessary to rely on the physical understanding of the problem and on dimensional or order-of-magnitude analysis. In this section the experimental methods, the dimensionless groups, and the functional form of the relationships expected between them will be discussed; in addition the empirical formulas that will be used in the "Applications" section of this chapter will be summarized.

Functional form of solutions: The nondimensional Equations 49, 50, 51, and 78 are extremely useful from the standpoint of suggesting how important boundary layer results can be generalized. For example, the momentum equation, Equation 50, suggests that although conditions in the velocity boundary layer depend on the fluid properties, ρ and μ, the velocity, u_∞, and the length scale, L, this dependence may be simplified by grouping these variables in a nondimensional form called the Reynolds number. We therefore anticipate that the solution of Equation 50 will be of the form

$$u^* = f_1\left(x^*, y^*, \mathrm{Re}_L, \frac{dp^*}{dx^*}\right) \tag{101}$$

Note that the pressure distribution, $p^*(x^*)$, depends on the surface geometry and may be obtained independently by considering flow conditions outside the boundary layer in the free stream. Hence, as discussed in the section on complex geometry, the appearance of dp^*/dx^* in Equation 101 represents the influence of geometry on the velocity distribution. Note also that in Equation 50 the term dp^*/dx^* did not appear because it was equal to zero for a flat plate.

Similarly we anticipate that the solution of Equation 78 will be of the form

$$u^* = f_2(x^*, y^*, \mathrm{Gr}_L, \mathrm{Pr}) \tag{102}$$

Here, the Prandtl number is included because of the coupling between Equations 78 and 79. If the flow is mixed, that is, buoyant as well as forced, then the Reynolds number must also be included in the functional relationship expressed by Equation 102.

From Equation 1, the shear stress at the surface, $y^* = 0$, may be expressed as

$$\tau_s = \mu \left.\frac{\partial u}{\partial y}\right|_{y=0} = \left(\frac{\mu u_\infty}{L}\right) \left.\frac{\partial u^*}{\partial y^*}\right|_{y^*=0}$$

and from Equation 10 it follows that the friction coefficient is

$$C_f = \frac{\tau_s}{1/2\rho u_\infty^2} = \frac{2}{\mathrm{Re}_L}\left.\frac{\partial u^*}{\partial y^*}\right|_{y^*=0} \tag{103}$$

From Equation 101 it is clear that

$$\left.\frac{\partial u^*}{\partial y^*}\right|_{y^*=0} = f_3\left(x^*, \mathrm{Re}_L, \frac{dp^*}{dx^*}\right) \tag{104}$$

Hence, for a prescribed geometry (i.e., dp^*/dx^* is known from the free stream conditions) we have

$$C_f = \frac{2}{\mathrm{Re}_L} f_3(x^*, \mathrm{Re}_L) \tag{105}$$

Equation 105 is very significant because it states that the friction coefficient may be expressed exclusively in terms of a dimensionless space coordinate and the Reynolds number. For a prescribed geometry, the function that relates C_f to x^* and Re_L can be expected to be *universally* applicable. That is, it can be expected to apply to different fluids and over a wide range of values for u_∞ and L.

Similar results may be obtained for the heat transfer coefficient. Equation 51 suggests that the solution may be expressed in the form

$$T^* = f_4\left(x^*, y^*, \mathrm{Re}_L, \frac{dp^*}{dx^*}\right) \tag{106}$$

for forced flow, and

$$T^* = f_5(x^*, y^*, \mathrm{Gr}_L, \mathrm{Pr}) \tag{107}$$

for free convective flow. Here Re_L, Gr_L, and dp^*/dx^* originate from the influence of fluid motion (u^* and v^*) on Equation 51.

From the definition of the convection heat transfer coefficient, Equation 5, and Equation 40 with $y^* = y/L$ we obtain

$$h = -\frac{k(\partial T/\partial y)\big|_{y=0}}{(T_s - T_\infty)} = +\frac{k}{L}\left.\frac{\partial T^*}{\partial y^*}\right|_{y^*=0} \tag{108}$$

Thus

$$\mathrm{Nu} \equiv \frac{hL}{k} = \left.\frac{\partial T^*}{\partial y^*}\right|_{y^*=0}$$

Note that the Nusselt number, Nu, is equal to the dimensionless temperature gradient at the surface. From Equation 106 or 107 it follows that for a prescribed geometry, i.e., known dp^*/dx^*

$$\mathrm{Nu} = f_6(x^*, \mathrm{Re}_L, \mathrm{Pr}) \tag{109}$$

for forced flow, and

$$\mathrm{Nu} = f_7(x^*, \mathrm{Gr}_L, \mathrm{Pr}) \tag{110}$$

for free convective flow. The Nusselt number is to the thermal boundary layer what the friction factor is to the velocity boundary layer. Equations 109 and 110 imply that for a given geometry, the Nusselt number must be some *universal* function of x^*, Re_L, and Pr. If this function were known, it could be used to compute the value of Nu for different fluids and different values of u_∞, T_∞ and L. Furthermore, since the average heat transfer coefficient is obtained by integrating over the surface of the body, it must be independent of the spatial variable, x^*. Hence, the functional dependence of the average Nusselt number is

$$\overline{\mathrm{Nu}} = \frac{\bar{h}L}{k} = f_8(\mathrm{Re}_L, \mathrm{Pr}) \tag{111}$$

for forced flow, and

$$\overline{\mathrm{Nu}} = f_9(\mathrm{Gr}_L, \mathrm{Pr}) \tag{112}$$

for free convective flows.

Although it is very helpful to know the functional dependence of Nu, the task is far from complete, because the function may be any of millions of possibilities. It may be a sine, exponential, or a logarithmic function. The exact form of this function can only be determined by an analytical solution of the governing equations, such as Equations 70 and 91.

Experimental determination of heat transfer coefficient: The manner in which a convection heat transfer correlation may be obtained experimentally is illustrated in Figure 1-3.23. If a prescribed geometry, such as the flat plate in parallel flow, is heated electrically to maintain $T_s > T_\infty$ convection heat transfer occurs from the surface to the fluid. It would be a simple matter to measure T_s and T_∞ as well as the electrical power, $E \cdot I$, which is equal to the total heat transfer rate, $\dot{q}$. The average convection coefficient, $\bar{h}_L$, can now easily be computed from Equation 7. Also, from the knowledge of the characteristic length, L, and the fluid properties, the values of the various nondimensional numbers—such as the Nusselt, Reynolds, Grashof, and Prandtl numbers—can be easily computed from their definitions.

The foregoing procedure is repeated for a variety of test conditions. We could vary the velocity, u_∞, the plate length, L, and the temperature difference $(T_s - T_\infty)$, as well as the fluid properties, using, for example, fluids such as air, water, and engine oil, which have substantially different Prandtl numbers. Many different values of the Nus-

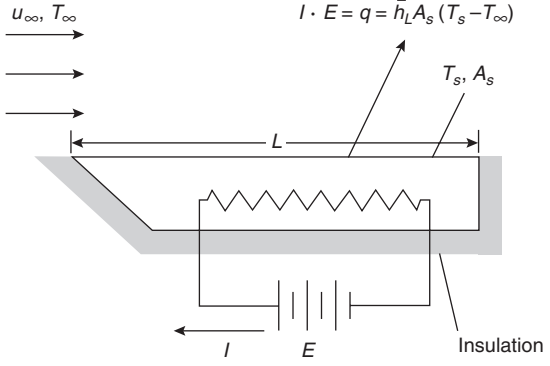

Figure 1-3.23. ***Experiment for measuring the average convection heat transfer coefficient, $\bar{h}_L$.***

selt number would result, corresponding to a wide range of Reynolds and Prandtl numbers. At this stage, an analytical solution to a similar but simpler problem proves very useful in guiding how the various nondimensional numbers should be correlated. For laminar flow over a flat plate it has been seen that in Equation 70 the relationship is of the form

$$\overline{\mathrm{Nu}} = C\,\mathrm{Re}_L^m \mathrm{Pr}^n$$

Thus, we plot the results on a log-log graph as shown in Figure 1-3.24 and determine the values of C, m, and n. Because such a relationship is inferred from experimental measurements, it is called an empirical correlation. Along with this empirical correlation it is specified how the temperature-dependent properties were determined for calculating the various nondimensional numbers. When such a correlation is used, it is important that the properties must be calculated in exactly the manner specified. If they are not specified, then the mean boundary layer temperature, T_f, called the film temperature, must be used.

$$T_f \equiv \frac{T_s + T_\infty}{2} \tag{113}$$

A summary of empirical and practical formulas: In this section selected dimensionless groups (Table 1-3.2) and a variety of convection correlations (Tables 1-3.3 and 1-3.4) for external flow conditions are tabulated. Correlations for both forced and free convection are presented along with their range of applicability. The contents of this section are more or less a collection of "recipes." Proper use of these recipes is essential to solving practical problems. The reader should not view these correlations as sacrosanct; each correlation is reasonable over the range of conditions specified, but for most engineering calculations one should not expect the accuracy to be much better than 20 percent.

For proper use of the foregoing correlations it is important to note that the flow may not be laminar or turbulent over the entire length of the plate under consideration. Instead, transition to turbulence may occur at a distance x_c ($x_c < L$, where L is the plate length) from the leading edge of the plate. In this mixed boundary layer situation, the average convection heat transfer coefficient for the entire plate is obtained by integrating first over the laminar region ($0 \le x \le x_c$) and then over the turbulent region ($x_c < x \le L$) as follows:

$$\overline{h}_L = \frac{1}{L}\left(\int_0^{x_c} h_{\mathrm{lam}}\,dx + \int_{x_c}^{L} h_{\mathrm{turb}}\,dx\right) \tag{114}$$

where x_c may be obtained from the critical Reynolds or Grashof numbers.

Also, several correlations given in Tables 1-3.3 and 1-3.4 are for the constant heat flux ($\dot{q}_s''$ = constant) boundary condition. Thus, the surface temperature of the object is unknown and yet the fluid properties are to be determined at $T_f = (T_s + T_\infty)/2$. For such cases an iterative procedure is employed and the average surface temperature can be determined as follows:

$$\dot{q}_s''(\text{known}) = \overline{h}(T_s - T_\infty) = \frac{\overline{\mathrm{Nu}}_L}{(L/k)}(T_s - T_\infty)$$

thus

$$T_s(\text{average}) = T_\infty + \frac{\dot{q}_s''(L/k)}{\overline{\mathrm{Nu}}_L} \tag{115}$$

The use of correlations given in Tables 1-3.3 and 1-3.4 is illustrated via examples in the next section.

Applications

This section briefly summarizes the methodology for convection calculations and then presents examples to illustrate the use of various correlations.

Methodology for convection calculations: The application of a convection correlation for any flow situation is facilitated by following a few simple rules:

1. Become immediately cognizant of the flow geometry. Does the problem involve flow over a flat plate, a sphere, a cylinder, and so forth? The specific form of the convection correlation depends, of course, on the geometry.

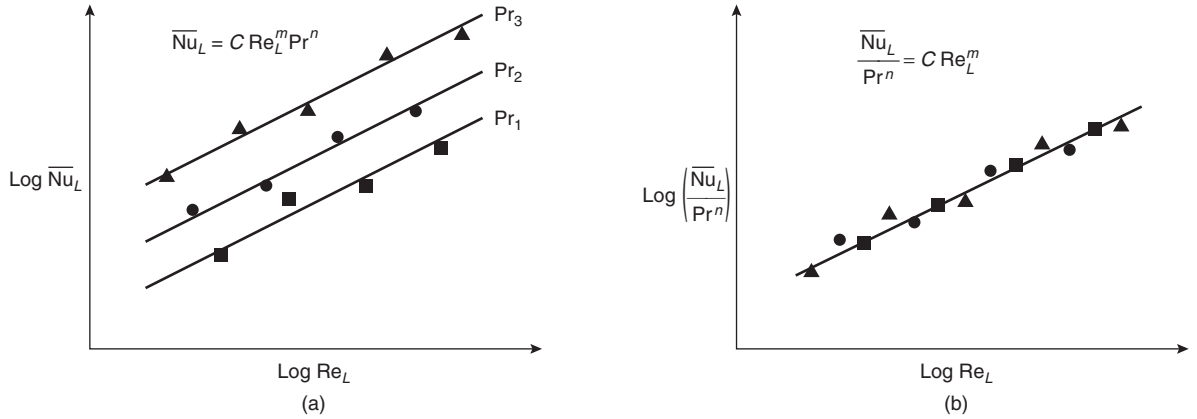

Figure 1-3.24. ***Dimensionless representation of convection heat transfer measurements.***

Table 1-3.2 ***Selected Dimensionless Groups***

Group		Definition	Interpretation
Friction coefficient	local	$C_f = \frac{\tau_2}{\rho u^{2}_{\infty}/2}$	Dimensionless surface shear stress
	average	$\bar{C}_f = \frac{\bar{\tau}_s}{\rho u^{2}_{\infty}/2}$	
Reynolds number	location x	$\mathrm{Re}_x = \frac{u_\infty x}{\nu}$	Ratio of inertia and viscous forces
	length L	$\mathrm{Re}_L = \frac{u_\infty L}{\nu}$	
	diameter D	$\mathrm{Re}_D = \frac{u_\infty D}{\nu}$	
Prandtl number		$\mathrm{Pr} = \frac{Cp\mu}{k} = \frac{\nu}{\alpha}$	Ratio or molecular momentum and thermal diffusivities
Grashof number	location x	$\mathrm{Gr}_x = \frac{g\beta(T_s - T_\infty)x^3}{\nu^2}$	Ratio of buoyancy to viscous forces
	length L	$\mathrm{Gr}_L = \frac{g\beta(T_s - T_\infty)L^3}{\nu^2}$	
	diameter D	$\mathrm{Gr}_D = \frac{g\beta(T_s - T_\infty)D^3}{\nu^2}$	
Rayleigh number	location x	$\mathrm{Ra}_x = \mathrm{Gr}_x\mathrm{Pr} = \frac{g\beta(T_s - T_\infty)x^3}{\nu\alpha}$	Product of Grashof and Prandtl numbers
		replace x by L and D to get Ra_L and Ra_D	
Nusselt number	location x	$\mathrm{Nu}_x = \frac{hx}{k}$	Ratio of convection heat transfer to conduction in a fluid slab of thickness x
		replace x by L and D to get Nu_L and Nu_D	
Modified Grashof number	location x	$\mathrm{Gr}^*_x = \mathrm{Gr}_x\mathrm{Nu}_x = \frac{g\beta\dot{q}''_s x^4}{k\nu^2}$	Product of Grashof and Nusselt numbers
Stanton number		$\mathrm{St} = \frac{h}{\rho u_\infty c_p} = \frac{\mathrm{Nu}}{\mathrm{Re}\,\mathrm{Pr}}$	Dimensionless heat transfer coefficient

2. Specify the appropriate reference temperature and then evaluate the pertinent fluid properties at that temperature. For moderate boundary layer temperature differences, it has been found that the film temperature may be used for this purpose. However, there are correlations that require property evaluation at the free stream temperature and include a property ratio to account for the nonconstant property effect.
3. Determine whether the flow is laminar or turbulent. This determination is made by calculating the Reynolds number and comparing the value with the appropriate transition criterion. For example, if a problem involves parallel flow over a flat plate for which the Reynolds number is $\mathrm{Re}_L = 10^6$ and the transition criterion is $\mathrm{Re}_{\mathrm{crit}} = 5 \times 10^5$, it is obvious that a mixed boundary layer condition exists.
4. Decide whether a local or surface average coefficient is required. Recall that the local coefficient is used to determine the flux at a particular point on the surface, whereas the average coefficient determines the transfer rate for the entire surface.

Having complied with the foregoing rules, sufficient information will be available to select the appropriate correlation for the problem.

EXAMPLE 1:

Electrical strip heaters are assembled to construct a flat radiant heater 1 m wide for conducting fire experiments in a wind tunnel. The heater strips are 5 cm wide and are independently controlled to maintain the surface temperature at 500°C. Construction details are shown in Figure 1-3.25. If air at 25°C and 60 m/s flows over the plate, at which strip is the electrical input maximum? What is the value of this input? The radiative heat loss is ignored.

Table 1-3.3 ***Summary of Forced Convection Correlations for External Flow Geometries***

Geometry/Flow	Type	Equation	Restrictions	Comments
Flat plate/laminar (T_s = constant)	Local:	$\mathrm{Nu}_x = 0.332\,\mathrm{Re}_x^{1/2}\mathrm{Pr}^{1/3}$	$\mathrm{Re}_x < 5 \times 10^5$	Properties evaluated at $T_f = (T_s + T_\infty)/2$
	Average:	$\overline{\mathrm{Nu}}_L = 0.664\,\mathrm{Re}_L^{1/2}\mathrm{Pr}^{1/3}$	$0.6 \le \mathrm{Pr} \le 50$	
	Boundary layer thickness:	$\frac{\delta}{x} = 5\,\mathrm{Re}_x^{-1/2}$		
Flat plate/laminar ($\dot{q}_s''$ = constant)	Local:	$\mathrm{Nu}_x = 0.453\,\mathrm{Re}_x^{1/2}\mathrm{Pr}^{1/3}$	$\mathrm{Re}_x < 5 \times 10^5$ $0.6 \le \mathrm{Pr} \le 50$	Properties evaluated at T_f. However, T_s is not known. Instead, q_s'' is known. Thus, $T_f = T_\infty + (\bar{T}_s - \bar{T}_\infty)/2$ where, $(\bar{T}_s - \bar{T}_\infty) = \frac{q_s L/K}{0.6795\,\mathrm{Re}_L^{1/2}\mathrm{Pr}^{1/3}}$
Flat plate/turbulent (T_s = constant)	Local:	$\mathrm{Nu}_x = 0.0296\,\mathrm{Re}_x^{4/5}\mathrm{Pr}^{1/3}$	$\mathrm{Re}_x < 10^8$	Properties evaluated at T_f.
	Boundary layer thickness:	$\frac{\delta}{x} = 0.37\,\mathrm{Re}_x^{-1/5}$	$0.6 \le \mathrm{Pr} \le 60$	
	Mixed average (laminar-turbulent):	$\overline{\mathrm{Nu}}_L = (0.037\,\mathrm{Re}_L^{4/5} - 871)\mathrm{Pr}^{1/3}$	Transition to turbulence at $\mathrm{Re}_{crit} = 5 \times 10^5$	
Flow across cylinders	Average:	$\overline{\mathrm{Nu}}_D = C\,\mathrm{Re}_D^m\mathrm{Pr}^{1/3}$	$0.4 < \mathrm{Re}_D < 4 \times 10^5$	Properties evaluated at T_f.
Circular cylinder		Re_D — C — m: $0.4 - 4$ — 0.989 — 0.330 $4 - 40$ — 0.911 — 0.385 $40 - 4000$ — 0.683 — 0.466 $4 \times 10^3 - 4 \times 10^4$ — 0.193 — 0.618 $4 \times 10^4 - 4 \times 10^5$ — 0.027 — 0.805		
Other Geometries Square 		$5 \times 10^3 - 10^5$ — 0.246 — 0.588 $5 \times 10^3 - 10^5$ — 0.102 — 0.675		
Hexagon 		$5 \times 10^3 - 1.95 \times 10^4$ — 0.160 — 0.638 $1.95 \times 10^4 - 10^5$ — 0.0385 — 0.782		
Vertical Plate 		$5 \times 10^3 - 10^5$ — 0.153 — 0.638 $4 \times 10^3 - 1.5 \times 10^4$ — 0.228 — 0.731		
Flow across spheres	Average:	$\overline{\mathrm{Nu}}_D = 2 + (0.4\,\mathrm{Re}_D^{1/2} + 0.06\,\mathrm{Re}_D^{2/3})\mathrm{Pr}^{0.4}\left(\frac{\mu_\infty}{\mu_s}\right)^{1/4}$	$3.5 < \mathrm{Re}_D < 7.6 \times 10^4$ $0.71 < \mathrm{Pr} < 380$ $1.0 < \left(\frac{\mu_\infty}{\mu_s}\right) < 3.2$	Properties evaluated at T_∞.
Falling drop	Average:	$\overline{\mathrm{Nu}}_D = 2 + 0.6\,\mathrm{Re}_D^{1/2}\mathrm{Pr}^{1/3} \cdot \left(25\left(\frac{x}{D}\right)^{-.07}\right)$	where x is the falling distance measured from rest.	Properties evaluated at T_∞.

Table 1-3.4 ***Summary of Free Convection Correlations for External Flow Geometries***

Geometry/Flow	Type	Equation	Restrictions	Comments
Vertical Plates  or	Local: (T_s = const)	$\mathrm{Nu}_x g(\mathrm{Pr})$ from Table 1-3.1 $= \left(\frac{\mathrm{Gr}_x}{4}\right)^{1/4} g(\mathrm{Pr})$	$\mathrm{Gr}_x \le 4 \times 10^8$ (Laminar)	Properties evaluated at $(T_f = T_s + T_\infty)/2$
	Average: (T_s = const)	$\overline{\mathrm{Nu}}_L = \frac{4}{3}\left(\frac{\mathrm{Gr}_L}{4}\right)^{1/4} g(\mathrm{Pr})$	$\mathrm{Gr}_x \le 4 \times 10^8$ (Laminar)	Properties at T_f
	Average: (T_s = const)	$\overline{\mathrm{Nu}}_L = \left\{0.825 + \frac{0.387\ \mathrm{Ra}_L^{1/6}}{[1+(0.492/\mathrm{Pr})^{9/16}]^{8/27}}\right\}^2$	none	Properties at T_f This correlation may be applied to vertical cylinders if $\left(\frac{D}{L}\right) \ge (35/\mathrm{Gr}_L^{1/4})$
	Local: ($\dot{q}_s''$ = const)	$\mathrm{Nu}_x = 0.6(\mathrm{Gr}_x^* \mathrm{Pr})^{1/5}$	$10^5 < \mathrm{Gr}_x^* 10^{11}$ (Laminar)	Properties at T_f
	Local: ($\dot{q}_s''$ = const)	$\mathrm{Nu}_x = 0.17(\mathrm{Gr}_x^* \mathrm{Pr})^{1/4}$	$2 \times 10^{13} < \mathrm{Gr}_x^* \mathrm{Pr} < 10^{16}$	Properties at T_f
	Average: ($\dot{q}_s''$ = const)	$\overline{\mathrm{Nu}}_L = 0.75(\mathrm{Gr}_L^* \mathrm{Pr})^{1/5}$	$10^5 < \mathrm{Gr}_x^* < 10^{11}$ (Laminar)	Properties at T_f

Spheres 	Average: (T_s = const)	$\overline{\mathrm{Nu}}_D = 2 + 0.43\ \mathrm{Ra}_D^{1/4}$ $\overline{\mathrm{Nu}}_D = 2 + 0.5\ \mathrm{Ra}_D^{1/4}$	$1 < \mathrm{Ra}_D < 10^5$ $\mathrm{Pr} \approx 1$ $3 \times 10^5 < \mathrm{Ra} < 8 \times 10^8$	Properties evaluated at T_f.

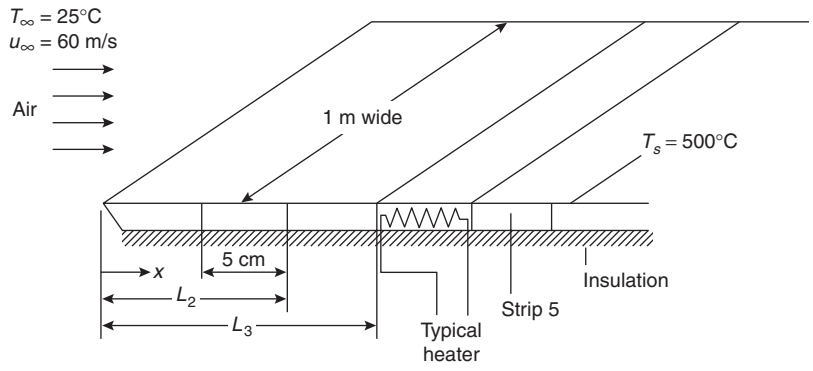

Figure 1-3.25. ***Construction details for wind tunnel experiments.***

SOLUTION:

Assumptions

Steady-state conditions, neglect radiation losses, and no heat loss through the bottom surface.

Properties

T_f = 535 K: ρ = 1 atm. From air property Table 1-3.5, k = 42.9 × 10^{-3} W/m K; ν = 43.5 × 10^{-6} m^2/s; Pr = 0.683.

Analysis

The strip heater requiring the maximum electrical power is that for which the average convection coefficient is the largest. From the knowledge of variation of the local convection coefficient with distance from the leading edge, the local maximum can be found. Figure 1-3.15 shows that a possible location is the leading edge on the first plate. A second likely location is where the flow becomes turbulent. To determine the point of boundary layer transition to turbulence assume that the critical Reynolds number is 5 × 10^5. It follows that transition will occur at x_c, where

$$x_c = \frac{\nu \, \mathrm{Re}_{\mathrm{crit}}}{u_\infty} = \frac{43.5 \times 10^{-6} \times 5 \times 10^5}{60} \, \mathrm{m}$$
$$= 0.36 \, \mathrm{m} \quad \text{or on the eighth strip}$$

Thus there are three possibilities:

1. Heater strip 1, since it corresponds to the largest local, laminar convection coefficient
2. Heater strip 8, since it corresponds to the largest local turbulent convection coefficient
3. Heater strip 9, since turbulent conditions exist over the entire heater

For the first heater strip

$$q_{\mathrm{conv},1} = \overline{h}_1 L_1 W (T_s - T_\infty)$$

where $\overline{h}_1$ is determined from the equation below (see also Table 1-3.3).

$$\overline{\mathrm{Nu}}_1 = 0.664 \, \mathrm{Re}_1^{1/2} \, \mathrm{Pr}^{1/3}$$
$$= 0.664 \left(\frac{60 \times 0.05}{43.5 \times 10^{-6}} \right)^{1/2} (0.683)^{1/3}$$
$$= 153.6$$

hence,

$$\overline{h}_1 = \frac{\overline{\mathrm{Nu}}_1 k}{L_1} = \frac{153.6 \times 42.9 \times 10^{-3}}{0.05}$$
$$= 131.8 \, \mathrm{W/m^2 \, K}$$

hence,

$$q_{\mathrm{conv},1} = (131.8)(0.05)(1 \, \mathrm{m})(500 - 25)$$
$$= 3129 \, \mathrm{W}$$

The power requirement for the eighth strip may be obtained by subtracting the total heat loss associated with the first seven heaters from that associated with the first eight heaters. Thus

$$q_{\mathrm{conv},8} = \overline{h}_{1-8} L_8 W (T_s - T_\infty) - \overline{h}_{1-7} L_7 W (T_s - T_\infty)$$

The value of $\overline{h}_{1-7}$ is obtained from the equation applicable to laminar conditions (Table 1-3.3). Thus

$$\overline{\mathrm{Nu}}_{1-7} = 0.664 \, \mathrm{Re}_7^{1/2} \, \mathrm{Pr}^{1/3}$$
$$= 0.664 \left(\frac{60 \times 7 \times 0.05}{43.5 \times 10^{-6}} \right)^{1/2} (0.683)^{1/3}$$
$$= 406.3$$
$$\overline{h}_{1-7} = \frac{\overline{\mathrm{Nu}}_{1-7} k}{L_7} = \frac{406.3 \times 42.9 \times 10^{-3}}{7 \times 0.05}$$
$$= 49.8 \, \mathrm{W/m^2 \, K}$$

By contrast, the eighth heater is characterized by mixed boundary layer conditions. Thus use the formula (Table 1-3.3).

$$\overline{\mathrm{Nu}}_{1-8} = (0.037\ \mathrm{Re}_8^{4/5} - 871)\ \mathrm{Pr}^{1/3}$$
$$\mathrm{Re}_8 = 8 \times \mathrm{Re}_1 = 5.52 \times 10^5$$
$$\overline{\mathrm{Nu}}_{1-8} = 510.5$$
$$\overline{h}_{1-8} = \frac{\overline{\mathrm{Nu}}_{1-8} k}{L_8} = 54.7\ \mathrm{W/m^2\ K}$$

The rate of heat transfer from the eighth strip is then

$$q_{\mathrm{conv},8} = (54.7 \times 8 \times 0.05 - 49.8 \times 7 \times 0.05)(500 - 25)$$
$$= 2113.8\ \mathrm{W}$$

The power requirement for the ninth heater strip may be obtained by either subtracting the total heat loss associated with the first eight from that associated with the first nine, or by integrating over the local turbulent expression, since the flow is completely turbulent over the entire width of the strip. The latter approach produces

$$\overline{h}_9 = \left(\frac{k}{L_9 - L_8}\right) 0.0296 \left(\frac{u_\infty}{v}\right)^{4/5} \mathrm{Pr}^{1/3} \int_{L_8}^{L_9} \frac{dx}{x^{1/5}}$$
$$\overline{h}_9 = \left(\frac{42.9 \times 10^{-3}}{0.05}\right) 0.0296 \left(\frac{60}{43.5 \times 10^{-6}}\right)^{4/5}$$
$$\times (0.683)^{1/3} \int_{L_8}^{L_9} \frac{dx}{x^{1/5}}$$
$$= 1825.22[(0.45)^{0.8} - (0.4)^{0.8}] = 86.7$$
$$q_{\mathrm{conv},9} = 86.7 \times 0.05 \times 1 \times (500 - 25) = 2059\ \mathrm{W}$$

hence

$$q_{\mathrm{conv},1} > q_{\mathrm{conv},8} > q_{\mathrm{conv},9}$$

and the first heater strip has the largest power requirement.

EXAMPLE 2:

A glass-door fire screen, shown in Figure 1-3.26, is used to reduce exfiltration of room air through a chimney. It has a height of 0.71 m, a width of 1.02 m, and reaches a temperature of 232°C. If the room temperature is 23°C, estimate the convection heat transfer rate from the fireplace to the room.

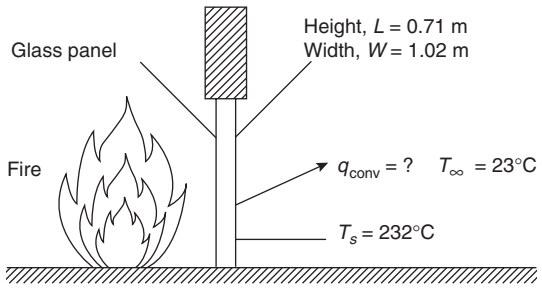

Figure 1-3.26. ***Glass panel fire screen.***

SOLUTION:

Assumptions

The screen is at a uniform temperature, T_s, and room air is quiescent.

Properties

$T_f = 400$ K, $P = 1$ atm. From air property table (Table 1-3.5):

$$k = 33.8 \times 10^{-3}\ \mathrm{W/m\ K}; \qquad \nu = 26.41 \times 10^6\ \mathrm{m^2/s};$$
$$\alpha = 38.3 \times 10^{-6}\ \mathrm{m^2/s};\ \ \mathrm{Pr} = 0.69;\ \ \beta = 1/T_f = 0.0025\ \mathrm{K^{-1}}$$

Analysis

The rate of heat transfer by free convection from the panel to the room is given by

$$q = \overline{h} A_s (T_s - T_\infty)$$

where $\overline{h}$ is obtained from the following equation from Table 1-3.4.

$$\overline{\mathrm{Nu}}_L = \left\{0.825 + \frac{0.387\ \mathrm{Re}_L^{1/6}}{[1 + (0.492/\mathrm{Pr})^{9/16}]^{8/27}}\right\}^2$$

here

$$\mathrm{Ra}_L = \frac{g\beta(T_s - T_\infty)L^3}{\alpha\nu}$$
$$= \frac{9.8 \times 0.0025 \times (232 - 23) \times (0.71)^3}{38.3 \times 10^{-6} \times 26.4 \times 10^{-6}}$$
$$= 1.813 \times 10^9$$

Since $\mathrm{Ra}_L > 10^9$, transition to turbulence will occur on the glass panel and the appropriate correlation from Table 1-3.4 has been chosen

$$\overline{\mathrm{Nu}}_L = \left\{0.825 + \frac{0.387(1.813 \times 10^9)^{1/6}}{[1 + (0.492/0.69)^{9/16}]^{8/27}}\right\}^2$$
$$= 147$$

Hence

$$\overline{h} = \frac{\overline{\mathrm{Nu}}_L \times k}{L} = \frac{147 \times 33.8 \times 10^{-3}}{0.71} = 7\ \mathrm{W/m^2\ K}$$

and

$$q = 7\ \frac{\mathrm{W}}{\mathrm{m^2\ K}}\ (1.02\ \mathrm{m} \times 0.71\ \mathrm{m}) \times (232 - 23)°\mathrm{C}$$
$$= 1060\ \mathrm{W}$$

Note: in this case radiation heat transfer calculations would show that radiant heat transfer is greater than free convection heat transfer.

Nomenclature

A	area (m²)
A_s	surface area (m²)
B_i	Biot number
C	molar concentration (kmol/m³)
C_f	friction coefficient
c_p	specific heat at constant pressure (J/kg·K)
c_v	specific heat at constant volume (J/kg·K)
D	diameter (m)
D_{AB}	binary mass diffusion coefficient (m²/s)
D_h	hydraulic diameter (m)
e	Specific internal or thermal (sensible) energy (J/kg)
f	friction factor
Gr	Grashof number
g	gravitational acceleration (m/s²)
h	convection heat transfer coefficient (W/m²·K)
$\overline{h}$	average convection heat transfer coefficient (W/m²·K)
h_m	convection mass transfer coefficient (m/s)
h_{rad}	radiation heat transfer coefficient (W/m²·K)
k	thermal conductivity (W/m·K)
L	characteristic length (m)
Le	Lewis number
M	mass (kg)
$\dot{M}$	mass flow rate (kg/s)
$\dot{m}''$	mass flux (kg/m²·s)
$\dot{m}_i''$	mass flux of species i (kg/m²·s)
Nu	Nusselt number
P	perimeter (m)
Pe	Peclet number (RePr)
Pr	Prandtl number
p	pressure (N/m²)
Q	energy generation rate per unit volume (W/m³)
$\dot{q}'$	heat transfer rate per unit length (W/m)

$\dot{q}''$	heat flux (W/m^2)
R	universal gas constant
Ra	Rayleigh number
Re	Reynolds number
r, ϕ, z	cylindrical coordinates
r, θ, ϕ	spherical coordinates
Sc	Schmidt number
Sh	Sherwood number
St	Stanton number
T	temperature (K)
t	time (s)
U	overall heat transfer coefficient (W/m^2·K)
u, v, w	mass average fluid velocity components (m/s)
F_{BX}, F_{BY}, F_{BZ}	components of the body force per unit volume (N/m^3)
F_{SX}, F_{SY}, F_{SZ}	components of the surface force
x, y, z	rectangular coordinates (m)
$x_{fd,h}$	hydrodynamic entry length (m)
$x_{rd,t}$	thermal entry length (m)

Greek Letters

α	thermal diffusivity (m^2/s)
β	volumetric thermal expansion coefficient (K^{-1})
δ	hydrodynamic boundary layer thickness (m)
δ_t	thermal boundary layer thickness (m)
δ_d	mass transfer boundary layer thickness (m)
η	similarity variable
θ	zenith angle (rad)
ϕ	azimuthal angle (rad)
μ	viscosity (kg/s·m)
ν	kinematic viscosity (m^2/s)
ρ	mass density (kg/m^3)
σ_{ij}	components of the stress tensor (N/m^2)
ψ	stream function (m^2/s)
τ	shear stress (N/m^2)

Subscripts

A,B	species in a binary mixture
conv	convection
D	diameter; drag
f	fluid properties
fd	fully developed conditions
H	heat transfer conditions
h	hydrodynamic; hot fluid
L	based on characteristic length
max	maximum fluid velocity
s	surface conditions
sur	surroundings
t	thermal
x	local conditions on a surface
∞	free stream conditions

CHAPTER 4

Radiation Heat Transfer

C. L. Tien, K. Y. Lee, and A. J. Stretton

Introduction

Researchers have become increasingly aware of the role of thermal radiation in fires, and a significant amount of recent research work has been published on the subject. An overview of the current understanding in this area can be found in the literature.[1–3] Human safety has made the assessment of fire hazard one of the most important concerns of fire protection engineers. Many fire research experiments in the past were performed in laboratories with very few attempts to simulate actual fire situations, due to the inherent expense and difficulty of controlling large fires. However, these experiments lacked information on thermal radiation, since reduced fire scales often reduce the proportion of radiation as compared to the other modes of heat transfer. It is now recognized that radiation is the dominant mode of heat transfer in flames with characteristic lengths exceeding 0.2 m, while convection is more significant in smaller flames.

Thermal radiation in fires involves energy exchange between surfaces (i.e., walls, ceilings, floors, furniture, etc.) as well as emission and absorption by various gases and soot particles. Among those gases of great practical importance to fire engineers are water vapor and carbon dioxide, which are strongly absorbing-emitting in the major thermal radiation spectrum of 1 to 100 μm (1 μm = 10^{-6} m). Many petroleum-based materials, such as plastics, evolve hydrocarbon gases upon heating, which are also strongly absorbing. In addition, the contribution of the soot particles is very important in evaluating the properties of the participating media and in most situations, soot radiation contributes more than gaseous radiation. Exact calculations of radiative exchanges in fire systems are often prohibitively expensive, even under idealized conditions, due to the dependence of the radiation properties of each material on geometry and wavelength. Many of the simplifying assumptions used in current analytical methods will be covered in this chapter.

This chapter will introduce the fundamentals of thermal radiation and offer simple methods of calculating radiant heat transfer in fires. The first section of the chapter, on basic concepts, deals with the theoretical framework for radiative heat transfer and is followed by the engineering assumptions and simple equations used for practical heat transfer calculations. The third section, on thermal radiation properties of combustion products, covers the properties of various gases and soot present in fires. The last section applies the preceding methods to several fire systems and shows some of the directions of current research.

Dr. C. L. Tien is professor of mechanical engineering at the University of California at Berkeley.

Dr. K. Y. Lee is Manager, New Engine Development, Daewoo Technical Center, Inchon, Korea.

A. J. Stretton is assistant professor of mechanical engineering at the University of Toronto.

Basic Concepts

Radiation Intensity and Energy Flux

Thermal radiation transport can be described by electromagnetic wave theory or by quantum mechanics. In the general quantum mechanical consideration, electromagnetic radiation is interpreted in terms of photons. Each photon possesses energy, $h\nu$, and momentum, $h\nu/c$, with h as the Planck constant (6.6256×10^{-34} J·s), ν the frequency of the radiation, and c the speed of light in the medium. A radiation field is fully described when the flux of photons (or energy) is known for all points in the field for all directions and for all frequencies. The net flow of thermal radiative energy for a single frequency, across a surface of an arbitrary orientation, is represented by the spectral radiative energy flux[4–6]

$$q_\nu = \int_0^{4\pi} I_\nu \vec{n} \cdot \vec{R}\, d\Omega = \int_0^{4\pi} I_\nu \cos\theta\, d\Omega \qquad (1)$$

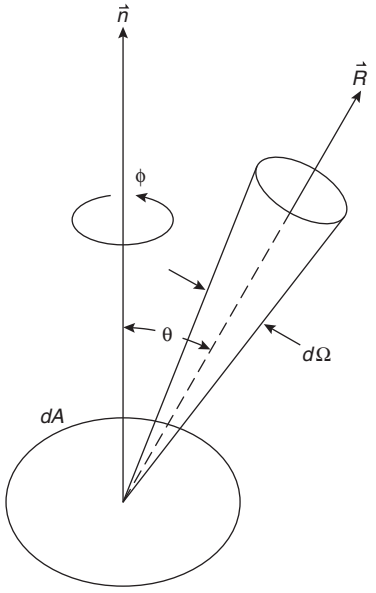

Figure 1-4.1. ***Coordinate system for radiation intensity.***

In Equation 1, Ω denotes solid angle ($d\Omega = \sin\theta\, d\theta\, d\phi$) and I_ν is the intensity of radiation expressed as energy per unit area per unit solid angle (Figure 1-4.1) within a unit frequency interval. Intensity is a useful measure for thermal radiation because the intensity of a radiant beam remains constant if it is traveling through a nonparticipating medium.

Planck's Law

The energy spectrum of the radiation given off by a surface that is a perfect emitter and absorber can be calculated by Planck's quantum theory. This theoretical surface is called a blackbody radiator, and is best simulated by a small opening into an enclosed cavity. The isotropic equilibrium radiation field within a uniform temperature enclosure is called blackbody radiation. The spectral (or monochromatic) intensity of blackbody radiation, $I_{b\nu}$, is often called the Planck function, illustrated in Figure 1-4.2, and is given by Equation 2.

$$I_{b\nu}(T) = \frac{2h\nu^3 n^2}{c_0^2[\exp(h\nu/kT) - 1]} \tag{2}$$

where

k = Boltzmann constant ($k = 1.3806 \times 10^{-23}$ J/K)

c_0 = speed of light in vacuum ($c_0 = 2.998 \times 10^8$ m/s)

n = index of refraction for the medium ($n = c_0/c$ is very close to one for most gases of interest in fires)

In many engineering applications and experimental measurements of thermal radiation properties, it is advantageous to use wavelength λ instead of ν. Equation 2 can then be expressed in the form

$$\frac{I_{b\lambda}}{T^5} = \frac{2hc_0^2}{n^2(\lambda T)^5[\exp(hc_0/n\lambda kT) - 1]} \tag{3}$$

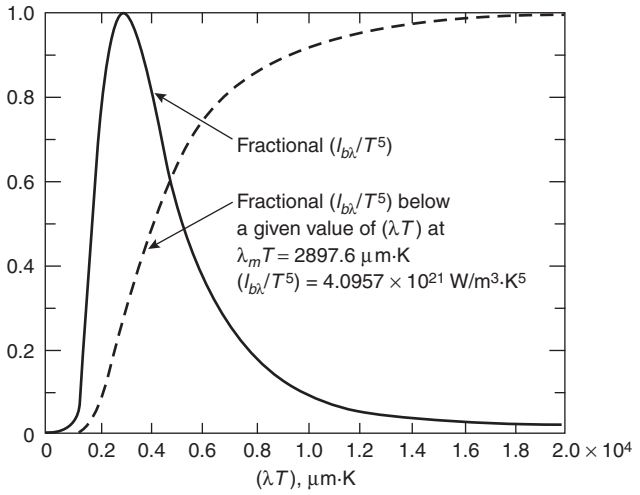

Figure 1-4.2. ***Planck's function.***

where the relations $\nu = c_0/n\lambda$ and $I_{b\lambda}d\lambda = -I_{b\nu}d\nu$ have been used. The wavelength at which radiation intensity becomes the maximum is readily obtainable by simple differentiation as

$$(n\lambda T)_{\max} = 2897.8\ \mu\text{m·K} \tag{4}$$

This relationship is known as Wien's displacement law, which shows that the maximum monochromatic emmisive power of a blackbody shifts to shorter wavelengths as its temperature increases. The total radiant intensity from a blackbody radiator can be obtained by integrating Equation 3 over the entire range of wavelengths, giving

$$I_b = \int_0^\infty I_{b\lambda}\, d\lambda = \frac{n^2\sigma T^4}{\pi} \tag{5}$$

where σ is the Stefan-Boltzmann constant (5.6696×10^{-8} W/m²·K⁴). The intensity of radiation from a blackbody is independent of direction, which allows integration of Equation 1 in a simple manner to give the total hemispherical emissive power per unit area of a blackbody

$$E_b = \int_0^{4\pi} I_b \cos\theta\, d\Omega \tag{6}$$

Kirchhoff's Law

If a fire in an isolated, uniform temperature enclosure that contains different media inside has reached its equilibrium state, the relation

$$\alpha_v + \rho_v + \tau_v = 1 \tag{7}$$

will hold at the interface between each medium, where α, ρ, and τ denote the fraction of energy absorbed by, reflected at, and transmitted through the interface, respectively. The assumption of the local thermodynamic equilibrium can be used to derive more extensive results and is used extensively in radiation heat transfer calculations. Kirchhoff's law states that in order to maintain

equilibrium, the spectral absorptivity and spectral emissivity must be related by

$$\alpha_v = \frac{I_v}{I_{bv}} = \varepsilon_v \tag{8}$$

More importantly, when Equation 8 is applied to total properties,

$$\alpha_t = \varepsilon_t \tag{9}$$

is valid for the special case when the incident radiation is independent of the incident angle and has the same spectral proportions as a blackbody radiator (i.e., a "gray body"). Fortunately, this is the case in many radiation heat transfer engineering models for participating media in fire applications. Although gas emissivity is only dependent on the state of the gas, the absorptivity is also a function of the source temperature of the incident beam of radiation, which may originate outside the gas body (e.g., wall temperature).

The Equation of Transfer

The equation of transfer describes the variation in intensity of a radiant beam at any position along its path in an absorbing-emitting-scattering medium. This equation is the foundation upon which detailed radiation analyses are based, and the source of approximate solutions when simplifying assumptions are made. For a given direction line in the medium, the equation of transfer is

$$\frac{1}{\kappa_\lambda(T, S)} \frac{dI_\lambda(S)}{dS} + I_\lambda(S) = I_{b\lambda}(T) \tag{10}$$

where S represents the physical pathlength and κ_λ represents the spectral extinction coefficient, which includes the effects of both absorption and scattering within the medium. The intensity, $I_\lambda(S)$, is coupled with the spatial distribution of the extinction coefficient and with temperature through conservation of energy in the medium. The contributions of intensity passing through an area must be integrated over all directions to calculate a net radiative energy flux. The integral nature of radiation makes analysis difficult and simplifications necessary for engineering practice.

Basic Calculation Methods

Energy Exchange in a Nonparticipating Medium

In this section, cases are examined where the surfaces are separated by a medium that does not emit, absorb, or scatter radiation. A vacuum meets this requirement exactly, and common diatomic gases of symmetric molecular structure such as N_2, O_2, and H_2 are very nearly nonparticipating media within the thermal radiation spectrum. The radiative energy transfer between the surfaces depends on the geometry, orientation, and temperature of the surfaces, while the material surface radiative properties are a function of temperature, bounding medium, direction, and polarization of radiation. In practice, most surfaces (either entire or subdivided) are assumed to be isothermal, surface radiation properties are approximated by those of ideal diffuse surfaces, and polarization effects are neglected. The geometry and orientation of each surface is commonly accounted for in calculations by one or more configuration factors, which are also known as view factors, shape factors, angle factors, and geometric factors.[5–8] A configuration factor is a purely geometrical relation between two surfaces, and is defined as the fraction of radiation leaving one surface which is intercepted by the other surface.

Configuration factors and their algebra: Consider the two arbitrarily oriented surfaces A_1 and A_2 in Figure 1-4.3. Assuming that the radiosity from dA_1 on A_1 is diffusely distributed, the configuration factor for the differential area dA_1 to the finite area A_2, F_{d1-2}, is given by

$$F_{d1-2} = \int_{A_2} \frac{\cos\beta_1 \cos\beta_2}{\pi |\vec{R}|^2} dA_2 \tag{11}$$

where

$|\vec{R}|$ = separation distance between the two surfaces

β = angle between the line of sight $\vec{R}$ and the surface normal $\vec{n}$

A_2 = area of surface 2

If the assumption of the radiosity distribution on surface A_1 is extended to include a uniform radiosity distribution over A_1 (physically, a uniform radiant heat flux from an isothermal surface), then the configuration factor for the finite area A_1 to A_2, F_{1-2}, is simply

$$F_{1-2} = \frac{1}{A_1} \int_{A_1} \int_{A_2} \frac{\cos\beta_1 \cos\beta_2}{\pi |\vec{R}|^2} dA_1 \, dA_2 \tag{12}$$

When the radiant fluxes from both surfaces are uniformly and diffusely distributed (a common engineering assumption), a reciprocity relation for the configuration factors for

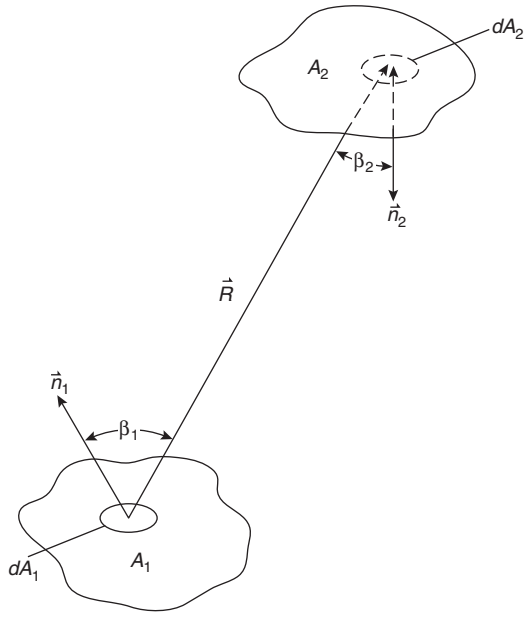

Figure 1-4.3. ***Coordinate system for shape factors.***

any given pair in a group of exchanging surfaces can readily be obtained to be

$$A_i F_{i-j} = A_j F_{j-i} \tag{13}$$

The summation rule is another useful relation for calculating unknown configuration factors

$$\sum_j F_{i-j} = 1 \tag{14}$$

where F_{i-j} relate to surfaces that subtend a closed system. Note that it is possible for a concave surface to "see" itself, which can make F_{i-i} important.

All configuration factors can be derived using the multiple integration of Equations 11 and 12, but this is generally very tedious except for simple geometries. A large number of cases have already been tabulated with the numerical results or algebraic formulas available in various references.[5–7] A catalog of common configuration factors is provided in Table 1-4.1. This data base can be extended to cover many other situations by the use of configuration algebra and the method of surface decomposition. In surface decomposition, unknown factors can be determined from known factors for convenient areas or for imaginary surfaces which can extend real surfaces or form an enclosure.[5,6]

Gray diffuse surfaces: For engineering purposes, the emittance from most surfaces is treated as having diffuse directional characteristics independent of wavelength and temperature. Real surfaces exhibit radiation properties that are so complex that information about these property measurements for many common materials is not available. The uncertainties associated with the property measurements, combined with the simplifying assumptions used in the calculations, usually reduce the knowledge of the radiative energy transfer to a simple overall flux. The gray diffuse surface is a useful model that alleviates many of the complexities associated with a detailed radiation analysis, while providing reasonably accurate results in many practical situations. The advantage of diffuse surface analysis is that radiation leaving the surface is independent of the direction of the incoming radiation, which greatly reduces the amount of computation required to solve the governing equations. Discussions for specularly reflecting surfaces and nongray surfaces can be found in the literature.[5,6]

A convenient method to analyze radiative energy exchange in an enclosure of diffuse gray surfaces is based on the concept of radiosity and irradiation. The irradiation, G_i, represents the radiative flux reaching the ith surface regardless of its origin

$$G_i = \sum_j F_{i-j} J_j \tag{15}$$

where J_j is the surface radiosity, defined as the total radiative flux leaving the jth surface (including both emission and reflection)

$$J_i = \varepsilon_i E_{bi} + \rho_i G_i \tag{16}$$

The net loss of radiative energy is then given by

$$Q_i = (J_i - G_i) A_i \tag{17}$$

It should be reemphasized that the radiosity-irradiation formulation is based on the assumption that each surface has uniform radiosity and irradiation (or equivalently, uniform temperature and uniform heat flux). Physically unrealistic calculations can result if each surface does not approximately satisfy this condition. Larger surfaces should be subdivided into smaller surfaces if necessary.

Resistance network method: The radiosity-irradiation formulation allows a more physical and graphic interpretation using the resistance network analogy. Eliminating the irradiation G_i from Equations 15 through 17, and substituting $\rho_i = 1 - \varepsilon_i$ gives

$$Q_i = \frac{E_{bi} - J_i}{(1 - \varepsilon_i)/(\varepsilon_i A_i)} = \sum_j \frac{J_i - J_j}{1/(A_i F_{i-j})} \tag{18}$$

The denominator in the last term of Equation 18 corresponds to resistance in electric circuits. As illustrated in Figure 1-4.4, the diffuse-gray surface has a radiation potential difference $(E_{bi} - J_i)$ and a resistance $(1 - \varepsilon_i)/\varepsilon_i A_i$. This simple example also illustrates that an adiabatic surface, such as a reradiating or refractory wall, exhibits a surface temperature that is independent of the surface emissivity or reflectivity.

Thermal Radiation in Participating Media

Spectral emissivity and absorptivity: From a microscopic viewpoint, emission and absorption of radiation are caused by the change in energy levels of atoms and molecules due to interactions with photons. A summary and discussion of these effects in gases from an engineering perspective has been written by Tien.[9] Consider a monochromatic beam of radiation passing through a radiating layer of thickness L; provided that the temperature and properties of the medium are uniform along the path, the intensity of radiant beam at point x is given by integration of Equation 10 as

$$I_\lambda(x) = I_\lambda(0) e^{-\kappa_\lambda x} + I_{b\lambda}\left(1 - e^{-\kappa_\lambda x}\right) \tag{19}$$

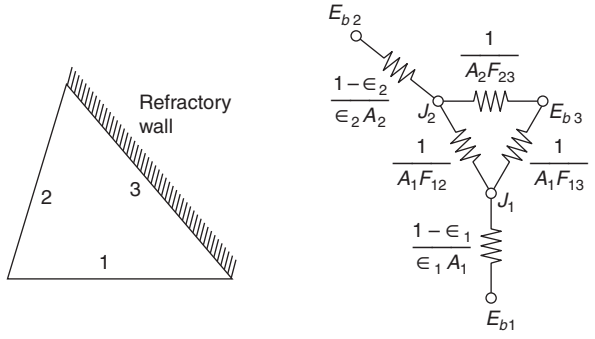

Figure 1-4.4. ***Network analogy for radiative exchange.***

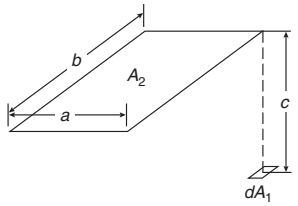
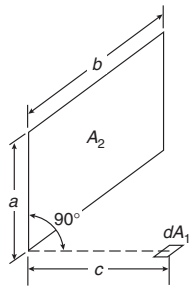
Table 1-4.1 ***Common Configuration Factors***



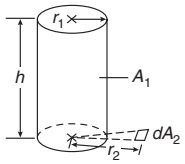
$$X = a/c \qquad Y = b/c$$

$$F_{d1-2} = \frac{1}{2\pi}\left[\frac{X}{\sqrt{1+X^2}}\tan^{-1}\left(\frac{Y}{\sqrt{1+X^2}}\right) + \frac{Y}{\sqrt{1+Y^2}}\tan^{-1}\left(\frac{X}{\sqrt{1+Y^2}}\right)\right]$$



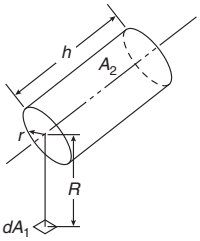
$$X = a/b \qquad Y = c/b \qquad A = 1/\sqrt{X^2+Y^2}$$

$$F_{d1-2} = \frac{1}{2\pi}\left[\tan^{-1}(1/Y) - AY\tan^{-1}A\right]$$



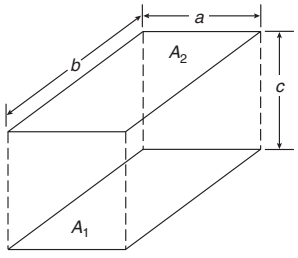
$$R = r_1/r_2 \qquad L = h/r_2 \qquad X = \sqrt{(1+L^2+R^2)^2 - 4R^2}$$

$$F_{d1-2} = \frac{1}{2\pi}\cos^{-1}R + \frac{1}{\pi}\left[\tan^{-1}\left(\frac{R}{\sqrt{1-R^2}}\right) - \frac{1+L^2-R^2}{X}\tan^{-1}\left(\frac{X\tan(0.5\cos^{-1}R)}{1+L^2+R^2-2R}\right)\right]$$



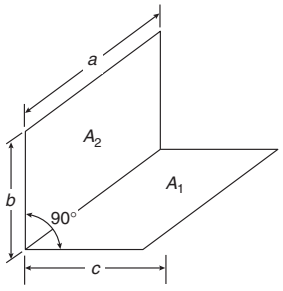
$$L = h/r \qquad H = R/r \qquad X = (1+H)^2 + L^2 \qquad Y = (1-H)^2 + L^2$$

$$F_{d1-2} = \frac{1}{\pi H}\tan^{-1}\left(\frac{L}{\sqrt{H^2-1}}\right) + \frac{L}{\pi}\left[\frac{X-2H}{H\sqrt{XY}}\tan^{-1}\sqrt{\frac{X(H-1)}{Y(H+1)}} - \frac{1}{H}\tan^{-1}\sqrt{\frac{H-1}{H+1}}\right]$$



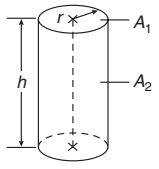
$$X = a/c \qquad Y = b/c$$

$$F_{1-2} = \frac{2}{\pi XY}\left[\ln\sqrt{\frac{(1+X^2)(1+Y^2)}{1+X^2+Y^2}} + X\sqrt{1+Y^2}\tan^{-1}\left(\frac{X}{\sqrt{1+Y^2}}\right) + Y\sqrt{1+X^2}\tan^{-1}\left(\frac{X}{\sqrt{1+X^2}}\right) - X\tan^{-1}X - Y\tan^{-1}Y\right]$$



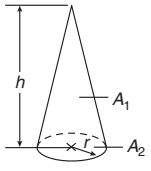
$$X = b/a \qquad Y = c/a$$

$$F_{1-2} = \frac{1}{\pi Y}\left(Y\tan^{-1}\left(\frac{1}{Y}\right) + X\tan^{-1}\left(\frac{1}{X}\right) - \sqrt{X^2+Y^2}\tan^{-1}\left(\frac{1}{\sqrt{X^2+Y^2}}\right) + \frac{1}{4}\ln\left\{\frac{(1+X^2)(1+Y^2)}{1+X^2+Y^2}\left[\frac{X^2(1+X^2+Y^2)}{(1+X^2)(X^2+Y^2)}\right]^{X^2}\left[\frac{Y^2(1+X^2+Y^2)}{(1+Y^2)(X^2+Y^2)}\right]^{Y^2}\right\}\right)$$



$$H = h2r$$

$$F_{1-2} = 2\left(\sqrt{1+H^2} - H\right)$$



$$H = h/r$$

$$F_{1-2} = 1/\sqrt{1+H^2}$$

which accounts for the loss of intensity by absorption and the gain by emission, and where κ_λ denotes the extinction coefficient. The extinction coefficient is generally the sum of two parts: the absorption coefficient and the scattering coefficient. In many engineering applications, the effects of scattering are negligible and the extinction coefficient represents only absorption. The spectral emissivity for pathlength S in a uniform gas volume can be readily expressed by considering the case of no incident radiation (or $I_\lambda(0) = 0$)

$$\varepsilon_\lambda = \frac{I_\lambda}{I_{b\lambda}} = 1 - e^{-\kappa_\lambda S} \tag{20}$$

which compares the fraction of energy emitted to the maximum (blackbody) emission at the same temperature for the pathlength S through the material.

The term $\kappa_\lambda S$ in Equation 20, called the optical pathlength or opacity, can be defined more generally for nonhomogeneous media as

$$\tau_\lambda = \int_o^S \kappa_\lambda(x)\, dx \tag{21}$$

If $\tau_\lambda \ll 1$, the medium is optically thin at wavelength λ and the properties of the participating medium can generally be expressed with the very simple approximation $\varepsilon_\lambda \approx \tau_\lambda$. The medium is considered optically thick when $\tau_\lambda \gg 1$, which implies that the mean penetration distance is much less than the characteristic length of the medium. In optically thick media, the local radiant intensity results only from local emission and the equation of transfer can be approximated by a diffusion equation.

Total emissivity: Total emissivity is an average property over all wavelengths, defined by

$$\varepsilon_t = \frac{\pi}{\sigma T^4} \int_0^\infty \varepsilon_\lambda I_{b\lambda}\, d\lambda \tag{22}$$

At moderate temperatures up to about 2000 K (which is the range of interest for fire protection engineers), the total emissivity of combustion gases consists of contributions from discrete bands, with negligible contributions from wavelengths between the bands. It is thus convenient to use

$$\varepsilon\left(T, S, P_e\right) \approx \pi \sum_i \left(\frac{I_{\lambda bi}}{\sigma T^4}\right) \varepsilon_i\left(T, X, P_e\right) \tag{23}$$

where $I_{\lambda bi}$ is the blackbody intensity evaluated at the center of the ith band, and ε_i is the total band absorption defined by

$$\varepsilon_i = \int_{(\Delta\lambda)_i} \left(1 - e^{-\kappa_\lambda S}\right) d\lambda \tag{24}$$

Recent progress on band structure and absorption has made it possible to determine total emissivity information by both theoretical and experimental means. Engineers traditionally determine the total emissivity of a homogeneous gas by graphical interpolation from charts with temperature and pressure-pathlength as parameters. The total emissivity of a mixture of gases cannot be determined simply by adding the total emissivities of the various components, because the active spectral bands for a combination of gases will often overlap. The correction for band overlapping should be calculated from spectral information for each gas, which can be estimated from the wide-band model of Edwards.[10,11]

Mean absorption coefficient: The mean absorption coefficient is often useful when radiative energy transport theory must be used to describe the local state of a gas at various locations. The mathematical complexity involved in the calculations often dictates a solution based on the gray-gas assumption, where all radiation parameters are considered to be wavelength independent. Thus, solutions are given in terms of mean (gray-gas) absorption coefficients representing average properties over the whole spectrum of wavelengths. It has been well established that the appropriate mean absorption coefficients are the Planck mean, κ_P, for optically thin mediums, and the Rosseland mean, κ_R, for optically thick mediums.[4–6,9]

The Planck mean absorption coefficient is defined as

$$\kappa_P \equiv \frac{\int_0^\infty I_{b\lambda}\kappa_\lambda\, d\lambda}{\int_0^\infty I_{b\lambda}\, d\lambda} = \frac{\pi}{\sigma T^4} \int_0^\infty I_{b\lambda}\kappa_\lambda\, d\lambda \tag{25}$$

It is important to note that this form of the absorption coefficient is a function of temperature alone and is independent of pressure. The effect of the beam source temperature (e.g., a hot or cold wall) in the gas absorptivity is approximated by a simple ratio correction[9,11]

$$\kappa_m = \kappa_P(T_s)\frac{T_s}{T_g} \tag{26}$$

where T_s is the source temperature and T_g is the gas temperature. When the Planck mean absorption coefficient is used to estimate the emissivity of a gas, the source temperature is set equal to the gas temperature.

The formulation of radiative transfer becomes relatively simple when the medium is optically thick. In this case, the radiative transfer can be regarded as a diffusion process (the Rosseland or diffusion approximation), and the governing equation is approximated by

$$q_\lambda \approx -\frac{4}{3\kappa_\lambda}\frac{\partial e_{b\lambda}}{\partial S} \tag{27}$$

Evaluation of the total heat flux in an optically thick medium is simplified by defining an average absorption coefficient which is independent of wavelength

$$\frac{1}{\kappa_R} \equiv \int_0^\infty \frac{1}{\kappa_\lambda}\frac{de_{b\lambda}}{de_b} d\lambda \tag{28}$$

The Rosseland mean absorption coefficient is not well defined for gases under ordinary conditions, because astronomically long pathlengths are required to make the windows between the bands optically thick. The Rosse-

land limit is, however, useful when dealing with gases in the presence of soot particles, which are characterized by a continuous spectrum. The source temperature effect is accounted for by using Equation 26 in the same manner as for the Planck mean absorption coefficient.

The radiating gas in many actual fire systems is neither optically thin nor optically thick, so it is necessary to use band theory to calculate a mean absorption coefficient, κ_m. However, with a reasonable estimate of the mean absorption coefficient radiative transport calculations are much more convenient.

Mean beam length for homogeneous gas bodies: The concept of mean beam length is a powerful and convenient tool to calculate the energy flux from a radiating homogeneous gas volume to its boundary surface. It may also be used to approximate radiative energy flux for a nonhomogeneous gas, especially when more elaborate calculations are not feasible. Consider the coordinate system given in Figure 1-4.1, where dA is a differential area on the boundary surface of the gas body. The radiative heat flux from the gas body to dA is

$$q = \int_0^\infty \int_\Omega \varepsilon_\lambda(X) I_{b\lambda} \cos\theta \, d\lambda \, d\Omega \tag{29}$$

where the spectral emissivity, ε_λ, is a function of pressure pathlength

$$X \equiv \int_0^S P_a x(\xi) \, d\xi$$

which in turn varies with solid angle Ω according to the gas body geometry.

In practical situations, the calculation of q is more convenient in terms of total emissivity, which is often available in chart form. From the definition of total emissivity, Equation 29 can be expressed as

$$q = \frac{\sigma T^4}{\pi} \int_\Omega \varepsilon_t(X) \cos\theta \, d\Omega \equiv \sigma T^4 \varepsilon_t(L) \tag{30}$$

which gives the definition of mean beam length, L, for a gas body, where $\varepsilon_t(L)$ has the same functional form as $\varepsilon_t(X)$. Physically, the mean beam length represents the equivalent radius of a hemispherical gas body such that it radiates a flux to the center of its base equal to the average flux radiated to the boundary surface by the actual volume of gas. The determination of the mean beam length is considerably simplified when the gas is optically thin and only the geometry of the gas body enters the calculation. In the optically thin limit, it is convenient to define

$$L = L_0 \equiv \frac{1}{\pi} \int_\Omega X \cos\theta \, d\Omega \tag{31}$$

where L_0 is called the geometric mean beam length. In the optically thick limit, it has been found that the use of a simple correction factor provides reasonable radiative fluxes

$$L \approx C L_0 \tag{32}$$

In Table 1-4.2, L_0 and C have been provided for a variety of gas body shapes. For an arbitrarily shaped gas volume, the geometric beam length from the gas volume to the entire boundary surface can be estimated by

$$L_0 = \frac{4V}{A} \tag{33}$$

where V and A are the volume and the area of the boundary surface of the gas body, respectively. The correction factor C should be estimated as 0.9, which is close to the known values for a wide range of geometries.

Thermal Radiation Properties of Combustion Products

Radiation Properties of Gases

The emissivity of any gas is a strong function of wavelength, varying by as much as several orders of magnitude over minute changes in wave number. However, the level of accuracy required in engineering calculations, where many of the parameters are difficult to measure or estimate, seldom requires high resolution spectra of emissivity. Where wavelength dependence of the radiative heat flux is a concern, the properties of the gas may be calculated by means of the exponential wide-band model.[10] The uncertainties involved in estimating parameters to calculate radiative heat flux make average properties such as total emissivity a useful tool. The first comprehensive total emissivity charts were formulated by H. C. Hottel and coworkers to summarize work performed up to about 1945. Modern formulations for the emissivity of gases have been summarized by Edwards.[11]

New total emissivity charts for water vapor and carbon dioxide[11] have been provided in Figures 1-4.5 and 1-4.6, respectively. The gas emittance can be found from the charts by knowing the partial pressure and temperature of each gas and the mean beam length for the gas volume geometry. Correction factors for the chart emissivities are available in the literature for the pressure effect on water vapor emissivity,[12] the pressure effect on carbon dioxide emissivity,[4,6] and the band overlap for mixtures of the two gases.[13] For most fire protection engineering applications, the pressure correction factors are 1.0 and the band overlap correction is approximately $\Delta\varepsilon \approx 1/2\varepsilon_{CO_2}$ for medium to large fires. Assuming the carrier gas is transparent (e.g., air), the emittance is given by

$$\varepsilon_g = C_{H_2O}\varepsilon_{H_2O} + C_{CO_2}\varepsilon_{CO_2} - \Delta\varepsilon \approx \varepsilon_{H_2O} + \frac{1}{2}\varepsilon_{CO_2} \tag{34}$$

At temperatures below 400 K, the older charts by Hottel[4,6] may be more reliable than the new charts used in Figure 1-4.5 and Figure 1-4.6, and the use of wide-band models is advised to estimate the band overlap correction instead of using the correction charts at these lower temperatures.[14] For crucial engineering decisions, wide-band model block calculations as detailed by Edwards[11] are recommended over the graphical chart method to determine total emissivity.

Table 1-4.2 ***Mean Beam Lengths for Various Gas Body Shapes***

Geometry of Gas Body		Radiating to	Geometric Mean Beam Length L_0	Correction Factor C
Sphere		Entire surface	0.66 D	0.97
Cylinder $H = 0.5D$		Plane and surface Concave surface Entire surface	0.48 D 0.52 D 0.50 D	0.90 0.88 0.90
Cylinder $H = D$		Center of base Entire surface	0.77 D 0.66 D	0.92 0.90
Cylinder $H = 2D$		Plane end surface Concave surface Entire surface	0.73 D 0.82 D 0.80 D	0.82 0.93 0.91
Semi-infinite cylinder $H \rightarrow \infty$		Center of base Entire base	1.00 D 0.81 D	0.90 0.80
Infinite slab		Surface element Both bounding planes	2.00 D 2.00 D	0.90 0.90
Cube $D \times D \times D$		Single face	0.66 D	0.90
Block $D \times D \times 4D$		1 × 4 face 1 × 1 face Entire surface	0.90 D 0.86 D 0.89 D	0.91 0.83 0.91

Other gases such as sulphur dioxide, ammonia, hydrogen chloride, nitric oxide, and methane have been summarized in chart form.[4] The carbon monoxide chart by Hottel is not recommended for use according to recent measurements[15] and other theoretical investigations, probably due to traces of carbon dioxide in the original experiments. Recent results, including both spectral and total properties, have recently been published for some of the important hydrocarbon gases, for example, methane, acetylene, and propylene.[16–18] Mixtures of several hydrocarbon gases are subject to band overlapping, and appropriate corrections must be made to avoid overestimating total emissivity of a mixture of fuels.

The total emissivity for a gas in the optically thin limit can be calculated from the Planck mean absorption coefficient. Graphs of the Planck mean absorption coefficient for various gases that are important in fires are shown in Figure 1-4.7, which can be used with Equation 20 to estimate the total emissivity (by assuming that total properties represent a spectral average value).

Radiation Properties of Soot

In a nonhomogeneous (e.g., with soot) medium, scattering becomes an important radiative mechanism in addition to absorption and emission. The absorption and scattering behavior of a single particle can be described by solving the electromagnetic field equations; however, many physical idealizations and mathematical approximations are necessary. The most common assumptions include perfectly spherical particles, uniformly or randomly

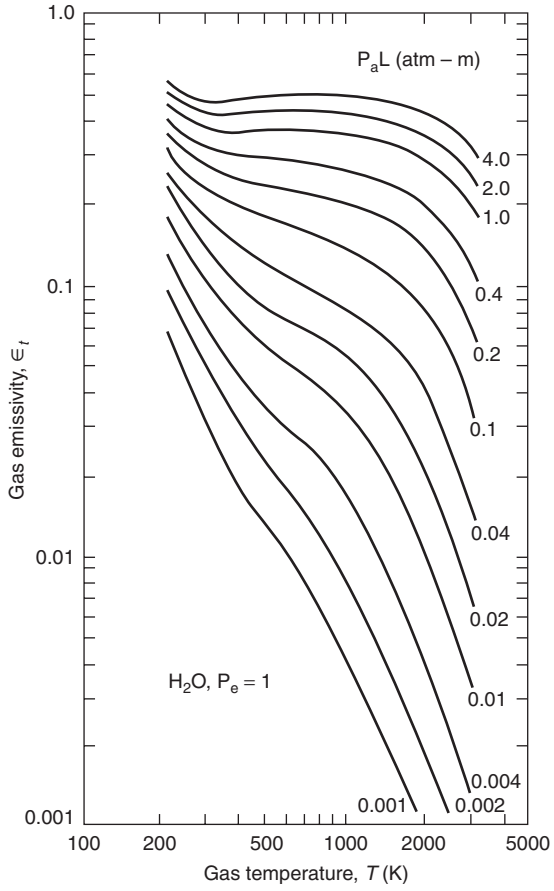


Figure 1-4.5. ***Total emittance of water vapor.***

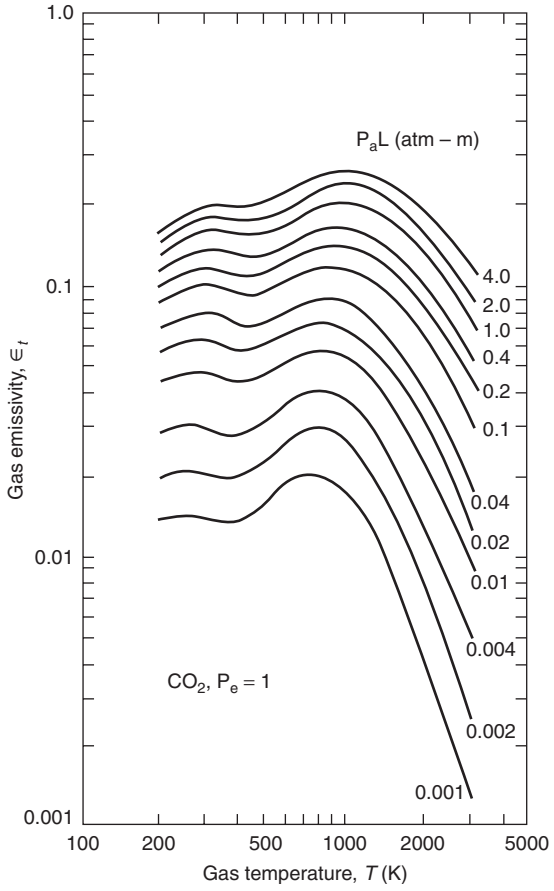

Figure 1-4.6. ***Total emittance of carbon dioxide.***

distributed particles, and interparticle spacing so large that the radiation for each particle can be treated independently.

Soot particles are produced as a result of incomplete soot combustion and are usually observed to be in the form of spheres, agglomerated chunks, and long chains. They are generally very small (50–1000 Å where 1 Å = 10^{-10} m = 10^{-4} μm) compared to infrared wavelengths, so that the Rayleigh limit is applicable to the calculation of radiation properties.[19,20] Soot particles are normally characterized by their optical properties, size, shape, and chemical composition (hydrogen-carbon ratio). From a heat transfer viewpoint, radiation from a soot cloud is predominantly affected by the particle size distribution and can be considered independent of the chemical composition.[19] Soot optical properties are relatively insensitive to temperature changes at elevated temperatures, but as shown in Figure 1-4.8, room temperature values representative of soot in smoke do show appreciable deviations. By choosing appropriate values of optical constants for soot, the solution for the electromagnetic field equations gives[21]

$$k_\lambda = \frac{C_0}{\lambda} f_v \tag{35}$$

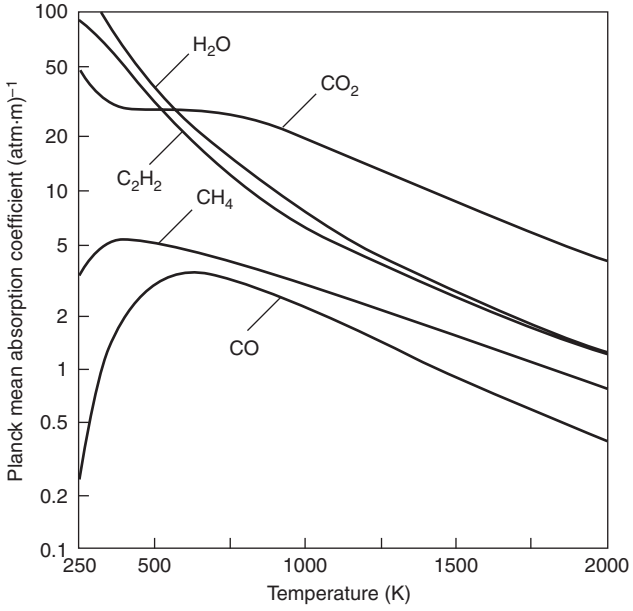

Figure 1-4.7. ***Planck mean absorption coefficient for various gases.***

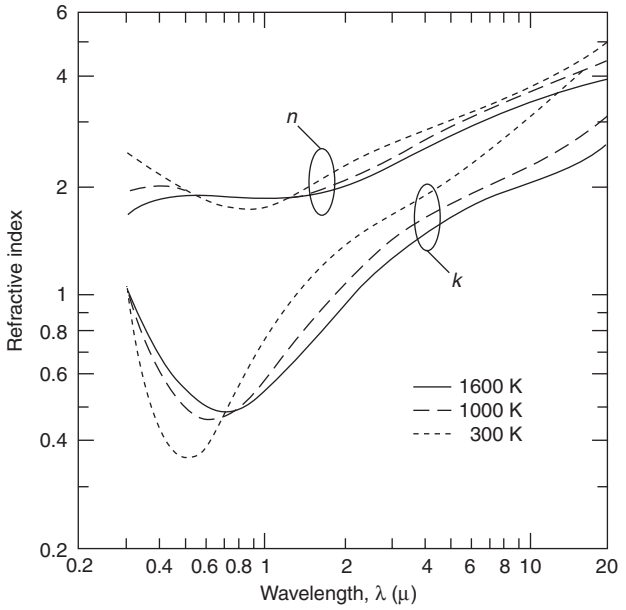

Figure 1-4.8. ***Optical constants for soot.***

where f_v is the soot volume fraction (generally about 10^{-6}), and C_0, a constant between 2 and 6 dependent on the complex index of refraction $m = n - ik$, is given by

$$C_0 = \frac{36\pi nk}{(n^2 - k^2 + 2)^2 + 4n^2k^2} \tag{36}$$

Equations 35 and 36 can be used to evaluate the Planck mean absorption coefficient in the optically thin limit,[22] giving

$$\kappa_P = 3.83 \frac{C_0}{C_2} f_v T \tag{37}$$

where C_2 is Planck's second constant (1.4388×10^{-2} m·K). The Rosseland mean absorption coefficient in the optically thick limit is

$$\kappa_R = 3.6 \frac{C_0}{C_2} f_v T \tag{38}$$

A mean coefficient that may be used for the entire range of optical thickness is suggested as

$$\kappa_m = 3.72 \frac{C_0}{C_2} f_v T \tag{39}$$

to be used in Equation 40 for the soot radiation calculations. Typical temperatures, volume fractions, and mean absorption coefficients for soot particles in the luminous flames of various fuels are tabulated in Table 1-4.3.[21,23]

Radiation Properties of Gas-Soot Mixtures

The calculation of the total emissivity of a gas-soot mixture requires information on basic flame parameters such as soot volume fraction, the absorption coefficient of the soot, the temperature and geometric length of the flame, and the partial pressure of the participating gas components.[24] These parameters can be estimated for various types of fuel when actual measurements are unavailable for a particular situation. Recent research to develop simple accurate formulas to predict total emissivities for homogeneous gas-soot mixtures has found the following equation to be an excellent approximation[23]

$$\varepsilon_t = (1 - e^{-\kappa S}) + \varepsilon_g e^{-\kappa_s S} \tag{40}$$

where

S = physical pathlength
ε_g = total emissivity of the gas alone
κ_s = effective absorption coefficient of the soot

The Planck mean absorption coefficients for gas-soot mixtures in luminous flames and smoke are shown in Figure 1-4.9. In situ measurements are currently the only way other than estimation to obtain the soot volume fraction in smoke, since the soot particle concentration can be either diluted or concentrated by the gas movements within the smoke region.

Table 1-4.3 ***Radiative Properties for Soot Particles***

Application to Flame and Fire

Heat Flux Calculation from a Flame

Prediction of the radiative heat flux from a flame is important in determining ignition and fire spread hazard, and in the development of fire detection devices. The shape of flames under actual conditions is arbitrary and time dependent, which makes detailed radiation analysis very cumbersome and uneconomical. In most calculations, flames are idealized as simple geometric shapes such as plane layers or axisymmetric cylinders and cones. A cylindrical geometry will be analyzed here and used in a sample calculation.

Assuming κ_λ is independent of pathlength, integration of the radiative transport of Equation 10 yields[25]

$$I_\lambda = I_{b\lambda}\left[1 - \exp\left(\frac{-2\kappa_\lambda}{\sin\theta}\sqrt{r^2 - L^2\cos^2\phi}\right)\right] \tag{41}$$

where θ, ϕ, r and L are geometric variables defined in Figure 1-4.10. The monochromatic radiative heat flux on the target element is given by

$$\frac{dq}{d\lambda} = \int_\Omega \frac{I_\lambda}{|\vec{R}|}(\vec{n}\cdot\vec{R})\,d\Omega \tag{42}$$

where $\vec{n}$ is a unit vector normal to the target element dA and $\vec{R}$ is the line-of-sight vector extending between dA and the far side of the flame cylinder. The evaluation of Equation 42 is quite lengthy, but under the condition of $L/r \gtrsim 3$, it can be simplified to[25]

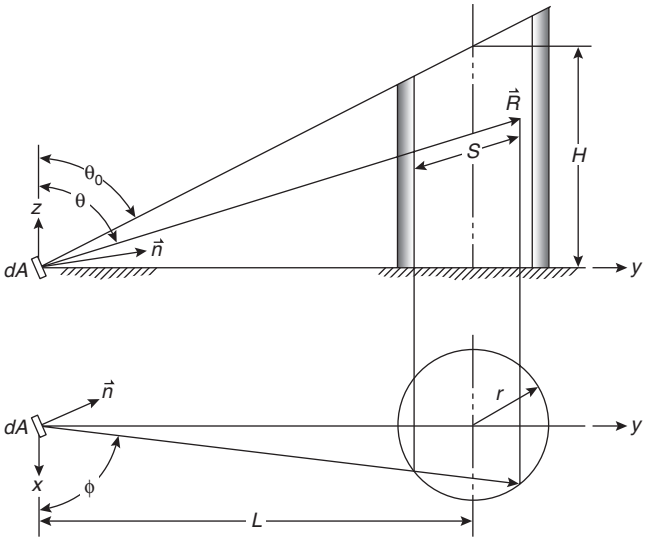

Figure 1-4.10. ***Schematic of a cylindrical flame.***

$$\frac{dq}{d\lambda} = \pi I_{b\lambda}\varepsilon_\lambda(F_1 + F_2 + F_3) \tag{43}$$

where the shape factor constants and emittance are defined as

$$F_1 = \frac{u}{4\pi}\left(\frac{r}{L}\right)^2[\pi - 2\theta_0 + \sin(2\theta_0)] \tag{44a}$$

$$F_2 = \frac{v}{2\pi}\left(\frac{r}{L}\right)[\pi - 2\theta_0 + \sin(2\theta_0)] \tag{44b}$$

$$F_3 = \frac{w}{\pi}\left(\frac{r}{L}\right)\cos^2\theta_0 \tag{44c}$$

$$\varepsilon_\lambda = 1 - \exp\left(-0.7\,\mu_\lambda\right) \tag{45}$$

The parameters in the definitions are given by

$$\theta_0 = \tan^{-1}\left(\frac{L}{H}\right) \tag{46a}$$

$$\mu_\lambda = 2r\,\frac{\kappa_\lambda}{\sin(1/2\theta_0 + 1/4\pi)} \tag{46b}$$

$$\vec{n} = u\vec{i} + v\vec{j} + w\vec{k} \tag{46c}$$

If the flame is considered to be homogeneous and Equation 43 is integrated over all wavelengths, the total heat flux is simply

$$q = \varepsilon_m E_b \sum_{j=1}^{3} F_j \tag{47}$$

EXAMPLE 1:

A fire detector is located at the center of the ceiling in a room (2.4 × 3.6 × 2.4 m) constructed of wood. (See

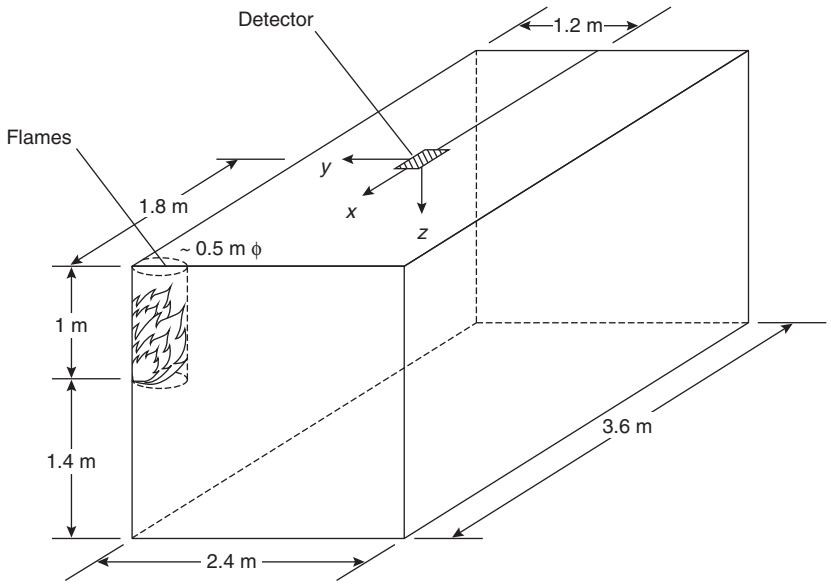

Figure 1-4.11. ***Example calculation for flux to target element from flame.***

Figure 1-4.11.) The sprinkler system is capable of extinguishing fires smaller than 0.5 m in diameter × 1.0 m high. For this example, determine the appropriate heat flux setting for the detector, using a worst case scenario of ignition in one of the upper ceiling corners.

SOLUTION:

First, the condition of $L/r \gtrsim 3$ should be checked to verify that the previous analysis is applicable.

$$\frac{L}{r} = \frac{\sqrt{(1.2^2) + (1.8^2)}}{0.25} = 8.65 > 3$$

The unit normal vector to the detector is given by $\vec{n} = \vec{k}$, the polar angle $\theta_0 = \tan^{-1}(1.818) = 1.068$ is determined from Equation 46a, and the shape factors are evaluated from Equations 44a, b, and c

$$F_1 = F_2 = 0.0$$
$$F_3 = \frac{1}{\pi}\left(\frac{0.25}{1.818}\right)\cos^2(1.068) = 0.0102$$

From Equation 47, the required heat flux can be obtained as

$$\begin{aligned} q &= \left(1 - e^{-\kappa_m S}\right)(\sigma T_f^4)F_3 \\ &= \left(1 - e^{0.8\times 0.5}\right)\left[5.67 \times 10^{-11} \times (1730)^4\right](0.0102) \\ &= 1.7 \text{ kW/m}^2 \end{aligned}$$

If the geometry of the example had been $L/r < 3$, it would have been necessary to interpolate between the $L/r = 3$ case and the $L/r = 0$ case, which has been obtained accurately.[6,25] If the detector is pointed directly at the burning corner in this example (i.e., $\vec{n} = 0.55\vec{i} + 0.83\vec{j}$), the calculated heat flux jumps to 9.0 kW/m², showing the strong influence of direction in calculations of radiation heat transfer.

Heat Flux Calculation from a Smoke Layer

Consider radiative heat transfer in a room fire situation where a smoke layer is built up below the ceiling. Typical smoke layers are generally at temperatures ranging up to 1100–1500 K, and are composed of strongly participating media such as carbon dioxide, water vapor, and soot particles. Heat flux from the smoke layer has been directly related to ignition of remote surface locations such as furniture or floor carpets. The schematic in Figure 1-4.12 will be considered in a radiative transport analysis and example calculation. The calculation is based on a considerably simplified formulation which provides reasonable results with only a small penalty in accuracy.

Integration of Equation 10 over the pathlength S through the smoke layer yields

$$I(S) = \frac{\sigma T^4}{\pi}\left\{1 - \left(\frac{T_w}{T}\right)^4\right\} e^{-\kappa S} \tag{48}$$

The monochromatic radiative heat flux on a differential target element is again given by Equation 42. However, for the present geometry of the ceiling layer and enclosure surface, integration of Equation 42 is quite time-consuming since the upper and lower bounds of the integral vary with the angle of the pathlength. The calculation can be simplified by assuming as a first order approximation that the lower face of the smoke layer is an isothermal surface. Using this assumption, the problem can be handled using the simple relations of radiative exchange in a nonparticipating medium between gray surfaces (the absorption of the clear air below the smoke layer is negligible). From basic

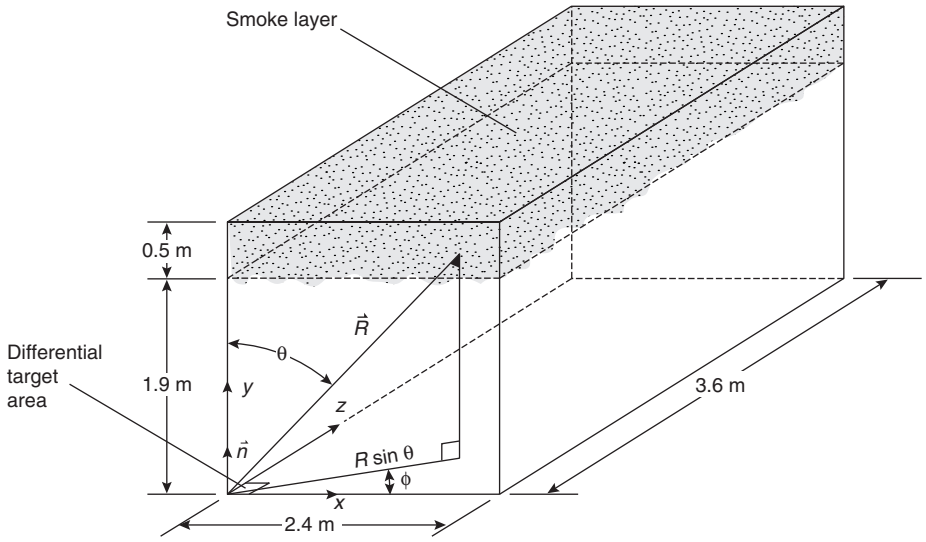

Figure 1-4.12. ***Example calculation for flux to target element from smoke layer.***

calculation methods we have the radiosity and the irradiation of each surface in the enclosure:

$$J_i = \varepsilon_i \sigma T_i^4 + (1 - \varepsilon_i) G_i \tag{49a}$$

$$G_i = \sum_j F_{i-j} J_j \tag{49b}$$

After solving the simultaneous equations for all J_i and G_i, the net heat flux on any of the surfaces can be calculated from

$$q_i = J_i - G_i \tag{50}$$

EXAMPLE 2:

A smoke layer 0.5 m thick is floating near the ceiling of a room with dimensions of 3.6 × 2.4 × 2.4 m. (See Figure 1-4.12.) The floor is made from wood, and the four side walls are concrete covered with zinc white oil paint. The calculation will determine the heat flux in a bottom corner of the room, assuming that each surface in the enclosure is kept at constant temperature: the smoke layer at 1400 K, the side walls at 800 K, and the floor at 300 K. Assume there is a differential target area 0.01 m² in one of the corners of the floor, and also at the floor temperature of 300 K.

SOLUTION:

The bottom of the smoke layer will be designated surface 1, the floor will be surface 2, and the differential target area in the bottom corner will be surface 3. Only four surfaces are required since the four side walls can be treated as a single surface 4. Shape factors F_{12} and F_{31} can be found in Table 1-4.1, and from these two factors, the remaining shape factors are determined by shape factor algebra:

$$F_{12} = 0.3242,$$
$$F_{31} = 0.1831,$$
$$F_{13} = \frac{A_3}{A_1} F_{31} = 0.0002,$$
$$F_{14} = 1 - F_{12} - F_{13} = 0.6756$$

Continuing in a similar fashion, the other shape factors are obtained as

$F_{21} = 0.3242$	$F_{31} = 0.1831$	$F_{41} = 0.2560$
$F_{22} = 0$	$F_{32} = 0$	$F_{42} = 0.2561$
$F_{23} = 0$	$F_{33} = 0$	$F_{43} = 0.0003$
$F_{24} = 0.6758$	$F_{34} = 0.8169$	$F_{44} = 0.4876$

The emissivity for wood and white zinc paint are 0.9 and 0.94, respectively,[6] and the emissivity for the smoke layer can be estimated from the mean absorption coefficient for a wood flame (Table 1-4.3) as

$$\varepsilon_1 = 1 - e^{-\kappa_m S} = 1 - e^{-0.8 \times 0.5} = 0.33$$

The blackbody emission flux from each surface is calculated by the simple relation of Equation 6, for example,

$$(\sigma T^4)_1 = 5.6696 \times 10^{-8} (1400)^4 = 217.8 \text{ kW/m}^2$$

From Equations 49a and 49b, the radiative fluxes to and from each surface are determined by solving the eight simultaneous equations

$J_1 = 88.7$ kW/m²	$G_1 = 17.7$ kW/m²
$J_2 = 4.7$ kW/m²	$G_2 = 43.3$ kW/m²
$J_3 = 3.9$ kW/m²	$G_3 = 34.8$ kW/m²
$J_4 = 23.9$ kW/m²	$G_4 = 34.3$ kW/m²

The net radiative heat flux on the target element from Equation 50 is

$$q_3 = J_3 - G_3 = -30.9 \text{ kW/m}^2$$

where the negative sign indicates that heat must be removed from the target element so it remains in equilibrium. This example also could have been solved by the resistance network method. (See Figure 1-4.13.)

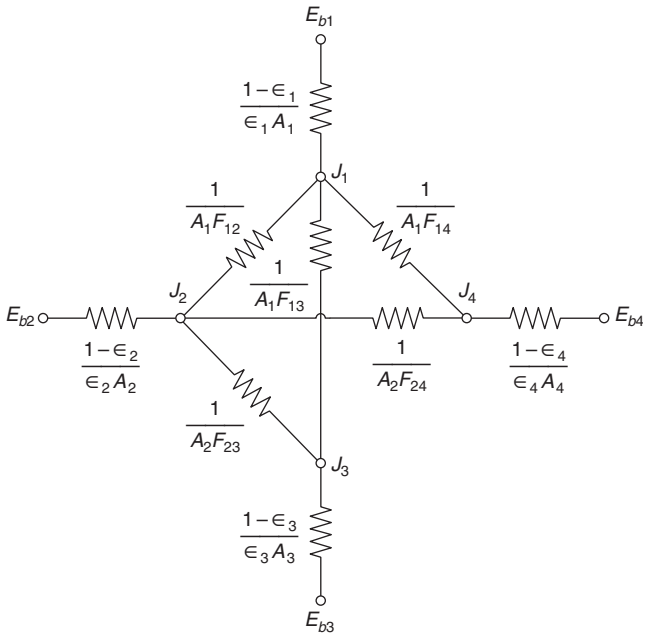

Figure 1-4.13. ***Equivalent resistance network for an enclosure problem.***

Fuel Pyrolysis Rate

Fuel pyrolysis is an important concern in the combustion of condensed fuels, which upon heating undergo gasification (sometimes preceded by liquefication for solid fuels) before combustion in the gaseous phase.[26] This process is often strongly influenced by radiative heat flux. Unlike an internal combustion engine or burner where the fuel is supplied externally, the fuel must be supplied by gasification of the material itself. The rate of gasification is sometimes called the pyrolysis rate or burning rate, and can serve as a measure of fire hazard since it is directly proportional to the growth rate of the fire. Because determination of the pyrolysis rate is based on conservation of energy and mass at the surface of the material, it is essential to know the total heat flux reaching the fuel surface. Assuming steady-state conditions, the energy balance can be expressed as

$$q_e + q_c + q_r + q_{rr} = \dot{m}''\Delta H \tag{51}$$

where

q = heat flux (the subscripts are external, convective, radiative, and reradiative, respectively)

$\dot{m}''$ = pyrolysis rate

ΔH = latent heat of gasification

The configuration of the fire and the thermophysical properties of the fuel are required to calculate the terms in the energy balance, with the exception of the external flux term, which represents heat exchanged with the environment away from the fire.

Analysis of turbulent combustion with radiation in three-dimensional systems has been an ultimate research goal in the field of combustion for many years. Despite recent progress, the current state of the art is capable of handling only very limited problems in laminar combustion and turbulent combustion in simple geometries. Thermal radiation has been included in only a few special cases such as analysis of stagnation point combustion in boundary layer type flows,[27,28] and empirical studies of pool fire configurations.[29] In this section two cases will outline incorporating radiation into modeling the fuel pyrolysis rate, which can be applied to fire growth rate estimates.

Some basic concepts of the combustion phenomenon should be reviewed. Flames are often categorized as either diffusion or premixed, depending on the dominant physical processes controlling the burning. In a diffusion flame, the characteristic time for transport of the species is much longer than that required for the chemical reaction. Flames in which the oxygen initially separated from the fuel are generally considered to be diffusion flames. In a premixed flame, the fuel and oxygen are mixed together before reaching the combustion zone, so the characteristic times for transport and reaction are comparable in magnitude. The details of the chemical reaction, which even for simple reactions often involve many intermediate reactions and species conservation of intermediate products, are usually simplified in radiation analysis to a one-step irreversible global relationship such as

$$\text{fuel} + \text{oxygen} \rightarrow \text{products} + \text{heat} \tag{52}$$

Another major simplification that is frequently used is the flame sheet approximation, where it is assumed that the fuel and oxygen react nearly instantaneously upon contact, thus forming an infinitely thin reaction zone. This approximation is quite useful in the study of flames where the chemical reaction kinetics are dominated by the physical process of diffusion, such as a typical room fire. The counterpart to the flame sheet approximation is the flame layer approximation, where the chemical reaction is assumed to take place at a finite rate and creates a reaction zone of finite thickness. The flame layer approximation is applicable to the study of ignition, extinction, flame stability, and other transient flame phenomena.

Pyrolysis rate in boundary layer combustion: Due to the complicated nature of radiative calculations, only one-dimensional radiation in the limit of an optically thin medium has been attempted in boundary layer analysis. Kinoshita and Pagni[27] analyzed stagnation point flow under the approximations of the flame sheet model, unity Lewis number, and film optical depth of less than 0.1. The net effect of radiation heat transfer on the pyrolysis process was small, which is to be expected in an optically thin convective environment; however, the relative importance of the dimensionless parameters governing pyrolysis was dramatically altered by the inclusion of radiation in the analysis. The pyrolysis rate and excess (unburned) pyrolyzed gases were strongly dependent on both the wall temperature and the heat of combustion, which had been of secondary importance in the nonradiative analysis. In general, the effect of radiation is to reduce the pyrolysis rate by compensatory surface emission and by radiative loss from the flame to the cold environment, which lowers the flame temperature and decreases the conduction heat flux.

Pyrolysis rate in a pool fire: Applying energy conservation to find the fuel pyrolysis rate in a pool fire has been difficult due to a lack of appropriate information on both convective heat transfer and radiative feedback. Prediction of the pyrolysis rate is still largely dependent on correlations of limited experimental data, but effort has been made to theoretically formulate the convective and radiative contributions.[29] The pyrolysis rate can be calculated from Equation 51, assuming that the external heat supply can be neglected and the radiation terms are given by

$$q_{rr} = \varepsilon_s \sigma (T_s^4 - T_\infty^4) \tag{53}$$

$$q_r = \sigma T_f^4 [1 - e^{\kappa_f L_m}] \tag{54}$$

where ε_s is the fuel surface emissivity (typically 1.0 for liquids and char) and T_f is the flame temperature as represented by a homogeneous isothermal gas volume. The accuracy of Equation 54 is dependent on the values chosen for the flame absorption coefficient, κ_f, and the mean beam length, L. Orloff and deRis[29] have proposed the use of

$$\kappa_f = \frac{-1}{L_m} \ln \left(1 - \frac{\chi r \dot{q}_a''' L_m}{36 \chi_a \sigma T_f^4} \right) \tag{55}$$

$$L_m = 3.6 \frac{V_f}{A_b} \tag{56}$$

where

χ_α = fractional measure of the completeness of combustion lying in the range 0.6 to 0.95 depending on the type of fuel[30]

χ_r = fraction of heat lost by radiation in the flame[1,29,30]

$\dot{q}_a'''$ = volumetric heat output of the flame (typically on the order of 1200 kW/m^3 in many flames)

V_f = flame volume

T_f = flame temperature

A_b = area of the pool of fuel

Orloff and deRis also proposed an expression for the convective heat flux

$$q_c = \frac{h_c}{C_p} \left[\frac{\Delta H (\chi_a - \chi_r) r}{x_a} - C_p (T_s - T_\infty) \right] \left(\frac{y}{e^y - 1} \right) \tag{57}$$

where y is defined to be

$$\left(\frac{m'' C_p}{h_c} \right)$$

and r is the stoichiometric mass ratio of fuel to air.

Large-scale fires are distinctly nonhomogeneous in both temperature and gas species concentrations, which makes single-zone flame models difficult to correlate to the available experimental data. A two-zone model has recently been proposed;[31] it successfully predicts the pyrolysis rate of large PMMA (Plexiglas) fires. The flame is modeled as two conical homogeneous layers: a lower cool layer of pyrolyzed fuel gases, and an upper hot layer of product gases and soot. More experimental data on large-scale pool fires is required to verify the model for fuels other than PMMA.

Ignition Applications

Ignition is a branch of flammability-limiting behavior concerned with the initiation of burning. Ignition is a rate-controlled mechanism in which chemical reaction kinetics play an important role. Prediction of ignition phenomena is largely dependent on the ignition criteria chosen in the analysis.[26] These criteria are currently the center of a vigorous controversy and far from being uniquely defined. Many practical applications of ignition theory are based on knowledge of the ignition temperature, which in turn makes the heat flux directed at the fuel surface the most important physical quantity. Fire prediction often requires the determination of the ignition delay time after the fuel surface is exposed to a given heat flux. The transient nature of ignition makes it necessary to consider full transient energy equations unless the quasi-steady assumption can be invoked, which makes radiation analysis extremely difficult for many ignition applications.

Pilot ignition and spontaneous ignition are two of the main classes in the broad category of ignition. Pilot ignition is generally achieved through localized heating such as a spark or pilot flame, and the flame then propagates into the rest of the fuel material. In contrast, spontaneous or self-ignition occurs as a result of raising the bulk temperature of a combustible gas mixture, and does not require any further external heat supply once combustion has started. Spontaneous ignition requires a higher temperature for the same material than pilot ignition. Radiation heat transfer has generally been neglected in analyses of these mechanisms due to a lack of physical understanding and practical calculation methods,[32] and more work is required in this area to make the radiation calculations worthwhile.

A somewhat different phenomenon occurs in enclosure fires, where excessive radiant heat supply from the fire ignites material away from the flames. This is called secondary or remote ignition and is of special interest to fire protection engineers as a significant source of flame propagation. Quasi-steady analysis, where the gas is treated with a steady analysis and the solid fuel is handled with a transient analysis, has been shown to yield reasonably accurate results.[33] The chemical reaction terms can be neglected for a first order analysis, although they often play an important role in higher order models.

The relatively simple geometry of a semi-infinite solid bounded by a gas can illustrate a one-dimensional radiative analysis.[34] Attention will be focused on the solid region near the interface, so that the transient energy conservation equation is expressed as

$$\frac{\partial T}{\partial t} = \alpha \frac{\partial^2 T}{\partial x^2} \tag{58}$$

where α is the thermal diffusivity of the solid. The boundary conditions for Equation 58 are given by

$$T = T_i \qquad \text{at } t = 0, \quad x \to \infty \tag{59a}$$

$$k \frac{\partial T}{\partial x} + \varepsilon_s q_r = h_c (T - T_i) \quad \text{at } x = 0 \tag{59b}$$

Equation 59b states that conduction, convection, and radiation will be balanced at the fuel surface, and Equation 59a dictates the temperature level. Solution of Equation 58

is straightforward with the Laplace transform technique, giving the result[35]

$$T(x,t) = \left(T_i + \frac{\varepsilon_s q_r}{h_c}\right)\left[\operatorname{erfc}\left(\frac{x}{2\sqrt{\alpha t}}\right) - \exp\left(h_c x + \alpha h_c^2 t\right)\operatorname{erfc}\left(\frac{x}{2\sqrt{\alpha t}} + \frac{h_c}{k}\sqrt{\alpha t}\right)\right] \quad (60)$$

The ignition delay time (from initial application of the heat flux) can be accurately calculated from Equation 60 if the radiant heat flux, q_r, is known. The ignition delay time calculation is significantly affected by changes in q_r, which is dependent on the radiation properties of the smoke layer beneath the ceiling flames and the relatively cool pyrolyzed gases near the fuel surface. This effect is called radiation blockage or radiation blanketing, and is a current area of attention in the field of flame radiation research.[36] The blockage effect can be accurately calculated if the composition and properties of the smoke layer are known.[34] Another form of thermal energy blockage to the fuel surface is the surface emissivity, ε_s, which can have strong wavelength dependence. For example, a fuel such as PMMA is a poor absorber of radiation in wavelengths below 2.5 μm, where the radiant intensity is strongest from typical flame and smoke temperatures, and is an excellent absorber at wavelengths above 2.5 μm. In addition, the total emissivity of a surface can change as the fuel surface liquefies or begins to char due to pyrolysis. Care should be taken when considering the radiative properties of the fuel surface, which can be strongly dependent on the surface conditions.

Nomenclature

A	area (m^2)
C	correction factor for mean beam length
C_0	soot concentration parameter
C_p	specific heat (J/kg·K)
C_2	Planck's second constant (1.4388×10^{-2} m·K)
c	speed of light in the medium (m/s)
c_0	speed of light in a vacuum (2.998×10^8 m/s)
E	radiative emmisive power (W/m^2)
F_{i-j}	configuration factor from surface i to surface j
f_v	soot volume fraction
G	irradiation or radiative heat flux received by surface (W/m^2)
H	height (m)
h	Planck's constant (6.6256×10^{-34} J·s)
h_c	convective heat transfer coefficient ($W/m^2 \cdot K$)
I	radiation intensity (W/m^2)
$\vec{i}, \vec{j}, \vec{k}$	Cartesian coordinate direction vectors
J	radiosity or radiative heat flux leaving surface (W/m^2)
k	Boltzmann constant (1.3806×10^{-23} J/K), or infrared optical constant of soot (imaginary component), or thermal conductivity (W/m·K)
L	mean beam length or distance (m)
L_0	geometrical mean beam length (m)
M_i	molecular weight of species i
m''	mass loss rate or pyrolysis rate ($kg/m^2 \cdot s$)
n	index of refraction (c_0/c) or infrared optical constant of soot (real component)
$\vec{n}$	unit normal vector
P_a	partial pressure of absorbing gas (Pa)
P_e	effective pressure (Pa)
Q	energy rate (W)
q	heat flux (W/m^2)
q_a'''	volumetric heat output (W/m^3)
$\vec{R}$	line of sight vector
r	radius of cylinder (m) or fuel/air stoichiometric mass ratio
S	pathlength (m)
T	temperature (K)
t	time (s)
u, v, w	Cartesian components of unit vector $\vec{n}$ volume (m^3)
X	Pressure pathlength, $\int_0^s P_a x(\xi)\, d\xi$ (atm·m)
x	spatial coordinate (m)
y	defined parameter, Equation 57

Greek Symbols

α	absorptivity or thermal diffusivity $k/\rho C_p$ (m^2/s)
β	angle from normal (radians)
ΔH	latent heat of gasification (J/kg)
ε	emissivity
θ	polar angle (radians)
κ	extinction coefficient or absorption coefficient (m^{-1})
λ	wavelength (m)
μ	micron (10^{-6} m)
μ_λ	defined parameter, Equation 46b
ν	frequency (s^{-1})
ξ	integration dummy variable
ρ	reflectivity or density (kg/m^3)
Ω	solid angle (steradians)
σ	Stefan-Boltzmann constant (5.6696×10^{-8} $W/m^2 \cdot K^4$)
τ	transmissivity or optical pathlength
ϕ	azimuthal angle (radians)
χ	fractional measure

Subscripts

a	actual
b	blackbody or base
c	convective
e	external
f	flame or fuel
g	gas
i	initial or ith surface

j	summation variable or jth surface
m	mean value
0	original
P	Planck mean
R	Rosseland mean
r	radiative
rr	reradiative
s	surface or soot
t	total
w	wall
λ	spectral wavelength
ν	spectral frequency
∞	ambient

Thermochemistry

D. D. Drysdale

The Relevance of Thermochemistry in Fire Protection Engineering

Thermochemistry is the branch of physical chemistry that is concerned with the amounts of energy released or absorbed when a chemical change (reaction) takes place.[1,2] Inasmuch as fire is fundamentally a manifestation of a particular type of chemical reaction, viz., combustion, thermochemistry provides methods by which the energy released during fire processes can be calculated from data available in the scientific and technical literature.

To place it in context, thermochemistry is a major derivative of the first law of thermodynamics, which is a statement of the principle of conservation of energy. However, while concerned with chemical change, thermodynamics does not indicate anything about the rate at which such a change takes place or about the mechanism of conversion. Consequently, the information it provides is normally used in association with other data, for example, to enable the rate of heat release to be calculated from the rate of burning.

The First Law of Thermodynamics

It is convenient to limit the present discussion to chemical and physical changes involving gases; this is not unreasonable, as flaming combustion takes place in the gas phase. It may also be assumed that the ideal gas law applies, that is,

$$PV = n \cdot \mathrm{R}T \tag{1}$$

where P and V are the pressure and volume of n moles of gas at a temperature, T (in degrees Kelvin); values of the universal gas constant (R) in various sets of units are summarized in Table 1-5.1. At ambient temperatures, deviations from "ideal behavior" can be detected with most gases and vapors, while at elevated temperatures such deviations become less significant.

Internal Energy

As a statement of the principle of conservation of energy, the first law of thermodynamics deals with the relationship between work and heat. Confining our attention to a "closed system"—for which there is no exchange of matter with the surroundings—it is known that there will be a change if heat is added or taken away, or if work is done on or by "the system" (e.g., by compression). This change is usually accompanied by an increase or decrease in temperature and can be quantified if we first define a function of state known as the internal energy of the system, E. Any change in the internal energy of the system (ΔE) is then given by

$$\Delta E = q - w \tag{2}$$

where q is the heat transferred to the system, and w is the work done by the system. This can be expressed in differential form

$$dE = dq - dw \tag{3}$$

Table 1-5.1 ***Values of the Ideal Gas Constant,*** **R**

Units of Pressure	Units of Volume	Units of R	Value of R
Pa (N/m^2)	m^3	J/K·mol	8.31431
atm	cm^3	cm^3·atm/k·mol	82.0575
atm	ℓ	ℓ·atm/K·mol	0.0820575
atm	m^3	m^3·atm/K·mol	8.20575×10^{-5}

Dr. D. D. Drysdale is professor of fire safety engineering in the School of Civil and Environmental Engineering at the University of Edinburgh, Scotland. His research interests lie in fire science, fire dynamics, and the fire behavior of combustible materials.

Being a function of state, E varies with temperature and pressure, that is, $E = E(T, P)$.

According to the standard definition, work, w, is done when a force, F, moves its point of application through a distance, x, thus, in the limit

$$dw = F \cdot dx \tag{4}$$

The work done during the expansion of a gas can be derived by considering a cylinder/piston assembly (see Figure 1-5.1); thus

$$dw = P \cdot A \cdot dx = P\, dV \tag{5}$$

where

P = pressure of the gas

A = the area of the piston

dx = distance through which the piston is moved; the increment in volume is therefore $dV = A \cdot dx$

The total work done is obtained by integrating Equation 5 from the initial to the final state; that is,

$$w = \int_{\text{initial}}^{\text{final}} P \cdot dV \tag{6}$$

Combining Equations 3 and 5, the differential change in internal energy can be written

$$dE = dq - P \cdot dV \tag{7}$$

This shows that if the volume remains constant, as $P \cdot dV = 0$, then $dE = dq$; if this is integrated, we obtain

$$\Delta E = q_v \tag{8}$$

where q_v is the heat transferred to the constant volume system; that is, the change in internal energy is equal to the heat absorbed (or lost) at constant volume.

Enthalpy

With the exception of explosions in closed vessels, fires occur under conditions of constant pressure. Consequently, the work done as a result of expansion of the fire gases must be taken into account. At constant pressure, Equation 5 may be integrated to give

$$w = P \cdot (V_2 - V_1) \tag{9}$$

where V_1 and V_2 are the initial and final volumes, respectively. Equation 2 then becomes

$$\Delta E = E_2 - E_1 = q_p + PV_1 - PV_2 \tag{10}$$

or, rearranging,

$$q_p = (E_2 + PV_2) - (E_1 + PV_1) = H_2 - H_1 \tag{11}$$

where q_p is the heat transferred at constant pressure, and H is known as the enthalpy ($H \equiv E + PV$). The change in enthalpy is therefore the heat absorbed (or lost) at constant pressure (provided that only $P - V$ work is done), and consequently it is the change in enthalpy that must be considered in fire-related problems.

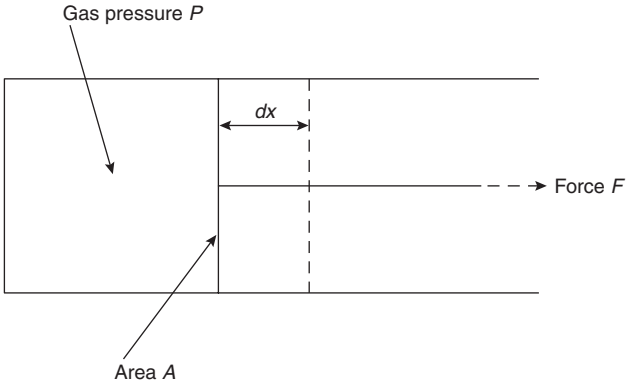

Figure 1-5.1. ***Cylinder/piston assembly.***

Specific Heat

Specific heat, or heat capacity, of a body or "system" is defined as the amount of heat required to raise the temperature of unit mass by one degree Celsius; the units are J/kg·K, although for most thermochemical problems the units J/mol·K are more convenient. The formal definition of the "mole" is the amount of a substance (solid, liquid, or gas) which contains as many elementary units (atoms or molecules) as there are carbon atoms in exactly 0.012 kg of carbon-12 (C^{12}). This number—known as Avogadro's number—is actually 6.023×10^{23}; in its original form, Avogadro's Hypothesis was applied to gases and stated that equal numbers of molecules of different gases at the same temperature and pressure occupy the same volume. Thus, the quantity of a substance which corresponds to a mole is simply the gram-molecular weight, but expressed in kilograms to conform with SI units. For example, the following quantities of the gases N_2, O_2, CO_2, and CO represent one mole of the respective gas and, according to Avogadro's Hypothesis, will each occupy 0.022414 m^3 at 273 K and 760 mm Hg (101.1 kPa):

0.028 kg nitrogen (N_2)
0.032 kg oxygen (O_2)
0.044 kg carbon dioxide (CO_2)
0.028 kg carbon monoxide (CO)
0.016 kg methane (CH_4)
0.044 kg propane (C_3H_8)

The concept of specific heat is normally associated with solids and liquids, but it is equally applicable to gases. Such specific heats are required for calculating flame temperatures, as described below. Values for a number of important gases at constant pressure and a range of temperatures are given in Table 1-5.2.

It is important to note that there are two distinct heat capacities; at constant pressure, C_p, and at constant volume, C_v. Thus, at constant pressure

$$dq_p = dH = C_p \cdot dT \tag{12}$$

Table 1-5.2 ***Heat Capacities of Selected Gases at Constant Pressure (101.1 kN/m²)***[5]

	C_p (J/mol·K)				
Temperature (K)	298	500	1000	1500	2000
Species					
CO	29.14	29.79	33.18	35.22	36.25
CO_2	37.129	44.626	54.308	58.379	60.350
H_2O(g)	33.577	35.208	41.217	46.999	51.103
N_2	29.125	29.577	32.698	34.852	35.987
O_2	29.372	31.091	34.878	36.560	37.777
He	20.786	20.786	20.786	20.786	20.786
CH_4	35.639	46.342	71.797	86.559	94.399

while at constant volume

$$dq_v = dE = C_v \cdot dT \tag{13}$$

For an ideal gas, $C_p = C_v + R$.

While the concept of specific heat is normally associated with solids and liquids, it is equally applicable to gases. Indeed, such specific heats are required for calculating flame temperatures. (See the section on calculation of adiabatic flame temperatures.)

Heats of Combustion

Chemical Reactions and Stoichiometry

When chemical reactions occur, they are normally accompanied by the release or absorption of heat. Thermochemistry deals with the quantification of the associated energy changes. This requires a definition of the initial and final states, normally expressed in terms of an appropriate chemical equation, for example,

$$C_3H_8 + 5O_2 \rightarrow 3CO_2 + 4H_2O \tag{R1}$$

in which the reactants (propane and oxygen) and products (carbon dioxide and water) are specified. This balanced chemical equation defines the *stoichiometry* of the reaction, that is, the exact proportions of the two reactants (propane and oxygen) for complete conversion to products (no reactants remaining). Note that the physical states of the reactants and products should also be specified. In most cases, the initial conditions correspond to ambient (i.e., 25°C and atmospheric pressure) so that there should be no doubt about the state of the reactants. In this case both are gaseous, but it is more common in fires for the "fuel" to be in a condensed state, either liquid or solid. As an example, the oxidation of n-hexane can be written

$$C_6H_{14} + 9.5O_2 \rightarrow 6CO_2 + 7H_2O \tag{R2}$$

but the fuel may be in either the liquid or the vapor state. The consequences of this will be discussed below.

Reaction 1 may be used to calculate the mass of oxygen or air required for the complete oxidation of a given mass of propane. Thus, we deduce that one mole of propane (44 g) reacts completely with five moles of oxygen (5 × 32 = 160 g); that is, 1 g propane requires 3.64 g oxygen. If the propane is burning in air, then the presence of nitrogen needs to be taken into account, although it does not participate to any significant extent in the chemical change. As the ratio of oxygen to nitrogen in air is approximately 21:79 (or 1:3.76), Reaction 1 can be rewritten

$$C_3H_8 + 5O_2 + 18.8N_2 \rightarrow 3CO_2 + 4H_2O + 18.8N_2 \tag{R3}$$

(where 18.8 = 5 × 3.76), showing that 44 g propane requires (160 + 18.8 × 28), or 686.4 g of "air" for complete combustion, that is, 15.6 g air/g propane. Calculations of this type are valuable in assessing the air requirements of fires.

Thus, on the assumption that wood has the empirical formula[3] $CH_{1.5}O_{0.75}$, it can be shown that its stoichiometric air requirement is 5.38 g air for each gram of fuel, assuming complete combustion of wood to CO_2 and H_2O. In this calculation no distinction is made of the fact that flaming combustion of wood involves oxidation of the volatile gases and vapors produced by the pyrolysis of wood, while the residual char burns much more slowly by surface oxidation.

Measurement of Heats of Combustion

The heat of combustion of a fuel is defined as the amount of heat released when unit quantity is oxidized completely to yield stable end products. In the present context, the relevant combustion processes occur at constant pressure so that we are concerned with an enthalpy change, ΔH_c. It should be remembered that as oxidation reactions are exothermic, ΔH_c is always negative, by convention.

Heats of combustion are measured by combustion bomb calorimetry in which a precise amount of fuel is burned in pure oxygen inside a pressure vessel whose temperature is strictly monitored. The apparatus is designed to reduce heat losses to a minimum so that the amount of heat released can be calculated from the rise in temperature and the total thermal capacity of the system; corrections can be made for any residual heat loss. Combustion bomb calorimetry has received a great deal of attention within physical chemistry[1] as the technique has provided a wealth of information relevant to thermochemistry. However, the experiment gives the heat re-

leased at constant volume; that is, the change in internal energy, ΔE (Equation 8). The change in enthalpy is given by

$$\Delta H = \Delta E + \Delta(PV) \quad (14)$$

where $\Delta(PV)$ is calculated using the ideal gas law

$$\Delta(PV) = \Delta(n\mathrm{R}T) \quad (15)$$

The method gives the gross heat of combustion; that is, in which the reactants and products are in their standard states. The net heat of combustion, on the other hand, refers specifically to the situation in which water as a product is in the vapor state. Net heat of combustion is less than the gross heat of combustion by an amount equal to the latent heat of evaporation of water (2.26 kJ/g) and is the value that should be used in fire calculations. It should be remembered that there is a heat of gasification associated with any condensed fuel (liquid or vapor); a correction must be made for this if the heat of combustion of the fuel vapor is required.

Table 1-5.3 contains the heats of combustion (ΔH_c) of a number of combustible gases, liquids, and solids, expressed in various ways, viz., kJ/mole (fuel), kJ/g (fuel), kJ/g (oxygen), and kJ/g (air). The first of these is the form normally encountered in chemistry texts and reference books, while the second is more commonly found in sources relating to chemical engineering and fuel technology and is more useful to the fire protection engineer. However, the third and, particularly, the fourth have very specific uses in relation to fire problems. It is immediately apparent from Table 1-5.3 that $\Delta H_c(O_2)$ and ΔH_c (air) are approximately constant for most of the fuels listed, having average values of 13.1 kJ/g and 3 kJ/g, respectively. (See the section on rate of heat release in fires.)

The data quoted in Table 1-5.3 refer to heats of combustion measured at ambient temperature, normally 25°C. These data will be satisfactory for virtually all relevant fire problems, but occasionally it may be necessary

Table 1-5.3 ***Heats of Combustion of Selected Fuels at 25°C (298 K)***[a]

Fuel	ΔH_c (kJ/mol)	ΔH_c (kJ/g)	ΔH_c[c] [kJ/g(O_2)]	ΔH_c [kJ/g(air)]

[a]Apart from the solids (d-glucose, etc.), the initial state of the fuel and of all the products is taken to be gaseous.

[b]Cotton and rayon are virtually pure cellulose and can be assumed to have the same heat of combustion.

[c]ΔH_c (O_2) = 13.1 kJ/g is used in the oxygen consumption method for calculating rate of heat release.

to consider the heat released when combustion takes place at higher temperatures. This requires a simple application of the first law of thermodynamics. If the reaction involves reactants at temperature T_0 reacting to give products at the final temperature T_F, the process can be regarded in two ways:

1. The products are formed at T_0, absorb the heat of combustion, and are heated to the final temperature T_F.
2. The heat of combustion is imagined first to heat the reactants to T_F, then the reaction proceeds to completion, with no further temperature rise.

By the first law, we can write

$$(\Delta H_c)^{T_0} + C_p^{\mathrm{Pr}} \cdot (T_F - T_0) = (\Delta H_c)^{T_F} + C_p^{\mathrm{R}} \cdot (T_F - T_0) \quad (16)$$

where C_p^{Pr} and C_p^{R} are the total heat capacities of the products and reactants, respectively. This may be rearranged to give

$$\frac{(\Delta H_c)^{T_F} - (\Delta H_c)^{T_0}}{T_F - T_0} = \Delta C_p \quad (17)$$

or, in differential form, we have Kirchoff's equation

$$\frac{d(\Delta H_c)}{dT} = \Delta C_p \quad (18)$$

where $\Delta C_p = C_p^{\mathrm{Pr}} - C_p^{\mathrm{R}}$. This may be used in integrated form to calculate the heat of combustion at temperature T_2 if ΔH_c is known at temperature T_1 and information is available on the heat capacities of the reactants and products, thus

$$(\Delta H_c)^{T_2} = (\Delta H_c)^{T_1} + \int_{T_1}^{T_2} \Delta C_p \cdot dT \quad (19)$$

where

$$\Delta C_p = \sum C_p(\text{products}) - \sum C_p(\text{reactants}) \quad (20)$$

and C_p is a function of temperature, which can normally be expressed as a power series in T, for example,

$$C_p = a + bT + cT^2 + \cdots \quad (21)$$

Information on heat capacities of a number of species and their variation with temperature may be found in References 4 and 5. Some data are summarized in Table 1-5.2.

Heats of Formation

The first law of thermodynamics implies that the change in internal energy (or enthalpy) of a system depends only on the initial and final states of the system and is thus independent of the intermediate stages. This is embodied in thermochemistry as Hess's Law, which applies directly to chemical reactions. From this, we can develop the concept of heat of formation, which provides a means of comparing the relative stabilities of different chemical compounds and may be used to calculate heats of chemical reactions which cannot be measured directly.

The heat of formation of a compound is defined as the enthalpy change when 1 mole of that compound is formed from its constituent elements in their standard state (at 1 atm pressure and 298 K). Thus, the heat of formation of liquid water is the enthalpy change of the reaction (at 298 K)

$$H_2(g) + 0.5O_2(g) \rightarrow H_2O(\mathrm{l})\ \Delta H_f = -285.8\ \mathrm{kJ/mol} \quad (R4)$$

so that ΔH_f (H_2O) (l) = −285.8 kJ/mole at 25°C. This differs from the heat of formation of water vapor [ΔH_f ($H_2O(g)$) = −241.84 kJ/mol] by the latent heat of evaporation of water at 25°C (43.96 kJ/mol).

By definition, the heats of formation of all the elements are set arbitrarily to zero at all temperatures. This then allows the heats of reaction to be calculated from the heats of formation of the reactants and products, thus

$$\Delta H = \Delta H_f(\text{products}) - \Delta H_f(\text{reactants}) \quad (22)$$

where ΔH is the heat (enthalpy) of the relevant reaction. However, most heats of formation cannot be obtained as easily as heats of combustion. The example given is unusual in that the heat of formation of water also happens to be the heat of combustion of hydrogen. Similarly, the heat of combustion of carbon in its most stable form under ambient conditions (graphite) is the heat of formation of carbon dioxide. Fortunately, combustion calorimetry can be used indirectly to calculate heats of formation.

The heat of formation of ethyne (acetylene), which is the enthalpy change of the reaction

$$2\mathrm{C(graphite)} + H_2 \rightarrow C_2H_2 \quad (R5)$$

can be deduced in the following way: the heat of combustion of ethyne has been determined by bomb calorimetry as −1255.5 kJ/mol at 25°C (298 K). This is the heat of the reaction

$$C_2H_2 + 2.5O_2 \rightarrow 2CO_2 + H_2O \quad (R6)$$

which, by Hess's Law (see Equation 22), can be equated to

$$(\Delta H_c)^{298}(C_2H_2) = 2(\Delta H_f)^{298}(CO_2) + (\Delta H_f)^{298}(H_2O) - (\Delta H_f)^{298}(C_2H_2) - 2.5(\Delta H_f)^{298}(O_2) \quad (23)$$

We know that

$$(\Delta H_c)^{298}(C_2H_2) = -1255.5\ \mathrm{kJ/mol}$$
$$(\Delta H_f)^{298}(CO_2) = -393.5\ \mathrm{kJ/mol}$$
$$(\Delta H_f)^{298}(H_2O) = -241.8\ \mathrm{kJ/mol}$$
$$(\Delta H_f)^{298}(O_2) = 0.0\ \mathrm{kJ/mol\ (by\ definition)},$$

so that by rearrangement, Equation 23 yields

$$(\Delta H_f)^{298}(C_2H_2) = +226.7\ \mathrm{kJ/mol}$$

This compound has a positive heat of formation, unlike CO_2 and H_2O. This indicates that it is an endothermic compound and is therefore less stable than the parent ele-

Table 1-5.4 ***Heats of Formation at 25°C (298 K)***

ments. Under appropriate conditions, ethyne can decompose violently to give more stable species.

The heats of formation of a number of compounds are given in Table 1-5.4. The most stable compounds (CO_2 and H_2O) have the largest negative values, while positive values tend to indicate an instability with respect to the parent elements. While this can indicate a high chemical reactivity, it gives no information about the rates at which chemical changes might take place (i.e., kinetics are ignored). However, heats of formation have been used in preliminary hazard assessment to provide an indication of the risks associated with new processes in the chemical industry. It should be noted that the heats of combustion of endothermic compounds do not give any indication of any associated reactivity (compare Tables 1-5.3 and 1-5.4).

Rate of Heat Release in Fires

While thermochemistry can give information relating to the total amount of energy that can be released when a fuel is burned to completion, it is rarely (if ever) possible to use heats of combustion directly to calculate the heat released in "real" fires. However, it can be argued that the *rate* of heat release is more important than the total available.[7] When a single item is burning in isolation, the rate of burning and the rate of heat release in the flame are coupled. Nevertheless, it is convenient to express the rate of heat release in terms of the burning rate, which is expressed as a rate of mass loss, $\dot{m}$ (kg/s)

$$\dot{Q}_c = \dot{m} \cdot \Delta H_c \tag{24}$$

where ΔH_c is the net heat of combustion of the fuel (kJ/kg). However, this assumes that combustion is complete, although it is known that this is never so in natural fires. Even under conditions of unrestricted ventilation, the products of combustion will contain some species which are only partially oxidized, such as carbon monoxide, aldehydes, ketones, and particulate matter in the form of soot or smoke. Their presence indicates that not all the available combustion energy has been released. The "combustion efficiency" is likely to vary from around 0.3 to 0.4 for heavily fire-retarded materials to 0.9 or higher in the case of oxygen-containing products (e.g., polyoxymethylene).[8]

Fires burning in compartments present a completely different problem. In the first place, there is likely to be a range of different fuels present, each with a different stoichiometric air requirement. These will all burn at different rates, dictated not just by the nature of the fuel but also by the levels of radiant heat existing within the compartment during the fire. The rate of heat release during the fully developed stage of a compartment fire is required for calculating post-flashover temperature-time histories for estimating fire exposure of elements of structure, as in the method developed by Pettersson et al.[9] Calculating the rate of heat release is apparently complicated by the fact that not all of the fuel may burn within the compartment; some of the fuel volatiles can escape to burn outside as they mix with fresh air. The proportion of the heat of combustion that is effectively lost in this way cannot easily be estimated.

However, if it is assumed that the fire is ventilation controlled and that all of the air that enters the compartment is "burned" therein, then the rate of heat release within the compartment can be calculated from the expression

$$\dot{Q}_c = \dot{m}_{\text{air}} \cdot \Delta H_c(\text{air}) \tag{25}$$

where $\dot{m}_{\text{air}}$ is the mass flow rate of air into the compartment, and ΔH_c(air) is the heat of combustion per unit mass of air consumed (3 kJ/g, see Table 1-5.3). The mass flow rate of air can be approximated by the expression

$$\dot{m}_{\text{air}} = 0.52 A_w h^{1/2} \quad \text{(kg/s)} \tag{26}$$

where A_w is the effective area of ventilation (m^2) and h is the height of the ventilation opening (m).[10]

In this, it is tacitly assumed that the combustion process is stoichiometric, although in fact the rate of supply of air may not be sufficient to burn all the fuel vapors within the compartment. Indeed, if the equivalence ratio $\dot{m}_{\text{air}}/\dot{m}$ is less than the stoichiometric ratio, excess fuel will escape from the compartment and mix with air to give external flames whose length will depend *inter alia* on the equivalence ratio.[11] Furthermore, in using Equation 26 to calculate the temperature-time course of a fire, it is implied that the fire remains at its maximum rate of burning for its duration, the latter being controlled by the quantity of fuel present (the fire load). This method will overestimate the severity of fuel-controlled fires in which the ventilation openings are large.[12]

Much useful data on the fire behavior of combustible materials can be obtained by using the technique of "oxygen consumption calorimetry." This is the basis of the

"cone calorimeter," in which the rate of heat release from a small sample of material burning under an imposed radiant heat flux is determined by measuring the rate of oxygen consumption.[13] The latter can be converted into a rate of heat release using the conversion factor 13.1 kJ/g of oxygen consumed. (A small correction is required for incomplete combustion, based on the yield of CO.) This technique can be used on a larger scale to measure the rate of heat release from items of furniture, wall lining materials, and so on[14,15] and is now used routinely in both fire research and fire testing facilities.

Calculation of Adiabatic Flame Temperatures

In the previous sections, no consideration has been given to the fate of the energy released by the combustion reactions. Initially it will be absorbed within the reaction system itself by (1) unreacted reactants, (2) combustion products, and (3) diluents, although it will ultimately be lost from the system by various heat transfer processes. This is particularly true for natural fires in enclosed spaces. However, if we consider a premixed reaction system, such as a flammable vapor/air mixture, and assume it to be adiabatic, that is, there is no transfer of heat to or from the system, then we can calculate the maximum theoretical temperature, the adiabatic flame temperature.

Consider a flame propagating through a stoichiometric propane/air mixture of infinite extent (i.e., there are no surfaces to which heat may be transferred) and which is initially at 25°C. The appropriate equation is given by Reaction 7:

$$C_3H_8 + 5O_2 + 18.8N_2 \rightarrow 3CO_2 + 4H_2O + 18.8N_2 \qquad (R7)$$

This reaction releases 2044 kJ for every mole of propane consumed. This quantity of energy goes toward heating the reaction products, that is, 3 moles of carbon dioxide, 4 moles of water (vapor), and 18.8 moles of nitrogen for every mole of propane burned. The thermal capacity of this mixture can be calculated from the thermal capacities of the individual gases, which are available in the literature (e.g., JANAF).[5] The procedure is straightforward, provided that an average value of C_p is taken for each gas in the temperature range involved. (See Table 1-5.5.)

Table 1-5.5 ***Thermal Capacity of the Products of Combustion of a Stoichiometric Propane/Air Mixture***

		Thermal Capacity at 1000 K	
	No. of Moles	(J/mol·K)	(J/K)
CO_2	3	54.3	162.9
H_2O	4	41.2	164.8
N_2	18.8	32.7	614.8
Total thermal capacity (per mole of propane) =			942.5 J/K

As 2044 kJ are released at the same time as these species are formed, the maximum temperature rise will be

$$\Delta T = \frac{2044000}{942.5} = 2169 \text{ K}$$

giving the final (adiabatic) temperature as 2169 + 298 = 2467 K. In fact, this figure is approximate for the following reasons:

1. Thermal capacities change with temperature, and average values over the range of temperatures appropriate to the problem have been used.
2. The system cannot be adiabatic as there will be heat loss by radiation from the hot gases (CO_2 and H_2O).
3. At high temperatures, dissociation of the products will occur; as these are endothermic processes, there will be a reduction in the final temperature.

Of these, (2) and (3) determine that the actual flame temperature will be much lower than predicted. These effects can be taken into account. Thus, with propane burning in air, the final temperature may not exceed 2000 K.

If the propane were burning as a stoichiometric mixture in pure oxygen, then in the absence of nitrogen as a "heat sink," much higher temperatures would be achieved. The total thermal capacity would be (942.5 − 614.8) = 327.7 J/K. However, the amount of heat released remains unchanged (2044 kJ) so that the maximum temperature rise would be

$$\Delta T = \frac{2044000}{327.7} = 6238 \text{ K}$$

predicting a final temperature of 6263°C. Because dissociation will be a dominant factor, this cannot be achieved and the temperature of the flame will not exceed ~3500 K.

The occurrence of dissociation at temperatures in the region of 2000 K and above makes it necessary to take dissociation into account. Dissociation is discussed in Section 1, Chapter 6. However, the simple calculation outlined above can be used to estimate the temperatures of near-limit flames, when the temperature is significantly lower and dissociation can be neglected.

It is known that the lower flammability limit of propane is 2.2 percent. The oxidation reaction taking place in this mixture can be described by the following equation:

$$0.022C_3H_8 + 0.978(0.21O_2 + 0.79N_2) \rightarrow \text{products}$$

Dividing through by 0.022 allows this to be written

$$C_3H_8 + 9.34O_2 + 35.12N_2 \rightarrow 3CO_2 + 4H_2O + 4.34O_2 + 35.12N_2 \qquad (R8)$$

showing that the heat released by the oxidation of 1 mole of propane is now absorbed by excess oxygen (4.34 moles) and an increased amount of nitrogen. Carrying out the same calculation as before, it can be shown that the adiabatic flame temperature for this limiting mixture is 1281°C (1554 K). If the same calculation is carried out for the other hydrocarbon gases, it is found that the adiabatic limiting flame temperature lies in a fairly narrow band,

Table 1-5.6 ***Adiabatic Flame Temperature of Lower-Limiting Hydrocarbon/Air Mixtures***

Gas	Adiabatic Flame Temperature at Lower Flammability Limit (K)
Methane	1446
Ethane	1502
Propane	1554
n-Butane	1612
n-Pentane	1564
n-Heptane	1692
n-Octane	1632

1600 ± 100 K. (See Table 1-5.6.) This can be interpreted by assuming that the limit exists because heat losses (by radiation from the flame) exceed the rate of heat production (within the flame). As a consequence, flame cannot sustain itself. This concept can be applied to certain practical problems relating to the lower flammability limit.

EXAMPLE:

A mechanical engineering research laboratory contains a six-cylinder internal combustion engine which is being used for research into the performance of spark plugs. The fuel being used is methane, CH_4, and the fuel/air mixture can be adjusted at will. The combustion products are extracted from the exhaust manifold through a 30 cm square duct, 20 m long. It is found that the engine will continue to operate with a stoichiometric mixture when only three of the cylinders are firing. If under these conditions the average temperature of the gases entering the duct from the manifold is 700 K, is there a risk of an explosion in the duct?

SOLUTION:

The stoichiometric reaction for methane in air is

$$CH_4 + 2O_2 + 7.52N_2 \rightarrow CO_2 + 2H_2O + 7.52N_2 \qquad \text{(R9)}$$

If we consider that one mole of fuel passes through each of the six cylinders, but of the six moles only three are burned, we have overall

$$6CH_4 + 12O_2 + 45.12N_2 \rightarrow 3CH_4 + 3CO_2 + 6H_2O + 6O_2 + 45.12N_2 \qquad \text{(R10)}$$

Dividing through by 3 gives

$$2CH_4 + 4O_2 + 15.04N_2 \rightarrow CH_4 + 2O_2 + CO_2 + 2H_2O + 15.04N_2 \qquad \text{(R11)}$$

The mixture discharged into the exhaust manifold has the composition given by the right-hand side of Reaction 11. If this "burns" at 700 K, the final abiabatic flame temperature may be calculated on the basis of the reaction

$$CH_4 + 2O_2 + CO_2 + 2H_2O + 15.04N_2 \rightarrow 2CO_2 + 4H_2O + 15.04N_2 \qquad \text{(R12)}$$

The total thermal capacity of the product gases ($2CO_2 + 4H_2O + 15.04N_2$) (at 1000 K) can be shown to be 765.3 J per mole of methane burned. Using Kirchoff's Equation (Equation 19), $\Delta H_c(CH_4)$ at 700 K is calculated as 802.8 kJ/mol, giving $T = 802800/765.3 = 1049$ K. This gives a final temperature of 1749 K, which is significantly higher than the limiting flame temperature (1600 K) discussed above. This indicates that there is a risk of explosion, and measures should be applied to prevent this mixture being discharged into the duct.

It should be noted that at 700 K there will be a "slow" reaction between methane and the oxygen present, which could invalidate the tacit assumption that the duct becomes completely filled with the mixture described by the right-hand side of Reaction 10. However, slow oxidation of the methane will tend to make the mixture less flammable, and so the calculation gives a conservative answer.

Nomenclature

A	area (Equation 5)
A_w	area of ventilation opening
C_p	specific heat
E	internal energy
F	force (Equation 4)
h	height of ventilation opening
H	enthalpy
ΔH_c	heat of combustion
ΔH_f	heat of formation
$\dot{m}$	mass rate of burning
$\dot{m}_{\text{air}}$	mass flow rate of air
n	number of moles
P	pressure
q	energy
Q_c	rate of heat release
R	universal gas constant
T	temperature
V	volume
w	work

Subscripts

c	combustion
F	final
f	formation
o	initial
p	constant pressure
v	constant volume

Superscripts

Pr	products
R	reactants

CHAPTER 6

Chemical Equilibrium

Raymond Friedman

Relevance of Chemical Equilibrium to Fire Protection

The temperature of a flame must be known in order to calculate convective and radiative heat transfer rates, which control pool-fire burning rates, flame spread rates, remote ignitions, damage to exposed items (e.g., structural steel, wiring), and response of thermal fire detectors or automatic sprinklers.

Section 1, Chapter 5, "Thermochemistry," provides a simple technique for calculating flame temperature, based on ignoring the dissociations that occur at high temperature. This technique gives answers that are too high. For example, if propane (C_3H_8) burns in stoichiometric proportions with air at 300 K, and it is assumed that the only products are CO_2, H_2O, and N_2, then the simple thermochemical calculation yields a flame temperature of 2394 K. On the other hand, if chemical equilibrium is considered, so that the species CO, O_2, H_2, OH, H, O, and NO are assumed present in the products, then the flame temperature, calculated by methods described in this section, comes out to be 2268 K. Flame temperature measurements in laminar premixed propane-air flames agree with the latter value. (The discrepancy in flame temperature caused by neglecting dissociation would be even greater for fires in oxygen-enriched atmospheres.)

The chemical equilibrium calculation yields not only the temperature but the equilibrium composition of the products. Thus, the generation rate of certain toxic or corrosive products such as carbon monoxide, nitric oxide, or hydrogen chloride may be calculated, insofar as the assumption of equilibrium is valid.

For a fire in a closed volume, the final pressure as well as the temperature will depend on the dissociations and therefore require a calculation taking chemical equilibrium into account.

From a fire research viewpoint, there is interest in correlating flammability limits, extinguishment, soot formation, toxicity, flame radiation, or other phenomena; and chemical equilibrium calculations in some cases will be a useful tool in such correlations.

In a later part of this chapter, departure of actual fires from chemical equilibrium will be discussed.

Introduction to the Chemical Equilibrium Constant

Consider a chemical transformation, such as

$$2CO + O_2 \rightarrow 2CO_2 \tag{1}$$

If this process can occur, presumably the reverse process can also occur (principle of microscopic reversibility, or principle of detailed balancing):

$$2CO_2 \rightarrow 2CO + O_2 \tag{2}$$

If both processes occur at finite rates in a closed system, then, after a sufficient time, a condition of *chemical equilibrium* will be reached, after which no further change occurs as long as the temperature and pressure remain constant and no additional reactants are introduced. This condition of equilibrium can be expressed as a *mathematical constraint* on the system, which, for the gaseous reaction $2CO + O_2 \rightleftarrows 2CO_2$, can be written

$$K_3 = \frac{p_{CO_2}^2}{p_{CO}^2 p_{O_2}} \tag{3}$$

Dr. Raymond Friedman was with Factory Mutual Research from 1969 through 1993. During most of this time he was vice president and manager of their Research Division. Currently he is an independent consultant. He has past experience at Westinghouse Research Laboratories and Atlantic Research Corporation. He is a past president of The Combustion Institute, past vice chairman and current secretary of the International Association for Fire Safety Science, and an expert in fire research and combustion.

where the p_i are partial pressures (atm), and K_3 is the equilibrium constant. This expression can be rationalized by the following argument.

According to the chemical "law of mass action," first stated a century ago, the rate of the forward reaction (Equation 1) at a given temperature is given by $k_f p_{CO}^2 p_{O_2}$, while the rate of the reverse reaction (Equation 2) is given by $k_r p_{CO_2}^2$. At equilibrium, the forward rate must be equal to the reverse rate:

$$k_f p_{CO}^2 p_{O_2} = k_r p_{CO_2}^2 \tag{4}$$

which may be rearranged to

$$\frac{p_{CO_2}^2}{p_{CO}^2 p_{O_2}} = \frac{k_f}{k_r} = K_3 \tag{5}$$

While this appears to be a satisfactory explanation, research over the past hundred years has shown that chemical reactions in fact rarely proceed as suggested by the stoichiometric equation. For example, the three-body collision of two CO molecules and an O_2 molecule, resulting in the formation of two CO_2 molecules, simply does not happen. Rather, the reaction would occur as follows:

$$O_2 + M \rightarrow 2O + M \tag{6}$$

(where M is any molecule) followed by

$$O + CO + M \rightarrow CO_2 + M \tag{7}$$

Now, observe how Equation 3 can be obtained from this reaction sequence.

The reverse of $O_2 + M \rightarrow 2O + M$, namely $2O + M \rightarrow O_2 + M$, can also occur, and the equilibrium constant for this pair of reactions, which actually do occur, is $K_6 = p_O^2 p_M / p_{O_2} p_M = p_O^2 / p_{O_2}$. (The p_M term cancels.)

Similarly the reverse reaction $CO_2 + M \rightarrow O + CO + M$ can occur, and the equilibrium constant is $K_7 = p_{CO_2} / p_{CO} p_O$. If we now multiply K_7^2 by K_6, we obtain

$$K_7^2 K_6 = \left(\frac{p_{CO_2}}{p_{CO} p_O}\right)^2 \frac{p_O^2}{p_{O_2}} = \frac{p_{CO_2}^2}{p_{CO}^2 p_{O_2}} = K_3 \tag{8}$$

Thus, Equation 3 is perfectly valid, even if the "law of mass action" does not correctly describe the reaction process involving CO and O_2.

To get a further understanding of the validity of the equilibrium constant concept, consider the following facts: CO will not react with O_2—even by the above mechanism involving O atoms—unless first heated to quite high temperatures. However, at least a trace of moisture is usually present, and in such cases the reaction occurs by the following process, which can occur at lower temperatures. First, H and OH are formed by dissociation of H_2O. Then, the CO is converted by

$$CO + OH \rightleftarrows CO_2 + H \qquad K_9 = \frac{p_{CO_2} p_H}{p_{CO} p_{OH}} \tag{9}$$

while the O_2 reacts with H:

$$O_2 + H \rightleftarrows OH + O \qquad K_{10} = \frac{p_{OH} p_O}{p_{O_2} p_H} \tag{10}$$

If the quantity $K_9^2 K_{10}$ is now calculated,

$$K_9^2 K_{10} = \frac{p_{CO_2}^2}{p_{CO}^2 p_{O_2}} \frac{p_H p_O}{p_{OH}} \tag{11}$$

But, the reaction $H + O + M \rightarrow OH + M$ can occur, as well as its reverse, $OH + M \rightarrow H + O + M$. It does not matter if these reactions are actually important in the rate of oxidation of CO in the presence of H_2O. As long as these reactions can occur, then at equilibrium

$$k_f p_H p_O p_M = k_r p_{OH} p_M$$

and

$$\frac{k_f}{k_r} = K_{12} = \frac{p_{OH}}{p_H p_O} \tag{12}$$

Substituting this into Equation 11

$$\frac{p_{CO_2}^2}{p_{CO}^2 p_{O_2}} = K_9^2 K_{10} K^{12} = K_3 \tag{13}$$

Thus, the ratio $p_{CO_2}^2 / p_{CO}^2 p_{O_2}$ is a constant at equilibrium (at a given temperature) regardless of the reaction mechanism, even if other (hydrogen-containing) species are involved, because by the principle of microscopic reversibility, these other species (catalysts) affect the reverse reaction as well as the forward reaction.

Let us now consider the mathematical specification of the CO-CO_2-O_2 system at equilibrium. The system, at a given temperature and pressure, may be described by three variables, namely the partial pressures of the three species: p_{CO}, p_{O_2}, and p_{CO_2}. There are already two well-known constraints on the system: (1) The sum of the partial pressures must equal the total pressure, p

$$p_{CO} + p_{O_2} + p_{CO_2} = p \tag{14}$$

and (2) the ratio of carbon atoms to oxygen atoms in the system must remain at the original, presumably known, value of C/O:

$$\frac{C}{O} = \frac{p_{CO} + p_{CO_2}}{p_{CO} + 2p_{O_2} + 2p_{CO_2}} \tag{15}$$

A third constraint, that of chemical equilibrium, provides a third equation involving p_{CO}, p_{O_2}, and p_{CO_2}:

$$\frac{p_{CO_2}^2}{p_{CO}^2 p_{O_2}} = K_3 \tag{3}$$

Now the system is completely defined by the simultaneous solution of these three equations. The equilibrium constant varies with temperature but is independent of pressure (except at rather high pressures). It is also independent of the presence of other reactive chemical species.

Generalized Definition of Equilibrium Constant

For a generalized reaction

$$aX_1 + bX_2 \rightleftarrows cY_1 + dY_2$$

K would be given by

$$K = \frac{(p_{Y_1})^c (p_{Y_2})^d}{(p_{X_1})^a (p_{X_2})^b}$$

Notice that, instead of writing $2CO + O_2 \leftrightarrows 2CO_2$, one could equally well have written $CO + \frac{1}{2}O_2 \leftrightarrows CO_2$. The equilibrium constant for the latter formulation is

$$K_{16} = \frac{p_{CO_2}}{p_{CO} p_{O_2}^{1/2}} \tag{16}$$

By comparison of Equation 16 with Equation 3, it is clear that $K_{16} = \sqrt{K_3}$. Again, the equilibrium constant for the reaction, if written $2CO_2 \leftrightarrows 2CO + O_2$, would be equal to $1/K_3$.

Simultaneous Equilibria

In most real chemical systems, one must deal with a number of simultaneous chemical equilibria. For example, air at 2500 K will contain the species N_2, O_2, NO, and O. The following simultaneous equilibria may be considered

$$O_2 = 2O \qquad K_{17} = \frac{p_O^2}{p_{O_2}} \tag{17}$$

$$N_2 + O_2 = 2NO \qquad K_{18} = \frac{p_{NO}^2}{p_{N_2} p_{O_2}} \tag{18}$$

$$N_2 + 2O = 2NO \qquad K_{19} = \frac{p_{NO}^2}{p_{N_2} p_O^2} \tag{19}$$

It is easily seen from the above relations that $K_{19} = K_{18}/K_{17}$. Hence, Equations 17, 18, and 19 are not three independent equations, and any *two* of these equations may be used to describe the equilibrium condition; the third would be redundant. To determine the four unknowns, p_{N_2}, p_{O_2}, p_{NO}, and p_O, one would solve the selected two equilibrium relations plus the following two relations:

$$p_{NO} + p_{N_2} + p_{O_2} + p_O = p \tag{20}$$

and

$$\frac{p_{NO} + 2p_{N_2}}{p_{NO} + 2p_{O_2} + p_O} = 3.76 \tag{21}$$

where 3.76 is the ratio of nitrogen atoms to oxygen atoms in air.

If one knows the temperature, the equilibrium constants may be calculated from the thermodynamic properties of the reactants and products, as discussed in the next section. However, since the various equilibrium reactions release or absorb energy, and accordingly raise or lower the temperature of an adiabatic system, the determination of equilibrium composition of an adiabatic system must proceed simultaneously with the calculation of its temperature; that is, an energy balance must be satisfied as well as the equilibrium equations, the atom-ratio equations, and the $p = \sum p_i$ equation.

As a general rule, a gaseous chemical system *at a given temperature*, containing s kinds of chemical species involving e chemical elements, requires s-e equilibrium relations, e-1 atom-ratio relations, and a $p = \sum p_i$ equation, in order to specify it. If the temperature is unknown, an energy balance equation is also needed. (If the pressure is unknown but the volume is known, then the equation of state must be used in the pressure equation.)

In order to solve an actual problem, one must select the species to be considered. The more species one includes, the more difficult is the calculation. There is no need to include any species that will be present in very small quantity at equilibrium. Some guidelines can be provided.

For combustion of a C–H–O compound in air, it is usually sufficient to include the species CO_2, H_2O, N_2, O_2, CO, H_2, OH, H, O, and NO. These species are adequate if the air-fuel ratio is sufficiently large so that the O/C atomic ratio is greater than one. If the O/C atomic ratio is less than one, then solid carbon must be considered, as well as many additional gaseous species. If chlorine is present, then HCl, Cl_2, and Cl must be added. If sulfur is present, then SO_2 and SO_3 are the primary species, unless there is a deficiency of oxygen.

The Quantification of Equilibrium Constants

While a chemist might establish the numerical value of an equilibrium constant for $A \leftrightarrows 2B$ by direct measurement of the partial pressures of A and B in a system at equilibrium, this is rarely done because it is difficult to make such measurements in a high-temperature system, and it takes a long time to establish equilibrium in a low-temperature system. Instead, the equilibrium constant is generally determined from the thermodynamic relation first deduced by van't Hoff in 1886[1]

$$\Delta F^\circ = -RT \ln K \tag{22}$$

If this equation is applied to $A \leftrightarrows 2B$ at absolute temperature T, then $K = p_B^2/p_A$, and ΔF° is the free energy of two moles (mol) of B at 1 atm and temperature T, minus the free energy of 1 mol of A at 1 atm and temperature T. (The superscript o designates that each substance is in its "standard state," that is, an ideal gas at one atmosphere.) By definition

$$\Delta F^\circ = \Delta H^\circ - T\Delta S^\circ = \Delta E^\circ + \Delta(pV^\circ) - T\Delta S^\circ \tag{23}$$

Accordingly, if $\Delta S°$, the entropy difference, and either $\Delta H°$, the enthalpy difference, or $\Delta E°$, the energy difference, are known for the substances involved in an equilibrium at temperature T, then the equilibrium constant, K, may be calculated. It happens that $\Delta S°$, $\Delta H°$, and $\Delta E°$ are well known for almost all substances expected to be present at equilibrium in combustion gases at any temperature up to 4000 K, so the calculation of equilibrium constants is straightforward.

The variation of the equilibrium constant with temperature was shown by van't Hoff[1] to be given by

$$\frac{d \ln K}{dT} = \frac{\Delta H°}{RT^2} \left[= \frac{\Delta H}{RT^2} \text{ for ideal gases} \right] \tag{24}$$

Thus, for an exothermic reaction occurring at temperature T, ΔH is negative and K decreases as T increases. The converse is true for endothermic reactions.

It is appropriate to inquire about the underlying physical reason for the value of K to be governed by $\Delta F°$ (actually $\Delta H°$ and $\Delta S°$). An explanation is as follows: any chemical system being held at constant temperature will seek to reduce its energy, E, and to increase its entropy, S. The reduction of energy is analogous to a ball rolling downhill. The increase of entropy is analogous to shuffling a sequentially arranged deck of cards, yielding a random arrangement. These two tendencies will often affect the equilibrium constant in opposite directions.

Consider the equation

$$\ln K = \frac{\Delta S°}{R} - \frac{\Delta E°}{RT} - \Delta n \tag{25}$$

where Δn is the increase in the number of moles of product relative to reactant. Equation 25 is obtained by combining Equations 22 and 23 with the ideal gas law at constant temperature $\Delta(pV°) = \Delta nRT$. Inspection of Equation 25 shows that, if $\Delta S°$ is a large positive quantity and $\Delta S°/R$ dominates the other terms, K will be large, that is, the reaction is driven by the "urge" to increase entropy. Again, if the reaction is highly endothermic, then $-\Delta E°/RT$ will be a large negative number and can dominate the other terms to cause K to be small, that is, the reaction prefers to go in the reverse, or exothermic, direction and reduces the energy of the system. (Most spontaneous reactions are exothermic.) The Δn term is generally small compared with the other terms and represents the work done by the expanding system on the surroundings, or the work done on the contracting system by the surroundings.

In summary, Equation 25 represents the balance of these various tendencies and determines the relative proportions of reactants and products at equilibrium. Notice that the term $\Delta E°/RT$ becomes small at sufficiently high temperature, and the entropy term then dominates. In other words, all molecules break down into atoms at sufficiently high temperature, to maximize entropy. The important conclusion from this discussion is that there is no need to consider rates of forward and reverse processes to determine equilibrium.

Table 1-6.1 provides values of equilibrium constants for 13 reactions involving most species found in fire products at equilibrium, over a temperature range from 600 K to 4000 K. Equilibrium constants for other reactions involving the same species may be obtained by combining these constants, as in Equation 13, or as illustrated in the examples below.

Table 1-6.1 does not include the $\frac{1}{2}N_2 = N$ equilibrium, because fire temperatures are generally not high enough for significant N to form. Tables 1-6.2 and 1-6.3 present information on the degree to which various gases are dissociated at various temperatures.

In performing calculations, remember that even if a relatively small fraction of dissociation occurs, a rather large amount of energy may be absorbed in the dissociation, with a corresponding large increase in the energy of the system. For example, if water vapor initially at 2800 K is allowed to dissociate adiabatically at 1 atm, only 5.7 percent of the H_2O molecules will dissociate, but the temperature will drop from 2800 K to 2491 K; that is, the temperature relative to a 300 K baseline is lower by 12.4 percent.

Carbon Formation in Oxygen-Deficient Systems

Solid carbon (soot) may be expected to form in oxygen-deficient combustion products, under some conditions. Since solid carbon does not melt or boil until extremely high temperatures (~4000 K), we only need concern ourselves with solid carbon $C_{(s)}$, not liquid $C_{(l)}$ or gaseous carbon $C_{(g)}$.

Consider pure carbon monoxide at 2000 K. There are three conceivable ways in which it might form solid carbon:

$$\alpha: \quad CO \rightleftarrows \frac{1}{2} C_{(s)} + \frac{1}{2} CO_2 \qquad K_\alpha = \frac{(p_{CO_2})^{1/2}}{p_{CO}}$$

$$\beta: \quad CO \rightleftarrows C_{(s)} + \frac{1}{2} O_2 \qquad K_\beta = \frac{(p_{O_2})^{1/2}}{p_{CO}}$$

$$\gamma: \quad CO \rightleftarrows C_{(s)} + O \qquad K_\gamma = \frac{p_O}{p_{CO}}$$

Note that solid carbon does not appear in any of the equilibrium expressions. (By convention, a solid in equilibrium with gases is assigned a value of unity.)

From Table 1-6.1, we see that, at 2000 K,

$$K_\alpha = \frac{K_E^{1/2}}{K_F} = \text{antilog}_{10}\left[\left(\frac{10.353}{2} \right) - 7.469 \right]$$
$$= 5.1 \times 10^{-3}$$

$$K_\beta = \frac{1}{K_F} = \text{antilog}_{10}[0 - 7.469] = 3.4 \times 10^{-8}$$

$$K_\gamma = \frac{K_A}{K_F} = \text{antilog}_{10}[-3.178 - 7.469] = 2.2 \times 10^{-11}$$

Table 1-6.1 ***Values of Log_{10} K for Selected Reactions***

Partial pressures of all gases are expressed in atmospheres (Pascals/101,325). Graphite, $C_{(S)}$, is assigned a value of unity in the equilibrium expressions for K_E and K_F.

Table 1-6.2 ***Temperature (K) at Which a Given Fraction of a Pure Gas at 1 atm Is Dissociated***

Table 1-6.3 ***Temperature at Which Air at Equilibrium Contains a Given Fraction of Nitric Oxide, at 1 atm***

Fraction	Temperature (K)
0.001	1450
0.004	1750
0.01	2100
0.04	2800

We see that K_α, K_β, and K_γ are all small compared with unity, so very little of the CO would decompose by any of these modes. However, K_α is much larger than either K_β or K_γ, so it is the dominant mode for whatever decomposition may occur.

Thus, from the expression $p_{CO_2} = (K_\alpha p_{CO})^2$, and taking p_{CO} as 1 atm, we calculate $p_{CO_2} = (5.1 \times 10^{-3})^2 = 2.6 \times 10^{-5}$ atm. Since, by process α, 2 mol of CO must decompose for each mole of CO_2 formed, we conclude that $2 \times 2.6 \times 10^{-5}$ or 5.2×10^{-5} mol of CO will decompose to $C_{(s)}$ plus CO_2, per mole of CO originally present, after which we will have reached an equilibrium state. In other words, about 1/20,000 of the CO will decompose.

If the original mixture had consisted of CO at 1 atm plus CO_2 at any pressure greater than 2.6×10^{-5} atm, at 2000 K, then we could conclude that no carbon whatsoever would form.

It can also be shown that addition of a trace of O_2 or H_2O to CO at 2000 K would completely suppress carbon formation. As a general statement, for a chemical system containing fewer carbon atoms than oxygen atoms, the equilibrium condition will favor CO formation rather than that of solid carbon.

For a carbon-containing system with little or no oxygen, carbon may or may not form, depending on the hydrogen partial pressure. For example, carbon may form according to $C_2H_2 \leftrightarrows C_{(s)} + H_2$. The equilibrium expression for this reaction is written

$$\frac{p_{H_2}}{p_{C_2H_2}} = K(=13.9 \text{ at } 3000 \text{ K})$$

Again, note that solid carbon does not appear in the expression. If we rewrite the expression in the form $p_{H_2} > 13.9\, p_{C_2H_2}$, it becomes the criterion for suppression of carbon formation at 3000 K. In other words, as long as p_{H_2} is more than 13.9 times as large as $p_{C_2H_2}$, no carbon will form at 3000 K and any carbon present will be converted to C_2H_2. On the other hand, pure C_2H_2 will decompose to $C_{(s)}$ plus H_2 until the H_2/C_2H_2 ratio reaches 13.9, after which no further decomposition will occur at 300 K.

Another way to view this is to say that H_2, C_2H_2, and solid carbon at 3000 K will be in a state of equilibrium if and only if the ratio $p_{H_2}/p_{C_2H_2} = 13.9$, and this is true regardless of the quantity of solid carbon present, and also regardless of the presence of other gases.

For a C–H–O–N system, the threshold conditions for equilibrium carbon formation are somewhat more complicated, but the trends are illustrated by the calculated values shown in Table 1-6.4 for carbon formation thresholds in carbon-hydrogen-air systems at 1 atm.

It must be noted that carbon forms more readily in actual flames than Table 1-6.4 indicates, because of nonequilibrium effects. In premixed laminar flames, incipient carbon formation occurs at a C/O ratio roughly 60 percent of the values shown in Table 1-6.4. See the next section for further comments on nonequilibrium.

Departure from Equilibrium

This procedure of specifying chemical systems by equilibrium equations will only yield correct results if the system is truly in equilibrium. If one prepares a mixture of H_2 and O_2 at room temperature and then ages the mixture for a year, it will be found that essentially nothing has happened and the system will still be very far from equilibrium. On the other hand, such a system at a high temperature characteristic of combustion will reach equilibrium in a small fraction of a second. For example, a hydrogen atom, H, in the presence of O_2 at partial pressure 0.1 atm will react so fast at 1400 K that its half-life is only about 2 microseconds. (At room temperature, the half-life of this reaction is about 300 days.)

Since peak flame temperatures are almost always above 1400 K, and sometimes as high as 2400 K, it would appear that equilibrium would always be reached in flames. However, luminous (yellow) flames rapidly lose heat by radiation, turbulent flames may be partially quenched by the action of steep velocity gradients, and flames burning very close to a cold wall may be partially quenched by heat conductivity to the wall. Thus, the equilibrium condition is only a limiting case that real flames may approach. The products of a nonluminous laminar flame more than a few millimeters from any cold surface will always be very nearly in equilibrium.

Table 1-6.4 ***Threshold Atomic C/O Ratios for Carbon Formation (Equilibrium at 1 atm, N/O = 3.76)***

Temperature (K)	1600	2000	2400	2800
Atomic H/C Ratio				
0	1.00	1.00	1.00	1.00
2	1.00	1.02	1.09	1.30
4	1.00	1.05	1.16	1.56

Sample Problems

EXAMPLE 1:

Given a mixture of an equal number of moles of steam and carbon monoxide, what will the equilibrium composition be at 1700 K and 1 atm?

SOLUTION:

We would expect the species CO, H_2O, CO_2, and H_2 to be present. From Table 1-6.2, we see that the equilibria $H_2 \leftrightarrows 2H$, $O_2 \leftrightarrows 2O$, and $H_2O \leftrightarrows \frac{1}{2}H_2 + OH$ can all be neglected at 1700 K, so the species H, O, and OH will not be present in significant quantities.

Since we have four species involving three chemical elements, we will require $4 - 3$, or 1, equilibrium relationship, for the equilibrium $H_2O + CO \leftrightarrows H_2 + CO_2$.

The relationship is

$$\frac{p_{H_2} \cdot p_{CO_2}}{p_{H_2O} \cdot p_{CO}} = K \tag{26}$$

In addition, we need $3 - 1$, or 2, atom-ratio relations, which are

$$\frac{H}{C}: \quad \frac{2p_{H_2} + 2p_{H_2O}}{p_{CO} + p_{CO_2}} = 2 \tag{27}$$

(because the original mixture of H_2O + CO contains two H atoms per C atom) and

$$\frac{O}{C}: \qquad \frac{p_{H_2O} + p_{CO} + 2p_{CO_2}}{p_{CO} + p_{CO_2}} = 2 \tag{28}$$

(because the original mixture of H_2O + CO contains two O atoms per C atom). Finally, the sum of the partial pressures equals 1 atm:

$$p_{H_2O} + p_{CO} + p_{H_2} + p_{CO_2} = 1 \tag{29}$$

We now have a well-set problem, four equations and four unknowns, which may be solved as soon as K is quantified.

We do not find the equilibrium $H_2O + CO \leftrightarrows H_2 + CO_2$ in Table 1-6.1. However, if we calculate $K_E/(K_FK_C)$ from Table 1-6.1, we see that

$$\frac{K_E}{K_FK_C} = \frac{p_{CO_2}}{(1)\cdot p_{O_2}} \cdot \frac{(1)\cdot (p_{O_2})^{1/2}}{p_{CO}} \cdot \frac{p_{H_2}\cdot (p_{O_2})^{1/2}}{p_{H_2O}}$$

$$= \frac{p_{CO_2}\cdot p_{H_2}}{p_{CO}\cdot p_{H_2O}} = K$$

From Table 1-6.1, $\log_{10}(K_E/K_FK_C)$ at 1700 K = 12.180 – 8.011 – 4.699 = –0.51, and K = antilog$_{10}$ (–0.51) = 0.309.

Upon substituting K = 0.309 into Equation 26, and then simultaneously solving Equations 26 through 29, we obtain

$$p_{CO_2} = p_{H_2} = 0.179 \text{ atm}$$

and

$$p_{H_2O} = p_{CO} = 0.321 \text{ atm}$$

EXAMPLE 2:

One mole of hydrogen is introduced into a 50-L vessel that is maintained at 2500 K. How much dissociation will occur, and what will the pressure be?

SOLUTION:

Let α be the degree of dissociation of the hydrogen defined by $\alpha = (p_H/2)/[p_{H_2} + (p_H/2)]$. Thus, α ranges from zero to one. One mole of H_2 partially dissociates to produce 2α mol of H, leaving $1 - \alpha$ mol of H_2. The total number of moles is then $2\alpha + 1 - \alpha$, or $\alpha + 1$. In view of the definition of α, the total number of moles present is $(p_H + p_{H_2})/[p_{H_2} + (p_H/2)]$.

By the ideal gas law, $PV = nRT$.

$$(p_H + p_{H_2})(50) = \frac{p_H + p_{H_2}}{p_{H_2} + (p_H/2)} \quad (0.08206)(2500) \tag{30}$$

which reduces to

$$p_{H_2} + \frac{p_H}{2} = 4.103 \tag{31}$$

The equilibrium equation is

$$\frac{p_H}{(p_{H_2})^{1/2}} = K_B \tag{32}$$

From Table 1-6.1, $\log_{10}K_B$ = –1.601 at 2500 K, and therefore K_B = 0.0251. Upon substitution into Equation 32 and elimination of p_{H_2} between Equations 31 and 32, one obtains

$$p_H^2 + 0.000315p_H - 0.00258 = 0 \tag{33}$$

This equation yields a positive and a negative root. The negative root has no physical significance. The positive root is p_H = 0.0506 atm. Then, Equation 32 yields p_{H_2} = 4.08 atm, and the total final pressure is 4.08 + 0.0506 = 4.13 atm. The degree of dissociation, α, comes out to be 0.0062. (This is less dissociation than indicated by Table 1-6.2 because the pressure is well above 1 atm.)

EXAMPLE 3:

Propane is burned adiabatically at 1 atm with a stoichiometric proportion of air. Calculate the final temperature and composition. The initial temperature is 300 K.

SOLUTION:

The problem must be solved by a series of iterations. The first step is to assume a final temperature, either based on experience or by selecting a temperature substantially below the value calculated by assuming that CO_2 and H_2O are the only products of combustion. The second step is to solve the set of equations that specify the equilibrium composition at the assumed final temperature. The third step is to consult an overall enthalpy balance equation, which will show that the assumed final temperature was either too high or too low. The fourth step is to assume an appropriate new final temperature. The fifth and sixth steps are repeats of the second and third steps. If the correct final temperature is now found to be bracketed between these two assumed temperatures, then an interpolation should give a fairly accurate value of the true final temperature. Additional iterations may be made to improve the accuracy of the results to the degree desired. As a guess, the final temperature is assumed to be 2300 K.

Now the equilibrium equations at 2300 K are set up. The species to be considered are three principal species: CO_2, H_2O, and N_2, and seven minor species: H_2, O_2, OH, H, O, CO, and NO. (Based on chemical experience, the following possible species may be neglected at 2300 K when stoichiometric oxygen is present: N, $C_{(g)}$, NH, CN, CH, C_2, HO_2, HCN, O_3, C_3, NO_2, HNO, C_2H, CH_2, C_2O, CHO, and NH_2.) Thus, we consider ten species involving four elements, so $10 - 4$, or 6, equilibrium equations are needed. Any six *independent* equilibria may be selected. We can assure independence by requiring that each successive equilibrium expression we write will introduce at least one new chemical species. Observe that this requirement is met in the following list:

$$CO + \frac{1}{2}O_2 = CO_2 \qquad \frac{p_{CO_2}}{p_{CO}\cdot (p_{O_2})^{1/2}} = K = \frac{K_E}{K_F} \tag{34}$$

$$\frac{1}{2}O_2 = O \qquad \frac{p_O}{(p_{O_2})^{1/2}} = K_A \tag{35}$$

$$\frac{1}{2}O_2 + \frac{1}{2}N_2 = NO \qquad \frac{p_{NO}}{(p_{O_2} \cdot p_{N_2})^{1/2}} = K_G \tag{36}$$

$$H_2 + \frac{1}{2}O_2 = H_2O \qquad \frac{p_{H_2O}}{p_{H_2}(p_{O_2})^{1/2}} = K_C \tag{37}$$

$$\frac{1}{2}H_2 + \frac{1}{2}O_2 = OH \qquad \frac{p_{OH}}{(p_{H_2} \cdot p_{O_2})^{1/2}} = K_D \tag{38}$$

$$\frac{1}{2}H_2 = H \qquad \frac{p_H}{(p_{H_2})^{1/2}} = K_B \tag{39}$$

Four additional equations are needed to determine the ten unknown partial pressures. These are three atom-ratio equations and a summation of the partial pressures to equal the total pressure. To obtain the atom ratios, we take air to consist of 3.76 parts of N_2 (by volume) per part of O_2, neglecting argon, and other species. Then, from stoichiometry, $C_3H_8 + 5O_2 + (5 \cdot 3.76)N_2 \rightarrow 3CO_2 + 4H_2O + 18.8N_2$.

$$\frac{H}{C}: \qquad \frac{8}{3} = \frac{p_H + p_{OH} + 2p_{H_2O} + 2p_{H_2}}{p_{CO_2} + p_{CO}} \tag{40}$$

$$\frac{H}{N}: \qquad \frac{8}{37.6} = \frac{p_H + p_{OH} + 2p_{H_2O} + 2p_{H_2}}{2p_{N_2} + p_{NO}} \tag{41}$$

$$\frac{O}{C}: \qquad \frac{10}{3} = \frac{p_O + p_{OH} + p_{NO} + p_{CO} + p_{H_2O} + 2p_{O_2} + 2p_{CO_2}}{p_{CO_2} + p_{CO}} \tag{42}$$

Finally,

$$p_{CO_2} + p_{H_2O} + p_{N_2} + p_{H_2} + p_{O_2} + p_{OH} + p_H + p_O + p_{CO} + p_{NO} = 1 \tag{43}$$

From Table 1-6.1 at 2300 K:

x	$\log_{10} x$	x
K_E	9.001	—
K_F	7.061	—

K_A	–2.307	0.00493
K_G	–1.391	0.0406
K_C	2.682	481
K_D	–0.116	0.766
K_B	–2.016	0.00964

We insert these K values into Equations 34 through 39, and then solve the set of 10 equations, Equations 34 through 43, for the equilibrium values of the 10 partial pressures at 2300 K. This solution may be obtained by a tedious set of successive approximations. The first approximation is obtained by solving for the three principal species N_2, CO_2, and H_2O, assuming the partial pressures of the remaining species are zero. Then, using this trial value of p_{CO_2}, solve for p_{CO} and p_{O_2}, using Equation 34 and assuming that $p_{CO} = 2\,p_{O_2}$. Next, using p_{H_2O} and p_{O_2} as determined, use Equation 37 to determine a trial value of p_{H_2}. Then, using all the foregoing partial pressures, determine p_O from Equation 35, p_{NO} from Equation 36, p_{OH} from Equation 38, and p_H from Equation 39. Thus, ten trial values of the partial pressures are found. However, upon substitution into Equations 40, 41, 42, and 43, none of these equations will be quite satisfied. The partial pressures of the principal species must then be adjusted so as to satisfy Equations 40 through 43, and then a second iteration with the equilibrium equations must be carried out to establish new values for the minor species. After four or five such iterations, the results should converge to a set of partial pressures satisfying all equations.

A faster method is to use a computer program to solve the equations. (See the following section.)

The equilibrium partial pressures at 2300 K will come out to be:

P_{N_2}	0.7195 atm
P_{H_2O}	0.1474 atm
P_{CO_2}	0.1006 atm
P_{CO}	0.0143 atm
P_{O_2}	0.0066 atm
P_{H_2}	0.0038 atm
P_{OH}	0.0037 atm
P_{NO}	0.0028 atm
P_H	0.0006 atm
P_O	0.0004 atm

Now, we must determine if 2300 K was too high or too low a guess, by writing the enthalpy balance equation. (See Section 1, Chapter 5 on thermochemistry).

As a basis for the enthalpy balance, we assume that we have exactly 1 mol of products, at 1 atm. Then, if $p_{CO_2} = 0.1006$ atm (see above), we must have 0.1006 mol of CO_2. Similarly, we have 0.0143 mol of CO. Since these are the only two carbon compounds in the products, and since 3 mol of CO_2 plus CO must form from each mole of C_3H_8 burned, it follows that $(0.1006 + 0.0143)/3 = 0.0383$ mol of C_3H_8 must have burned. Since the original C_3H_8-air mixture was stoichiometric, it follows that the reactants also consisted of $5 \times 0.0383 = 0.1915$ mol of O_2 and $3.76 \times 0.1915 = 0.7200$ mol of N_2. (Thus, a total of 0.9498 mol of reactant form 1 mol of product, if the product is indeed at equilibrium at 2300 K.)

The enthalpy balance equation is

$$\sum n_i H_{i,T_r} = \sum n_j H_{j,T_p} \tag{44}$$

where n_i and H_i are the number of moles and the enthalpy per mol of each reactant species at reactant temperature T_r, and n_j and H_j are the number of moles and the enthalpy per mol of each product species at product temperature T_p.

The enthalpy of each reactant or product species x at temperature T is given by

$$H_{x,T} = (\Delta H_f^\circ)_{298.15} + H^\circ - H_{298}^\circ \tag{45}$$

where $(\Delta H_{f,298.15}^\circ)_x$ is the enthalpy of formation of a mol of species x from its constituent elements in their standard

states at 298 K. These constituent elements are H_2, O_2, N_2, and $C_{(s)}$, so $\Delta H^\circ_{f,298.15}$ for each of these four species is zero, by definition.

Values of $(\Delta H^\circ_f)_{298.15}$ and $H^\circ - H^\circ_{298}$* for various species are contained in Table 1-6.5. Substitution of numerical values into Equation 44 yields:

Reactant Species	$(\Delta H^\circ_f)_{298.15}$ (kJ/mol)	$H^\circ_{300} - H^\circ_{298}$ (kJ/mol)	H°_{300} (kJ/mol)	n_i (mol)	$n_i H^\circ_{i,300}$ (kJ)
C_3H_8	–103.85	0.16	–103.69	0.0383	–3.971
O_2	0	0.05	0.05	0.1915	+0.010
N_2	0	0.05	0.05	0.7200	+0.036
					–3.925

*If $H^\circ - H^\circ_{298}$ is not available from a table, it may be evaluated from the equation $H^\circ - H^\circ_{298} = \int_{298}^{T} C_p dT$. For C_3H_8, $C_p = 0.09$ kJ/mol·K at 298 K.

and

The enthalpy of the products (–1.794 kJ) is seen to be 2.131 kJ larger than the enthalpy of the reactants (–3.925 kJ). To put this 2.131 kJ difference in perspective, note that the heat of combustion of 0.0383 mol of propane at 298 K, to form 3 mol of CO_2 and 4 mol of H_2O per mole of propane, is $0.0383\ (3 \times 393.52 + 4 \times 241.83 - 103.85) = 78.29$ kJ. Thus, the 2.131 kJ discrepancy when compared with 78.29 kJ is rather small, showing that the 2300 K "first guess" was very close. Since the products, at 2300 K, are seen to have a slightly higher enthalpy than the reactants, the correct temperature must be slightly less than 2300 K.

To continue the calculation, the next step is to assume that the final temperature is 2200 K instead of 2300 K. The details will not be presented, but this will yield a new and slightly different set of values of the ten partial pressures of the products. Thus, a new enthalpy balance may be attempted, in the same manner as before. When this is done, the result will be that this time the enthalpy of the reactants will come out to be slightly higher than the enthalpy of the products, showing that the correct temperature is above 2200 K.

An interpolation may be made between the 2200 K enthalpy discrepancy and the 2300 K enthalpy discrepancy, which will show that the correct final temperature is 2268 K. Furthermore, the partial pressures of each product species may be obtained by interpolating between the 2200 K partial pressures and the 2300 K partial pressures, with results as follows:

$T = 2268$ K	P_{N_2}	0.7207 atm
	P_{H_2O}	0.1484 atm
	P_{CO_2}	0.1026 atm
	P_{CO}	0.0125 atm
	P_{O_2}	0.0059 atm
	P_{H_2}	0.0034 atm
	P_{OH}	0.0032 atm
	P_{NO}	0.0025 atm
	P_H	0.0005 atm
	P_O	0.0003 atm

Computer Programs for Chemical Equilibrium Calculations

In view of the extremely tedious calculations needed for determination of the equilibrium temperature and composition in a combustion process, a computer program for executing these calculations would be desirable. Fortunately, such programs have been developed.

However, the user of a computer program should be warned that thorough understanding of the material in this chapter is needed to avoid misinterpreting the computer output. Further, given such understanding, simple manual calculations can be performed to obtain independent checks of the computer output.

One program, entitled GASEQ, can be used with any computer using Windows. It can be downloaded from http://www.c.morley.ukgateway.net/gseqmain.htm. Alternatively, a program may be obtained from Reaction Design, 6440 Lusk Blvd, Suite D209, San Diego, CA 92121. Their e-mail address is <chemkin@Reaction.Design.com>.

These programs will calculate the final equilibrium conditions for adiabatic combustion at either constant pressure or constant volume, given the initial conditions. For the constant-pressure calculations, one specifies the initial temperature, the pressure, and the identities and relative proportions of the reactants. The computer programs contain the properties of selected reactants including: air, oxygen, nitrogen, hydrogen, graphite, methane, acetylene, ethylene, ethane, propane, butane, 1-butene, heptane, octane, benzene, toluene, JP-4, JP-5, methanol, ethanol, and polyethylene. If the fire only involves reactants from this list, no further input is necessary. If the fire involves a reactant not on this list, the input data must include the elemental composition and the enthalpy of formation of the reactant at 298 K, as well as enthalpy versus temperature data for the reactant over the temperature range from 298 K to the initial temperature. (If the initial temperature is 298 K, the last item is not needed.)

The computer programs can handle reactants containing any of the following elements: A, Al, B, Br, C, Cl, F, Fe, H, He, K, Li, Mg, N, Na, Ne, O, P, S, Si, and Xe. Data are included in the program on all known compounds, including liquids and solids, that can form at elevated temperatures from combinations of these elements. It is not necessary for the user to specify which product species to consider. The program can consider them all, and will print out all equilibrium species present with mole fractions greater than 5×10^{-6}, unless instructed to print out trace values down to some lower specified level.

The program can calculate Chapman-Jouguet detonation products as well as constant-pressure or constant-volume combustion products, if desired.

An addition to the program permits calculation of viscosity and thermal conductivity of gaseous mixtures, selected from 154 gaseous species, at temperatures from 300 K to 5000 K.

Nomenclature

C_p	heat capacity at constant pressure (kJ/mol·K)
$\Delta E°$	energy of products relative to energy of reactants, all at temperature T and 1 atm (kJ/mol)
$\Delta F°$	free energy of products relative to free energy of reactants, all at temperature T and 1 atm (kJ/mol)
$\Delta H°$	enthalpy of products relative to enthalpy of reactants, all at temperature T and 1 atm (kJ/mol)
K	equilibrium constant (based on partial pressures expressed in atmospheres)
K	degrees Kelvin
n	number of moles (e.g., a mole of oxygen is 32 g)
p_i	partial pressure of ith species (atm)
p	total pressure (atm)
R	gas constant (kJ/mol·K)
$\Delta S°$	entropy of products relative to entropy of reactants, all at temperature T and 1 atm (kJ/mol)
T	absolute temperature (K)

CHAPTER 7

Thermal Decomposition of Polymers

Craig L. Beyler and Marcelo M. Hirschler

Introduction

Solid polymeric materials undergo both physical and chemical changes when heat is applied; this will usually result in undesirable changes to the properties of the material. A clear distinction needs to be made between thermal decomposition and thermal degradation. The American Society for Testing and Materials' (ASTM) definitions should provide helpful guidelines. Thermal decomposition is "a process of extensive chemical species change caused by heat."[1] Thermal degradation is "a process whereby the action of heat or elevated temperature on a material, product, or assembly causes a loss of physical, mechanical, or electrical properties."[1] In terms of fire, the important change is thermal decomposition, whereby the chemical decomposition of a solid material generates gaseous fuel vapors, which can burn above the solid material. In order for the process to be self-sustaining, it is necessary for the burning gases to feed back sufficient heat to the material to continue the production of gaseous fuel vapors or volatiles. As such, the process can be a continuous feedback loop if the material continues burning. In that case, heat transferred to the polymer causes the generation of flammable volatiles; these volatiles react with the oxygen in the air above the polymer to generate heat, and a part of this heat is transferred back to the polymer to continue the process. (See Figure 1-7.1.) This chapter is concerned with chemical and physical aspects of thermal decomposition of polymers. The chemical processes are responsible for the generation of flammable volatiles while physical changes, such as melting and charring, can markedly alter the decomposition and burning characteristics of a material.

The gasification of polymers is generally much more complicated than that of flammable liquids. For most flammable liquids, the gasification process is simply evaporation. The liquid evaporates at a rate required to maintain the equilibrium vapor pressure above the liquid. In the case of polymeric materials, the original material itself is essentially involatile, and the quite large molecules must be broken down into smaller molecules that can vaporize. In most cases, a solid polymer breaks down into a variety of smaller molecular fragments made up of a number of different chemical species. Hence, each of the fragments has a different equilibrium vapor pressure. The lighter of the molecular fragments will vaporize immediately upon their creation while other heavier molecules will remain in the condensed phase (solid or liquid) for some time. While remaining in the condensed phase, these heavier molecules may undergo further decomposition to lighter fragments which are more easily vaporized. Some polymers break down completely so that virtually no solid residue remains. More often, however, not all the original fuel becomes fuel vapors since solid residues are left behind. These residues can be carbonaceous (char), inorganic (originating from heteroatoms contained in the original polymer, either within the structure or as a result of additive incorporations), or a combination of both. Charring materials, such as wood, leave large fractions of the original carbon content as carbonaceous residue, often as a porous char. When thermal decomposition of deeper layers of such a material continues, the volatiles produced must pass through the char above them to reach the surface. During this travel, the hot char may cause secondary reactions to occur in the volatiles. Carbonaceous chars can be intumescent layers, when appropriately formed, which slow down further thermal decomposition considerably. Inorganic residues, on the other hand, can form glassy lay-

Dr. Craig L. Beyler is the technical director of Hughes Associates, Fire Science and Engineering. He was the founding editor of the *Journal of Fire Protection Engineering* and serves on a wide range of committees in the fire research community.

Dr. Marcelo M. Hirschler is an independent consultant on fire safety with GBH International. He has over two decades of experience researching fire and polymers and has managed a plastics industry fire testing and research laboratory for seven years. He now serves on a variety of committees addressing the development of fire standards and codes, has published extensively, and is an associate editor of the journal *Fire and Materials.*

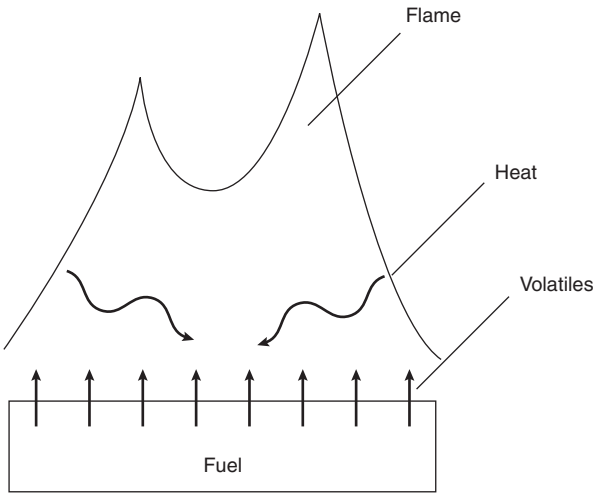

Figure 1-7.1. ***Energy feedback loop required for sustained burning.***

ers that may then become impenetrable to volatiles and protect the underlying layers from any further thermal breakdown. Unless such inorganic barriers form, purely carbonaceous chars can always be burned by surface oxidation at higher temperatures.

As this brief description of the thermal decomposition process indicates, the chemical processes are varied and complex. The rate, mechanism, and product composition of these thermal decomposition processes depend both on the physical properties of the original material and on its chemical composition.

Polymeric Materials

Polymeric materials can be classified in a variety of ways.[2] First, polymers are often classified, based on their origin, into natural and synthetic (and sometimes including a third category of seminatural or synthetic modifications of natural polymers). However, more useful is a classification based on physical properties, in particular the elastic modulus and the degree of elongation. Following this criterion, polymers can be classified into elastomers, plastics, and fibers. Elastomers (or rubbers) are characterized by a long-range extensibility that is almost completely reversible at room temperature. Plastics have only partially reversible deformability, while fibers have very high tensile strength but low extensibility. Plastics can be further subdivided into thermoplastics (whose deformation at elevated temperatures is reversible) and thermosets (which undergo irreversible changes when heated). Elastomers have elastic moduli between 10^5 and 10^6 N/m^2, while plastics have moduli between 10^7 and 10^8 N/m^2, and fibers have moduli between 10^9 and 10^{10} N/m^2. In terms of the elongation, elastomers can be stretched roughly up to 500 to 1000 percent, plastics between 100 to 200 percent, and fibers only 10 to 30 percent before fracture of the material is complete.

Polymers can also be classified in terms of their chemical composition; this gives a very important indication as to their reactivity, including their mechanism of thermal decomposition and their fire performance.

The main carbonaceous polymers with no heteroatoms are polyolefins, polydienes, and aromatic hydrocarbon polymers (typically styrenics). The main polyolefins are thermoplastics: polyethylene [repeating unit: $-(CH_2-CH_2)-$] and polypropylene {repeating unit: $-[CH(CH_3)-CH_2]-$}, which are two of the three most widely used synthetic polymers. Polydienes are generally elastomeric and contain one double bond per repeating unit. Other than polyisoprene (which can be synthetic or natural, e.g., natural rubber) and polybutadiene (used mostly as substitutes for rubber), most other polydienes are used as copolymers or blends with other materials [e.g., in ABS (acrylonitrile butadiene styrene terpolymers), SBR (styrene butadiene rubbers), MBS (methyl methacrylate butadiene styrene terpolymers), and EPDM (ethylene propylene diene rubbers)]. They are primarily used for their high abrasion resistance and high impact strength. The most important aromatic hydrocarbon polymers are based on polystyrene {repeating unit: $-[CH(phenyl)-CH_2]-$}. It is extensively used as a foam and as a plastic for injection-molded articles. A number of styrenic copolymers also have tremendous usage, for example, principally, ABS, styrene acrylonitrile polymers (SAN), and MBS.

The most important oxygen-containing polymers are cellulosics, polyacrylics, and polyesters. Polyacrylics are the only major oxygen-containing polymers with carbon–carbon chains. The most important oxygen-containing natural materials are cellulosics, mostly wood and paper products. Different grades of wood contain 20 to 50 percent cellulose. The most widely used polyacrylic is poly(methyl methacrylate) (PMMA) {repeating unit: $-[CH_2-C(CH_3)-CO-OCH_3]-$}. PMMA is valued for its high light transmittance, dyeability, and transparency. The most important polyesters are manufactured from glycols, for example, polyethylene terephthalate (PET) or polybutylene terephthalate (PBT), or from biphenol A (polycarbonate). They are used as engineering thermoplastics, as fibers, for injection-molded articles, and unbreakable replacements for glass. Other oxygenated polymers include phenolic resins (produced by the condensation of phenols and aldehydes, which are often used as polymeric additives), polyethers [such as polyphenylene oxide (PPO), a very thermally stable engineering polymer], and polyacetals (such as polyformaldehyde, used for its intense hardness and resistance to solvents).

Nitrogen-containing materials include nylons, polyurethanes, polyamides, and polyacrylonitrile. Nylons, having repeating units containing the characteristic group $-CO-NH-$, are made into fibers and also into a number of injection-molded articles. Nylons are synthetic aliphatic polyamides. There are also natural polyamides (e.g., wool, silk, and leather) and synthetic aromatic polyamides (of exceptionally high thermal stability and used for protective clothing). Polyurethanes (PU), with repeating units containing the characteristic group $-NH-COO-$, are normally manufactured from the condensation of polyisocyanates and polyols. Their principal area of application is as foams (flexible and rigid), or as thermal insulation.

Other polyurethanes are made into thermoplastic elastomers, which are chemically very inert. Both these types of polymers have carbon–nitrogen chains, but nitrogen can also be contained in materials with carbon–carbon chains, the main example being polyacrylonitrile [repeating unit: $-(CH_2-CH-CN-)$]. It is used mostly to make into fibers and as a constituent of engineering copolymers (e.g., SAN, ABS).

Chlorine-containing polymers are exemplified by poly(vinyl chloride) [PVC, repeating unit: $-(CH_2-CHCl)-$]. It is the most widely used synthetic polymer, together with polyethylene and polypropylene. It is unique in that it is used both as a rigid material (unplasticized) and as a flexible material (plasticized). Flexibility is achieved by adding plasticizers or flexibilizers. Through the additional chlorination of PVC, another member of the family of vinyl materials is made: chlorinated poly(vinyl chloride) (CPVC) with very different physical and fire properties from PVC. Two other chlorinated materials are of commercial interest: (1) polychloroprene (a polydiene, used for oil-resistant wire and cable materials and resilient foams) and (2) poly(vinylidene chloride) [PVDC, with a repeating unit: $-(CH_2-CCl_2)-$ used for making films and fibers]. All these polymers have carbon–carbon chains.

Fluorine-containing polymers are characterized by high thermal and chemical inertness and low coefficient of friction. The most important material in the family is polytetrafluoroethylene (PTFE); others are poly(vinylidene fluoride) (PVDF), poly(vinyl fluoride) (PVF), and fluorinated ethylene polymers (FEP).

Physical Processes

The various physical processes that occur during thermal decomposition can depend on the nature of the material. For example, as thermosetting polymeric materials are infusible and insoluble once they have been formed, simple phase changes upon heating are not possible. Thermoplastics, on the other hand, can be softened by heating without irreversible changes to the material, provided heating does not exceed the minimum thermal decomposition temperature. This provides a major advantage for thermoplastic materials in the ease of molding or thermoforming of products.

The physical behavior of thermoplastics in heating is dependent on the degree of order in molecular packing, that is, the degree of crystallinity. For crystalline materials, there exists a well-defined melting temperature. Materials that do not possess this ordered internal packing are amorphous. An example of an amorphous material is window glass. While it appears to be a solid, it is in fact a fluid that over long periods of time (centuries) will flow noticeably. Despite this, at low temperatures amorphous materials do have structural properties of normal solids. At a temperature known as the glass transition temperature in polymers, the material starts a transition toward a soft and rubbery state. For example, when using a rubber band, one would hope to use the material above its glass transition temperature. However, for materials requiring

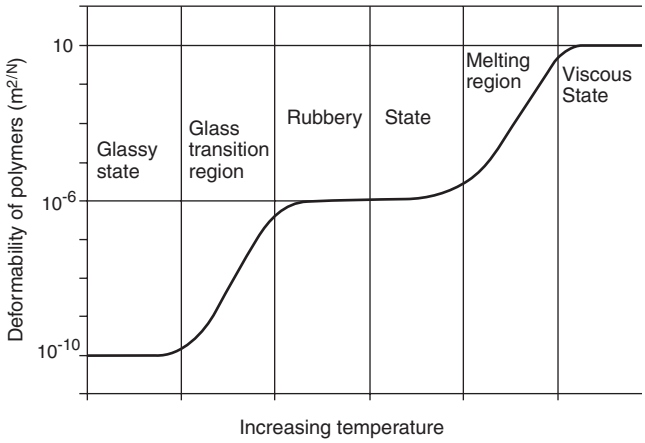

Figure 1-7.2. ***Idealized view of effect on deformability of thermoplastics with increasing temperature.***

rigidity and compressive strength, the glass transition temperature is an upper limit for practical use. In theoretical terms, this "deformability" of a polymer can be expressed as the ratio of the deformation (strain) resulting from a constant stress applied. Figure 1-7.2 shows an idealized view of the effect on the deformability of thermoplastics of increasing the temperature: a two-step increase. In practice, it can be stated that the glass transition temperature is the upper limit for use of a plastic material (as defined above, based on its elastic modulus and elongation) and the lower limit for use of an elastomeric material. Furthermore, many materials may not achieve a viscous state since they begin undergoing thermal decomposition before the polymer melts. Some typical glass transition temperatures are given in Table 1-7.1. As this type of physical transformation is less well defined than a phase transformation, it is known as a second order transition. Typically, materials are only partially crystalline, and, hence, the melting temperature is less well defined, usually extending over a range of 10°C or more.

Neither thermosetting nor cellulosic materials have a fluid state. Due to their structure, it is not possible for the original material to change state at temperatures below that at which thermal decomposition occurs. Hence, there are no notable physical transformations in the material before decomposition. In cellulosic materials, there is an important semi-physical change that always occurs on heating: desorption of the adsorbed water. As the water is both physically and chemically adsorbed, the temperature and rate of desorption will vary with the material. The activation energy for physical desorption of water is 30 to 40 kJ/mol, and it starts occurring at temperatures somewhat lower than the boiling point of water (100°C).

Many materials (whether cellulosic, thermosetting, or thermoplastic) produce carbonaceous chars on thermal decomposition. The physical structure of these chars will strongly affect the continued thermal decomposition

Table 1-7.1 ***Glass Transition and Crystalline Melting Temperatures***

Polymer	% Crystalline	Glass Transition Temperature (°C)	Crystalline Melting Temperature (°C)
Acetal	high		175–181
Acrylonitrile-butadiene-styrene	low	91–110	110–125
Cellulose	high		decomposes
Ethylene-vinyl acetate	high		65–110
Fluorinated ethylene propylene	high		275
High-density polyethylene	95	–125	130–135
Low-density polyethylene	60	–25	109–125
Natural rubber	low		30
Nylon 11	high		185–195
Nylon 6		75	215–220
Nylon 6-10		50	215
Nylon 6-6		57	250–260
Polyacrylonitrile	low	140	317
Poly(butene 1)		–25	124–142
Polybutylene		–26	126
Poly(butylene terephthalate)	high	40	232–267
Polycarbonate	low	145–150	215–230
Polychlorotrifluoroethylene	high	45	220
Poly(ether ether ketone)	high	143	334
Poly(ether imide)		217	
Poly(ethylene terephthalate)	high	70	265
Poly(hexene 1)			55
Poly(methylbutene 1)			300
Polymethylene	100		136
Poly(methyl methacrylate)	low	50	90–105
Polyoxymethylene	75–80	–85	175–180
Poly(pentene 1)			130
Poly(3-phenylbutene 1)			360
Poly(phenylene oxide)/polystyrene	low	100–135	110–135
Poly(phenylene sulphide)	high	88–93	277–282
Polypropylene	65	–20	170
Polystyrene	low	>80	230
Polysulphone	low	190	190
Polytetrafluoroethylene	100	125	327
Poly(vinyl chloride)	5–15	80–85	75–105 (212)
Poly(vinylidene chloride)	high	–18	210
Poly(vinylidene fluoride)	high	–30– –20	160–170
Poly(*p*-xylene)			>400
Styrene-acrylonitrile	low	100–120	120

process. Very often the physical characteristics of the char will dictate the rate of thermal decomposition of the remainder of the polymer. Among the most important characteristics of char are density, continuity, coherence, adherence, oxidation-resistance, thermal insulation properties, and permeability.[3] Low-density–high-porosity chars tend to be good thermal insulators; they can significantly inhibit the flow of heat from the gaseous combustion zone back to the condensed phase behind it, and thus slow down the thermal decomposition process. This is one of the better means of decreasing the flammability of a polymer (through additive or reactive flame retardants).[1,3,4] As the char layer thickens, the heat flux to the virgin material decreases, and the decomposition rate is reduced. The char itself can undergo glowing combustion when it is exposed to air. However, it is unlikely that both glowing combustion of the char and significant gas-phase combustion can occur simultaneously in the same zone above the surface, since the flow of volatiles through the char will tend to exclude air from direct contact with the char. Therefore, in general, solid-phase char combustion tends to occur after volatilization has largely ended.

Chemical Processes

The thermal decomposition of polymers may proceed by oxidative processes or simply by the action of heat. In many polymers, the thermal decomposition processes are accelerated by oxidants (such as air or oxygen). In that case, the minimum decomposition temperatures are lower in the presence of an oxidant. This significantly complicates the problem of predicting thermal decomposition rates, as the prediction of the concentration of oxygen at the polymer surface during thermal decomposition or combustion is quite difficult. Despite its importance to fire, there have been many fewer studies of thermal decomposition processes in oxygen or air than in inert atmospheres.

It is worthwhile highlighting, however, that some very detailed measurements of oxygen concentrations and of the effects of oxidants have been made by Stuetz et al. in the 1970s[5] and more recently by Kashiwagi et al.,[6–10] Brauman,[11] and Gijsman et al.[12] Stuetz found that oxygen can penetrate down to at least 10 mm below the surface of polypropylene. Moreover, for both polyethylene and polypropylene, this access to oxygen is very important in determining thermal decomposition rates and mechanisms. Another study of oxygen concentration inside polymers during thermal decomposition, by Brauman,[11] suggests that the thermal decomposition of polypropylene is affected by the presence of oxygen (a fact confirmed more recently by Gijsman et al.[12]) while poly(methyl methacrylate) thermal decomposition is not. Kashiwagi found that a number of properties affect the thermal and oxidative decomposition of thermoplastics, particularly molecular weight, prior thermal damage, weak linkages, and primary radicals. Of particular interest is the fact that the effect of oxygen (or air) on thermal decomposition depends on the mechanism of polymerization: free-radical polymerization leads to a neutralization of the effect of oxygen. A study on poly(vinylidene fluoride) indicated that the effect of oxygen can lead to changes in both reaction rate and kinetic order of reaction.[13]

Kashiwagi's work in particular has resulted in the development of models for the kinetics of general random-chain scission thermal decomposition,[14] as well as for the thermal decomposition of cellulosics[15] and thermoplastics.[16]

There are a number of general classes of chemical mechanisms important in the thermal decomposition of polymers: (1) random-chain scission, in which chain scissions occur at apparently random locations in the polymer chain; (2) end-chain scission, in which individual monomer units are successively removed at the chain end; (3) chain-stripping, in which atoms or groups not part of the polymer chain (or backbone) are cleaved; and (4) cross-linking, in which bonds are created between polymer chains. These are discussed in some detail under General Chemical Mechanisms, later in this chapter. It is sufficient here to note that thermal decomposition of a polymer generally involves more than one of these classes of reactions. Nonetheless, these general classes provide a conceptual framework useful for understanding and classifying polymer decomposition behavior.

Interaction of Chemical and Physical Processes

The nature of the volatile products of thermal decomposition is dictated by the chemical and physical properties of both the polymer and the products of decomposition. The size of the molecular fragments must be small enough to be volatile at the decomposition temperature. This effectively sets an upper limit on the molecular weight of the volatiles. If larger chain fragments are created, they will remain in the condensed phase and will be further decomposed to smaller fragments, which can vaporize.

Figure 1-7.3 shows examples of the range of chemical or physical changes that can occur when a solid polymer is volatilized. The changes range from simple phase transformations (solid going to liquid and then to gas, at the top of the figure), to complex combinations of chemical and physical changes (in the lower part of the figure). Water and many other liquids forming crystalline solids on freezing (e.g., most flammable liquids) undergo straightforward physical phase changes. Sublimation, that is, the direct phase change from a solid to a gas, without going through the liquid phase, will happen with materials such as carbon dioxide (e.g., CO_2, dry gas) or methenamine at normal temperatures and pressures. Methenamine is of interest in fires because methenamine pills are the ignition source in a standard test for carpets, ASTM D2859,[17] used in mandatory national regulations.[18,19] Thermoplastics can melt without chemical reaction to form a viscous state (polymer melt), but they often decompose thermally before melting. This polymer melt can then decompose into smaller liquid or gaseous fragments. The liquid fragments will then decompose further until they, too, are sufficiently volatile to vaporize. Some polymers, especially thermosets or cellulosics, have even more complex decomposition mechanisms. Polyurethanes (particularly flexible foams) can decompose by three different mechanisms. One of them involves the formation of gaseous isocyanates, which can then repolymerize in the gas phase and condense as a "yellow smoke." These iso-

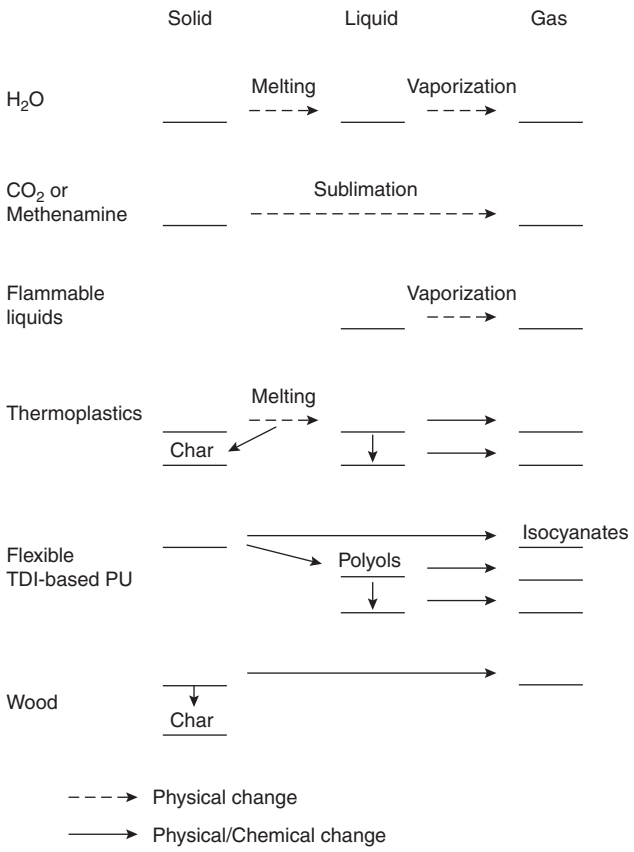

Figure 1-7.3. ***Physical and chemical changes during thermal decomposition.***

cyanates are usually accompanied by liquid polyols, which can then continue to decompose. Cellulosics, such as wood, decompose into three types of products: (1) laevoglucosan, which quickly breaks down to yield small volatile compounds; (2) a new solid, char; and (3) a series of high molecular weight semi-liquid materials generally known as tars. Figure 1-7.3 illustrates the complex and varied physicochemical decomposition pathways available, depending on the properties of the material in question. These varied thermal degradation/decomposition mechanisms have clear effects on fire behavior.

Experimental Methods

By far, the most commonly used thermal decomposition test is thermogravimetric analysis (TGA). In TGA experiments, the sample (mg size) is brought quickly up to the desired temperature (isothermal procedure) and the weight of the sample is monitored during the course of thermal decomposition. Because it is impossible in practice to bring the sample up to the desired temperature before significant thermal decomposition occurs, it is common to subject the sample to a linearly increasing temperature at a predetermined rate of temperature rise. One might hope to obtain the same results from one nonisothermal test that were possible only in a series of isothermal tests. In practice, this is not possible since the thermogram (plot of weight vs. temperature) obtained in a nonisothermal test is dependent on the heating rate chosen. Traditional equipment rarely exceed heating rates of 0.5 K/s, but modifications can be made to obtain rates of up to 10 K/s.[20,21] This dependence of thermal decomposition on heating rate is due to the fact that the rate of thermal decomposition is not only a function of the temperature, but also of the amount and nature of the decomposition process that has preceded it.

There are several reasons why the relevance of thermogravimetric studies to fire performance can be questioned: heating rate, amount of material, and lack of heat feedback are the major ones. For example, it is well known that heating rates of 10 to 100 K/s are common under fire conditions but are rare in thermal analysis. However, low heating rates *can* occur in real fires. More seriously, thermogravimetric studies are incapable of simulating the thermal effects due to large amounts of material burning and resupplying energy to the decomposing materials at different rates. However, analytical thermogravimetric studies do give important information about the decomposition process even though extreme caution must be exercised in their direct application to fire behavior.

Differential thermogravimetry (DTG) is exactly the same as TGA, except the mass loss versus time output is differentiated automatically to give the mass loss rate versus time. Often, both the mass loss and the mass loss rate versus time are produced automatically. This is, of course, quite convenient as the rate of thermal decomposition is proportional to the volatilization or mass loss rate. One of the main roles where DTG is useful is in mechanistic studies. For example, it is the best indicator of the temperatures at which the various stages of thermal decomposition take place and the order in which they occur as illustrated in Figure 1-7.4. Part (a) of this figure shows the DTG of a thermoplastic polymer, acrylonitrile-butadiene-styrene (ABS), and part (b) shows the same polymer containing 40 percent alumina trihydrate.[22] The polymer decomposes in two main stages. The addition of alumina trihydrate has a dual effect: (1) it makes the material less thermally stable, and (2) it introduces a third thermal decomposition stage. Moreover, the first stage is now the elimination of alumina trihydrate. A more complex example is shown in Figure 1-7.5, where the effects of a variety of additives are shown;[23] some of these additives are effective flame retardants and others are not: the amount of overlap between the thermal decomposition stages of polymer and additives is an indication of the effectiveness of the additive.

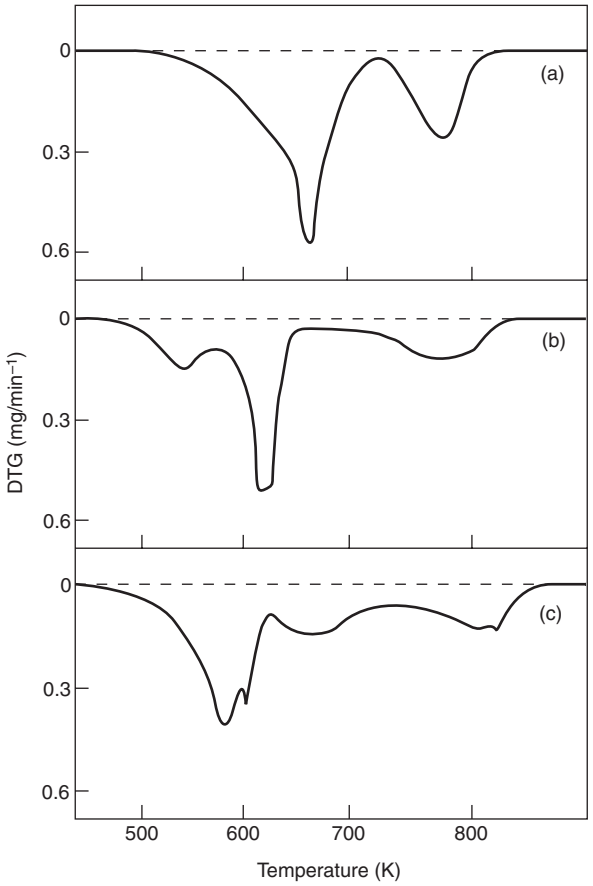

Figure 1-7.4. ***Effect of hydrated alumina and of antimony oxide-decabromobiphenyl (DBB) on DTG of ABS copolymer: (a) ABS; (b) ABS (60%) $A\ell_2O_3$, 3 H_2O (40%); (c) ABS (70%) + DBB (22.5%) + Sb_2O_3 (7.5%).***

Another method for determining the rate of mass loss is thermal volatilization analysis (TVA).[24] In this method, a sample is heated in a vacuum system (0.001 Pa) equipped with a liquid nitrogen trap (77 K) between the sample and the vacuum pump. Any volatiles produced will increase the pressure in the system until they reach the liquid nitrogen and condense out. The pressure is proportional to the mass volatilization rate, and a pressure transducer, rather

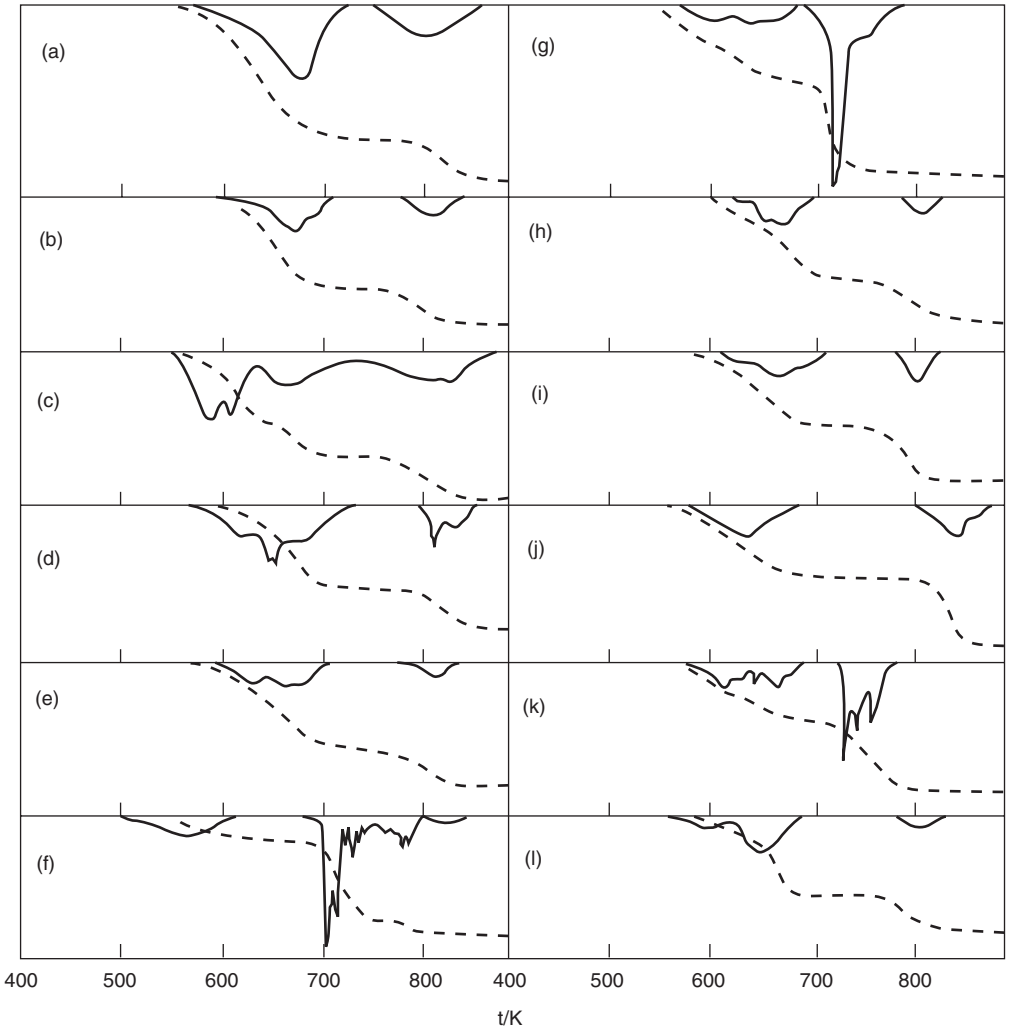

Figure 1-7.5. ***Thermal analyses of systems containing ABS, decabromobiphenyl (DBB), and one metal oxide, where DTG curves are indicated by a continuous line and TGA curves by a dashed line: (a) ABS; (b) ABS + DBB; (c) ABS + DBB + Sb_2O_3; (d) ABS + DBB + SnO; (e) ABS + DBB + $SnO_2 \cdot H_2O$; (f) ABS + DBB + ZnO; (g) ABS + DBB + Fe_2O_3; (h) ABS + DBB + AlOOH; (i) ABS + DBB + Al_2O_3; (j) ABS + DBB + $Al_2O_3 \cdot 3\,H_2O$; (k) ABS + DBB + ammonium molybdate; (l) ABS + DBB + talc. DTG (—); TGA (----).***

than a sample microbalance, is used to measure the decomposition rate.

In addition to the rate of decomposition, it is also of interest to determine the heat of reaction of the decomposition process. In almost all cases, heat must be supplied to the sample to get it to a temperature where significant thermal decomposition will occur. However, once at such a temperature, the thermal decomposition process may either generate or utilize additional heat. The magnitude of this energy generation (exothermicity) or energy requirement (endothermicity) can be determined in the following ways.

In differential thermal analysis (DTA), a sample and a reference inert material with approximately the same heat capacity are both subjected to the same linear temperature program. The sample and reference material temperatures are measured and compared. If the thermal decomposition of the sample is endothermic, the temperature of the sample will lag behind the reference material; if the decomposition is exothermic, the temperature of the sample will exceed the reference material temperature. Very often, the sample is held in a crucible, and an empty crucible is used as a reference. Such a test can be quite difficult to calibrate to get quantitative heats of reaction.

In view of the considerable importance of the exact process of thermal decomposition, it is advantageous to carry out simultaneously the measurements of TGA, DTG, and DTA. This can be achieved by using a simultaneous thermal analyzer (STA), which uses a dual sample/reference material system. In the majority of cases, polymeric materials are best represented by a reference material which is simply air, that is, an empty crucible. STA instru-

ments can then determine, at the same time, the amounts of polymer decomposed, the rates at which these stages/processes occur, and the amount of heat evolved or absorbed in each stage. Examples of the application of this technique are contained in References 20 and 21. Recently, STA equipment is often being connected to Fourier transform infrared spectrometers (FTIR) for a complete chemical identification and analysis of the gases evolved at each stage, making the technique even more powerful.

Another method, which yields quantitative results more easily than DTA, is differential scanning calorimetry (DSC). In this test procedure, both the sample and a reference material are kept at the same temperature during the linear temperature program, and the heat of reaction is measured as the difference in heat input required by the sample and the reference material. The system is calibrated using standard materials, such as melting salts, with well-defined melting temperatures and heats of fusion. In view of the fact that DSC experiments are normally carried out by placing the sample inside sealed sample holders, this technique is seldom suitable for thermal decomposition processes. Thus, it is ideally suited for physical changes, but not for chemical processes. Interestingly, some of the commercial STA apparatuses are, in fact, based on DSC rather than DTA techniques for obtaining the heat input.

So far the experimental methods discussed have been concerned with the kinetics and thermodynamics of the thermal decomposition process. There is also concern with the nature of the decomposition process from the viewpoints of combustibility and toxicity. Chemical analysis of the volatiles exiting from any of the above instruments is possible. However, it is often convenient to design a special decomposition apparatus to attach directly to an existing analytical instrument. This is particularly important when the heating rate to be studied is much higher than that which traditional instruments can achieve. Thermal breakdown of cellulosic materials, for example, has been investigated at heating rates as high as 10 K/s[25,26] or even more than 1000 K/s[27–29] in specialized equipment. The major reason this was done was in order to simulate the processes involved in "smoking," but the results are readily applicable to fire safety.

Given the vast numbers of different products that can result from the decomposition in a single experiment, separation of the products is often required. Hence, the pyrolysis is often carried out in the injector of a gas chromatograph (PGC). In its simplest but rarely used form, a gas chromatograph consists of a long tube with a well-controlled flow of a carrier gas through it. The tube or column is packed with a solid/liquid that will absorb and desorb constituents in the sample. A small sample of the decomposition products is injected into the carrier gas flow. If a particular decomposition product spends a lot of time adsorbed on the column packing, it will take a long time for it to reach the end of the column. Products with different adsorption properties relative to the column packing will reach the end of the column at different times. A detector placed at the exit of the gas chromatograph will respond to the flow rate of gases other than the carrier gas, and if separation is successful, the detector output will be a series of peaks. For a single peak, the time from injection is characteristic of the chemical species, and the area under the peak is proportional to the amount of the chemical species. Column packing, column temperature programming, carrier gas flow rate, sample size, and detector type must all be chosen and adjusted to achieve optimal discrimination of the decomposition products.

Once the gases have been separated, any number of analytical techniques can be used for identification. Perhaps the most powerful has been mass spectrometry (MS). Again speaking in very simple terms, in MS the chemical species is ionized, and the atomic mass of the ion can be determined by the deflection of the ion in a magnetic field. Generally, the ionization process will also result in the fragmentation of the molecule, so the "fingerprint" of the range of fragments and their masses must be interpreted to determine the identity of the original molecule. Gas chromatography and mass spectrometry are the subject of a vast literature, and many textbooks and specialized journals exist.

Useful physical data can be obtained by thermomechanical analysis (TMA). This is really a general name for the determination of a physical/mechanical property of a material subjected to high temperatures. Compressive and tensile strength, softening, shrinking, thermal expansion, glass transition, and melting can be studied by using TMA.

As displayed in Table 1-7.2, many of these tests can be performed *in vacuo,* in inert atmospheres, and in oxidizing atmospheres. Each has its place in the determination of the decomposition mechanism. Experiments performed *in vacuo* are of little practical value, but under vacuum the products of decomposition are efficiently carried away from the sample and its hot environment. Thus, secondary reactions are minimized so that the original decomposition product may reach a trap or analytical instrument intact. The practical significance of studies of thermal decomposition carried out in inert atmospheres may be

Table 1-7.2 ***Analytical Methods***

argued. However, when a material burns, the flow of combustible volatiles from the surface and the flame above the surface effectively exclude oxygen at the material's surface. Under these conditions, oxidative processes may be unimportant. In other situations, such as ignition where no flame yet exists, oxidative processes may be critical. Whether or not oxygen plays a role in decomposition can be determined by the effect of using air rather than nitrogen in thermal decomposition experiments.

The decomposition reactions in the tests of Table 1-7.2 are generally monitored by the mass loss of the sample. With the exception of charring materials (e.g., wood or thermosets), analysis of the partially decomposed solid sample is rarely carried out. When it is done, it usually involves the search for heteroatom components due to additives. Analysis of the composition of the volatiles can be carried out by a wide range of analytical procedures. Perhaps the simplest characterization of the products is the determination of the fraction of the volatiles that will condense at various trap temperatures. Typically, convenient temperatures are room temperature (298 K), dry-ice temperature (193 K), and liquid nitrogen temperature (77 K). The products are classified as to the fraction of the sample remaining as residue; the fraction volatile at the pyrolysis temperature, but not at room temperature, V_{pyr}; the fraction volatile at room temperature, but not at dry-ice temperature, V_{298}; the fraction volatile at dry-ice temperature, but not at liquid nitrogen temperature, V_{-193}; and the fraction volatile at liquid nitrogen temperature, V_{-77}. This characterization gives a general picture of the range of molecular weights of the decomposition products. The contents of each trap can also be analyzed further, perhaps by mass spectroscopy.

The residual polymer can be analyzed to determine the distribution of molecular weights of the remaining polymer chains. This information can be of great value in determining the mechanism of decomposition. The presence of free radicals in the residual polymer can be determined by electron spin resonance spectroscopy (ESR, EPR), which simplistically can be considered the determination of the concentration of unpaired electrons in the sample. Other techniques, like infrared spectroscopy (IR), can be usefully employed to detect the formation of bonds not present in the original polymer. Such changes in bonding may be due to double-bond formation due to chain-stripping or the incorporation of oxygen into the polymer, for example.

General Chemical Mechanisms

Four general mechanisms common in polymer decomposition are illustrated in Figure 1-7.6. These reactions can be divided into those involving atoms in the main polymer chain and those involving principally side chains or groups. While the decomposition of some polymers can be explained by one of these general mechanisms, others involve combinations of these four general mechanisms. Nonetheless, these categorizations are useful in the identification and understanding of particular decomposition mechanisms.

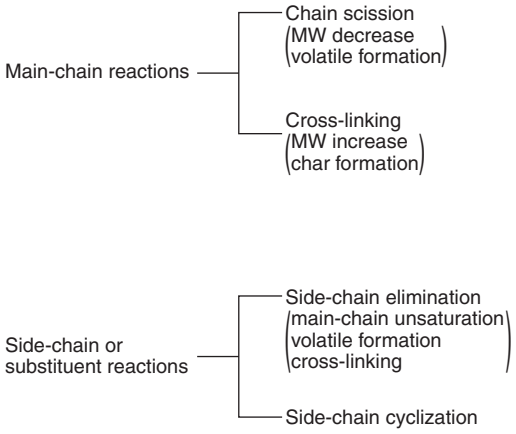

Figure 1-7.6. ***General decomposition mechanisms.***

Among simple thermoplastics, the most common reaction mechanism involves the breaking of bonds in the main polymer chain. These chain scissions may occur at the chain end or at random locations in the chain. End-chain scissions result in the production of monomer, and the process is often known as *unzipping*. Random-chain scissions generally result in the generation of both monomers and oligomers (polymer units with 10 or fewer monomer units) as well as a variety of other chemical species. The type and distribution of volatile products depend on the relative volatility of the resulting molecules.

Cross-linking is another reaction involving the main chain. It generally occurs after some stripping of substituents and involves the creation of bonds between two adjacent polymer chains. This process is very important in the formation of chars, since it generates a structure with a higher molecular weight that is less easily volatilized.

The main reaction types involving side chains or groups are elimination reactions and cyclization reactions. In elimination reactions, the bonds connecting side groups of the polymer chain to the chain itself are broken, with the side groups often reacting with other eliminated side groups. The products of these reactions are generally small enough to be volatile. In cyclization reactions, two adjacent side groups react to form a bond between them, resulting in the production of a cyclic structure. This process is also important in char formation because, as the reaction scheme shows, the residue is much richer in carbon than the original polymer as seen, for example, for poly(vinyl chloride):

$$-CH_2-CHCl-\Rightarrow -CH=CH-+HCl$$

which leads to a hydrogenated char or for poly(vinylidene chloride):

$$-CH_2-CCl_2-\Rightarrow -C\equiv C-+2HCl$$

which yields a purely carbonaceous char with an almost graphitic structure. These chars will tend to continue

breaking down by chain scission, but only at very high temperatures.

Chain-Scission Mechanisms

Decomposition by chain scission is a very typical mechanism for polymer decomposition. The process is a multistep radical chain reaction with all the general features of such reaction mechanisms: initiation, propagation, branching, and termination steps.

Initiation reactions are of two basic types: (1) random-chain scission and (2) end-chain scission. Both, of course, result in the production of free radicals. The random scission, as the name suggests, involves the breaking of a main chain bond at a seemingly random location, all such main chain bonds being equal in strength. End-chain initiation involves the breaking off of a small unit or group at the end of the chain. This may be a monomer unit or some smaller substituent. These two types of initiation reactions may be represented by the following generalized reactions:

$$P_n \Rightarrow R_r + R_{n-r} \qquad \text{(random-chain scission)}$$

$$P_n \Rightarrow R_n + R_E \qquad \text{(end-chain initiation)}$$

where P_n is a polymer containing n monomer units, and R_r is a radical containing r monomer units. R_E refers to an end group radical.

Propagation reactions in polymer decomposition are often called *depropagation reactions,* no doubt due to the polymer chemist's normal orientation toward polymer formation (polymerization) rather than decomposition. Regardless, there are several types of reactions in this class [see Figure 1-7.7, parts (a), (b), and (c)]:

$$R_n \Rightarrow R_{n-m} + P_m \qquad \text{(intramolecular H transfer, random-chain scission)}$$

$$P_m + R_n \Rightarrow P_{m-j} + P_n + R_j \qquad \text{(intermolecular H transfer)}$$

$$R_n \Rightarrow R_{n-1} + P_1 \qquad \text{(unzipping, depropagation, depolymerization)}$$

The first of these reactions involves the transfer of a hydrogen atom within a single polymer chain, that is, intramolecular hydrogen atom transfer. The value of m is usually between one and four as polymer molecules are often oriented such that the location of the nearest available H within the chain is one to four monomer units away from the radical site. The value of m need not be a constant for a specific polymer as the closest available hydrogen atom in the chain may vary due to conformational variations. Decomposition mechanisms based on this reaction are sometimes known as random-chain scission mechanisms. The second reaction involves the transfer of a hydrogen atom between polymer chains, that is, intermolecular hydrogen atom transfer. The original radical, R_n, abstracts a hydrogen atom from the polymer, P_m. As this makes P_m a radical with the radical site more often than not within the chain itself (i.e., not a terminal radical site), the newly formed radical breaks up into an unsaturated polymer, P_{m-j}, and a radical, R_j. In the final reaction, no hydrogen transfer occurs. It is essentially the reverse of the polymerization step and, hence, is called *unzipping, depropagation,* or *depolymerization.* Whether the decomposition involves principally hydrogen transfer reactions or unzipping can be determined by examining the structure of the polymer, at least for polymers with only carbon in the main chain. If hydrogen transfer is impeded, then it is likely that the unzipping reaction will occur.

Vinyl polymers, strictly speaking, are those derived from a vinyl repeating unit, namely

$$—[CH_2—CH_2]_n—$$

where n is the number of repeating monomers. Here, the hydrogen atoms can be substituted, leading to a repeating unit of the following form:

$$\begin{array}{c} W\ \ Y \\ |\ \ | \\ —[C—C]_n— \\ |\ \ | \\ X\ \ Z \end{array}$$

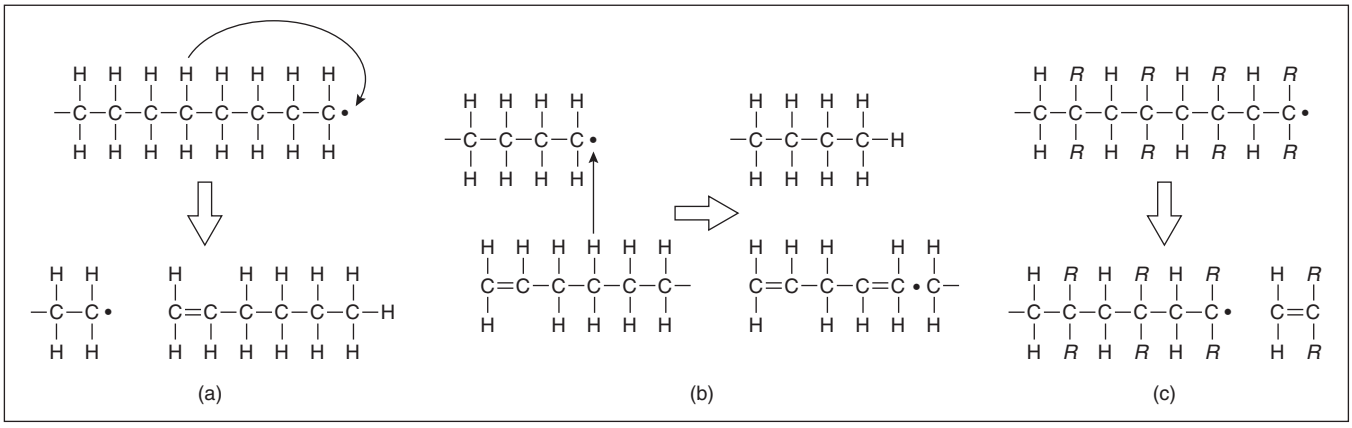

Figure 1-7.7. ***(a) Intramolecular H transfer, (b) intermolecular H transfer, (c) unzipping.***

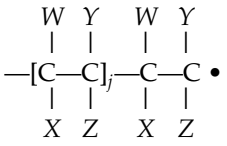
where *W, X, Y,* and *Z* are substituent groups, perhaps hydrogen, methyl groups, or larger groups. Consider that the C–C bond connecting monomer units is broken and that a radical site results from the scission shown as



where the symbol • indicates an unpaired electron and, hence, a radical site. In order for a hydrogen atom to be transferred from the chain to the radical site, it must pass around either *Y* or *Z*. If *Y* and *Z* are hydrogens, this is not at all difficult due to their small size. However, if the alpha carbon has larger substituents bound to it (i.e., *Y* and *Z* are larger groups), the transfer of hydrogen to the radical site is more difficult. This type of interference with hydrogen transfer is known as *steric hindrance.* Table 1-7.3 shows this effect.[2] Polymers near the top of Table 1-7.3 have *Y* and *Z* substituents that are generally large, with a resulting high monomer yield, characteristic of unzipping reactions. Near the bottom of Table 1-7.3, where *Y* and *Z* are small, the polymers form negligible amounts of monomer as other mechanisms dominate.

While chain-branching reactions seem to be of little importance in polymer decomposition, termination reactions are required in all chain mechanisms. Several types of termination reactions are common.

$$R_m \Rightarrow P_m \qquad \text{(unimolecular termination)}$$

$$R_m + R_n \Rightarrow P_{m+n} \qquad \text{(recombination)}$$

$$R_n + R_m \Rightarrow P_m + P_n \qquad \text{(disproportionation)}$$

[c]Cationic polymerization

[d]Free-radical polymerization

The first of these reactions is, strictly speaking, not generally possible. Nonetheless, there are instances where the observed termination reaction appears to be first order (at least empirically). It is impossible to remove the radical site from a polymer radical without adding or subtracting at least one hydrogen atom while still satisfying the valence requirements of the atoms. What probably occurs is that the termination reaction is, in fact, second order, but the other species involved is so little depleted by the termination reaction that the termination reaction appears not to be affected by the concentration of that species. This is known as a pseudo first-order reaction. The recombination reaction is a classical termination step that is actually just the reverse of the random-chain scission initiation reaction. Finally, the disproportionation reaction involves the transfer of a hydrogen atom from one radical to the other. The hydrogen donor forms a double bond as a result of the hydrogen loss, and the acceptor is fully saturated. If this sort of reaction occurs immediately after an initiation reaction, no unzipping or other propagation reaction occurs, and the polymer decomposition is fully characterized by a random process of bond scissions.

There is a natural tendency to regard all materials with the same generic name, such as poly(methyl methacrylate), as being the same material with the same properties. As these are commercial products, the preparation methods (including the polymerization process) are dictated by the required physical and chemical properties of the material for normal use. Additives, both intentional and inadvertent, may be present, and the method of polymerization and the molecular weight of the polymer chains may vary. This is particularly important in the case of polymeric "compounds" (the actual polymeric material that is used commercially to fabricate a product of any kind) that contain a large fraction of additives. In some polyolefins, the fraction of polymer (known as *resin*) may be much less than half of the total mass of the compound, because of the presence of large amounts of fillers. In some compounds derived from poly(vinyl chloride), flexibility is introduced by means of *plasticizers.*

In this regard, it is interesting and important to note that polymers tend to be less stable than their oligomer counterparts. This results from several effects involved in the production and aging of polymers as well as simply the chain length itself. Initiation reactions in a polymer can lead to far more monomer units being involved in decomposition reactions, relative to the polymer's short-chain oligomeric analog. In the production and aging of polymers, there are opportunities for the production of abnormalities in the polymer chains due to the mode of synthesis and thermal, mechanical, and radiation effects during aging.

In the synthesis of the polymer, abnormalities may result from several sources. Unsaturated bonds result from chain termination by free-radical termination reactions. End-chain unsaturation results from second-order disproportionation reactions, and midchain unsaturation often occurs due to chain-transfer reactions with subsequent intramolecular hydrogen transfer. Chain branching may result from the formation of midchain radicals. During synthesis, chain transfer reactions may cause midchain radicals that then go on to react with monomers or polymers to create a branched polymer structure. Termination of the polymerization reaction may also result in *head-to-head linkages*; that is, monomer units are attached such that some of the monomers are oriented opposite to the remainder of the chain. Lastly, foreign atoms or groups may be incorporated into the polymer chain. This may occur due to impurities, polymerization initiators, or catalysts. Oxygen is often a problem in this regard.

The purity and the molecular weight of the polymer can markedly affect not only the decomposition rates, but also the mechanism of decomposition. An example of such a change might involve chain initiations occurring at the location of impurities in the chain of a polymer which, if pure, would principally be subject to end-chain initiation. Both the mechanism and the decomposition rate would be affected. Not all polymer "defects" degrade polymer thermal performance. In a polymer that decomposes by unzipping, a head-to-head linkage can stop the unzipping process. Thus, for an initiation that would have led to the full polymer being decomposed, only the part between the initiation site and the head-to-head link is affected. At least one additional initiation step is required to fully decompose the chain. This has been studied in detail by Kashiwagi et al.[6–10]

Kinetics

Eight generic types of reaction involved in simple decomposition processes have been addressed in the previous sections. Even if only a subset of these reaction types are required and the reaction rates are not a strong function of the size of the polymer chains and radicals, the kinetics describing the process can be quite complex. In engineering applications, such complex reaction mechanisms are not used. Rather, simple overall kinetic expressions are generally utilized if, in fact, decomposition kinetics are considered at all. The most common assumption is that the reactions can be described by an Arrhenius expression of first order in the remaining polymer mass. Often one goes even further and ignores any dependence of the reaction rate on the remaining polymer or the thickness of the decomposition zone and simply expresses the volatilization rate per unit surface area as a zero-order Arrhenius expression. This effectively assumes that the decomposition zone is of constant thickness and fresh polymer replaces the decomposed polymer by surface regression. Such an approach would clearly not be satisfactory for charring materials where decomposition is clearly not a surface phenomenon. As some of the work quoted earlier has indicated (e.g., Reference 13), it is also not suitable for many thermoplastic polymers.

Despite the fact that detailed kinetic models are not used in engineering calculations, it is instructive to consider some very simple cases, by the use of overall kinetic expressions, to indicate what is being lost. The effect of the initiation mechanism on decomposition kinetics can be easily demonstrated by considering either random- or end-chain initiation with propagation by unzipping and no termination reactions other than exhaustion of the

polymer chain by unzipping. The rate of weight loss for random-chain initiation can be expressed as

$$\frac{dW}{dt} = D_p \cdot k_{ir} \cdot W$$

where D_p, the degree of polymerization, is the number of monomer units per polymer chain; and k_{ir} is the rate constant for the random-chain initiation reaction. Notice that the rate constant of the propagation reaction is not included in the expression. A further assumption that the propagation rate is much faster than the initiation rate has also been made. The initiation reaction is said to be the *rate-limiting step.* The degree of polymerization arises in the equation since, for each initiation, D_p monomer units will be released; and the remaining weight, W, arises because the number of bonds available for scission is proportional to W. Since the polymer unzips completely, the molecular weight of all remaining polymer chains is the same as the initial molecular weight.

Considering end-chain initiation, the rate of mass loss is given by

$$\frac{dW}{dt} = D_p \cdot (2n) \cdot k_{ie}$$

where n is the number of polymer chains, and, hence, $2n$ is the number of chain ends, and k_{ie} is the rate constant for end-chain initiation. The number of polymer chains is simply the mass of the sample divided by the molecular weight of each chain, or

$$n = \frac{W}{D_p \cdot MW_m}$$

where MW_m is the molecular weight of the monomer. Using this expression yields

$$\frac{dW}{dt} = \frac{2 \cdot k_{ie} \cdot W}{MW_m}$$

Comparing this with the random initiation expression, one can see that, for random initiation, the rate is dependent on the original degree of polymerization; whereas for end-chain initiation the rate is independent of the degree of polymerization or, equivalently, the original molecular weight of the polymer. In both cases, however, the rate is first order in the mass of the sample. This derivation has been for a monodisperse polymer; that is, all chains have been considered to be the same length initially.

Returning to the random-chain initiation expression, it is clear that longer chains are decomposed preferentially. If the initial sample had a range of molecular weights, the longer chains would disappear more quickly than shorter chains, and the molecular weight distribution would change with time, unlike in the monodisperse case. It can be shown that in this case the reaction order is no longer unity, but is between one and two, depending on the breadth of the distribution.[30] Thus,

$$\frac{dW}{dt} \sim W^n$$

with

$$1 < n < 2$$

for random-chain initiation and complete unzipping of a polydisperse system.

This simple comparison illustrates some of the ways in which the details of the polymerization process, which control variables like the molecular weight distribution, can alter the decomposition process. For a particular polymer sample, no single initiation reaction need be dominant, in general. The activation energies for the different initiation steps may be quite different, leading to large variations in the relative rates with temperature. For instance, in PMMA, the dominant initiation step at low temperatures (around 570 K) is end-chain initiation. At higher temperatures (around 770 K), the random-chain initiation step dominates. In a single nonisothermal TGA experiment, this temperature range can easily be traversed, and overall interpretation of the results in terms of a single mechanism would be unsatisfactory and misleading.

Nonetheless, simple overall kinetic expressions are likely to be dominant in engineering for some time. The pitfalls with this approach simply serve to reinforce the need to determine the kinetic parameters in an experiment that is as similar to the end use as is practical. This is one of the major reasons why the use of TGA results has been brought into question. As stated before, the heating rates often are far less than those generally found in fire situations. The low heating rates in TGA experiments tend to emphasize lower-temperature kinetics, which may be much less important at the heating rates characteristic of most fire situations.

One interesting study worth presenting here is a theoretical analysis of thermal decomposition that presents a technique for calculating the temperature at the beginning and end of thermal decomposition, based on structural data from the polymer and on scission at the weakest bond, with considerable degree of success, particularly for successive members of a polymeric family.[31] A subsequent analysis has also been published that is much simpler, but it has not been validated against experimental data.[32]

General Physical Changes during Decomposition

The physical changes that occur on heating a material are both important in their own right and also impact the course of chemical decomposition significantly. The nature of the physical changes and their impact on decomposition vary widely with material type. This section addresses the general physical changes that occur for thermoplastic (glass transition, melting) and thermosetting (charring, water desorption) materials.

Melting and Glass Transition

On heating a thermoplastic material, the principal physical change is the transformation from a glass or solid to the fluid state. (See Figure 1-7.2.) If this transformation

occurs at temperatures well below the decomposition temperature, it becomes more likely that the material will drip and/or flow. While such behavior is a complication, in terms of fire safety it can either improve or degrade the performance of the material. In some configurations, flowing of the material can remove it from the source of heat and thus avoid ignition or further fire growth. In other situations, the flow of material may be toward the heat source, leading to a worsened fire situation. Many standard fire tests that allow materials to flow away from the heat source have been shown to be unsuitable for assessing the hazards of flowing or dripping materials. Care must be taken in the evaluation of standard test results in this regard. However, many thermoplastics do not show marked tendencies to flow during heating and combustion. Whereas polyethylene melts and flows readily, high-quality cast poly(methyl methacrylate) shows only slight tendencies to flow under fire conditions.

When designing a material, there are several techniques that can be utilized to increase the temperature at which physical transformations occur. These strategies are generally aimed at increasing the stiffness of the polymer or increasing the interactions between polymer chains. It is clear that increasing the crystallinity of the polymer increases the interaction between polymer chains. In the highly ordered state associated with crystalline materials, it is less possible for polymer chains to move relative to one another, as additional forces must be overcome in the transformation to the unordered fluid state. Crystallinity is enhanced by symmetric regular polymer structure and highly polar side groups. Regular structure allows adjacent polymer chains to pack in a regular and tight fashion. As such, isotactic polymers are more likely to crystallize than atactic polymers, and random copolymers do not tend to crystallize. Polar side groups enhance the intermolecular forces. Regular polar polymers, such as polyesters and polyamides, crystallize readily. Even atactic polymers with OH and CN side groups will crystallize due to polarity. The melting temperature of a polymer is also increased with increasing molecular weight up to a molecular weight of about 10,000 to 20,000 g/mol.

Melting temperatures can also be increased by increasing the stiffness of the polymer chain. Aromatic polyamides melt at much higher temperatures than their aliphatic analogs due to stiffness effects. Aromatics are particularly useful for chain stiffening, as they provide stiffness without bulk which would hinder crystallinity. At the opposite extreme, the increased flexibility of the oxygen atom links in polyethers is responsible for a lowering of the melting temperature of polyethers relative to polymethylene. Chain stiffening must be accompanied by suitable thermal stability and oxidation resistance in order to achieve increased service temperatures. Many aromatic polymers have melting temperatures in excess of their decomposition temperatures, making these materials thermosetting.

Cross-linking also increases the melting temperature and, like chain stiffening, can render a material infusible. Cross-links created in fabrication or during heating are also important in thermoplastics. The glass transition temperature can be increased in amorphous polymers by the inclusion of cross-links during fabrication. Random-chain scissions can quickly render a material unusable by affecting its physical properties unless cross-linking occurs. Such cross-linking in thermoplastics on heating may be regarded as a form of repolymerization. The temperature above which depolymerization reactions are faster than polymerization reactions is known as *ceiling temperature.* Clearly, above this temperature catastrophic decomposition will occur.

Charring

While char formation is a chemical process, the significance of char formation is largely due to its physical properties. Clearly, if material is left in the solid phase as char, less flammable gas is given off during decomposition. More importantly, the remaining char can be a low-density material and is a barrier between the source of heat and the virgin polymer material. As such, the flow of heat to the virgin material is reduced as the char layer thickens, and the rate of decomposition is reduced, depending on the properties of the char.[3] If the heat source is the combustion energy of the burning volatiles, not only will the fraction of the incident heat flux flowing into the material be reduced, but the incident heat flux as a whole will be reduced as well. Unfortunately, char formation is not always an advantageous process. The solid-phase combustion of char can cause sustained smoldering combustion. Thus, by enhancing the charring tendency of a material, flaming combustion rates may be reduced, but perhaps at the expense of creating a source of smoldering combustion that would not otherwise have existed.

Charring is enhanced by many of the same methods used to increase the melting temperature. Thermosetting materials are typically highly cross-linked and/or chain-stiffened. However, charring is not restricted to thermosetting materials. Cross-linking may occur as a part of the decomposition process, as is the case in poly(vinyl chloride) and polyacrylonitrile.

Implications for Fire Performance

As explained earlier, one of the major reasons why thermal decomposition of polymers is studied is because of its importance in terms of fire performance. This issue has been studied extensively.

Early on, Van Krevelen[33,34] showed that, for many polymers, the limiting oxygen index (LOI, an early measure of flammability)[35] could be linearly related to char yield as measured by TGA under specified conditions. Then, since Van Krevelen showed how to compute char yield to a good approximation from structural parameters, LOI should be computable; and for pure polymers having substantial char yields, it is fairly computable. Somewhat later, comparisons were made between the minimum decomposition temperature (or, even better, the temperature for 1 percent thermal decomposition) and the LOI.[2,22] The conclusion was that, although in general low flammability resulted from high minimum thermal decomposition

temperatures, no easy comparison could be found between the two. There were some notable cases of polymers with both low thermal stability and low flammability. This type of approach has since fallen into disrepute, particularly in view of the lack of confidence remaining today in the LOI technique.[36] Table 1-7.4 shows some thermal decomposition temperatures and limiting oxygen indices[22] as well as heat release rate values, the latter as measured in the cone calorimeter.[37,38] It is clear from the data in Table 1-7.4 that thermal decomposition is *not* a stand-alone means of predicting fire performance. Promising work in this regard is being made by Lyon,[39] who appears to be able to preliminarily predict some heat release information from thermoanalytical data.

However, mechanisms of action of fire retardants and potential effectiveness of fire retardants can be well predicted from thermal decomposition activity (for example, see Figures 1-7.4 and 1-7.5).[22,23] It is often necessary to have some additional understanding of the chemical reactions involved. In Figure 1-7.5, for example, the systems containing ABS, decabromobiphenyl, and either antimony oxide (c) or ferric oxide (g) have very similar TGA/DTG curves, with continuous weight loss. This indicates that the Sb system is effective but the iron one is not, because antimony bromide can volatilize while iron bromide does not. On the other hand, the system containing zinc oxide (f) is inefficient because the zinc bromide volatilizes too early, that is, before the polymer starts breaking down. Some authors have used thermal decomposition techniques via the study of the resulting products to understand the mechanism of fire retardance (e.g., Grassie[40]), or together with a variety of other techniques (e.g., Camino et al.[41,42]).

Whatever the detailed degree of predictability of fire performance data from thermal decomposition data, its importance should not be underestimated: *polymers cannot burn if they do not break down.*

Table 1-7.4 ***Thermal Stability and Flammability of Polymers***

Polymer	T_d[a] (K)	$T_{1\%}$[b] (K)	LOI[c]	Pk RHR[d] (kW/m²)
Polyacetal	503	548	15.7	360

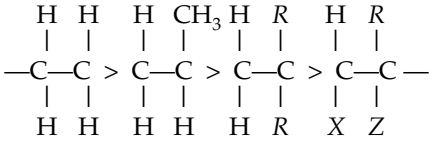
Behavior of Individual Polymers

The discussion, thus far, has been general, focusing on the essential aspects of thermal decomposition without the complications that inevitably arise in the treatment of a particular polymer. This approach may also tend to make the concepts abstract. Through the treatment of individual polymers by polymer class, this section provides an opportunity to apply the general concepts to real materials. In general, the section is restricted to polymers of commercial importance. More complete and detailed surveys of polymers and their thermal decomposition can be found in the literature.[2,30,43–52]

Polyolefins

Of the polyolefins, low-density polyethylene (LDPE), high-density polyethylene (HDPE), and polypropylene (PP) are of the greatest commercial importance because of their production volume. Upon thermal decomposition, very little monomer formation is observed for any of these polymers; they form a large number of different small molecules (up to 70), mostly hydrocarbons. Thermal stability of polyolefins is strongly affected by branching, with linear polyethylene most stable and polymers with branching less stable. The order of stability is illustrated as follows:



where *R* is any hydrocarbon group larger than a methyl group.

Polyethylene (PE): In an inert atmosphere, polyethylene begins to cross-link at 475 K and to decompose (reductions in molecular weight) at 565 K though extensive weight loss is not observed below 645 K. Piloted ignition of polyethylene due to radiative heating has been observed at a surface temperature of 640 K. The products of decomposition include a wide range of alkanes and alkenes. Branching of polyethylene causes enhanced intramolecular hydrogen transfer and results in lower thermal stability. The low-temperature molecular weight changes without volatilization are principally due to the scission of weak links, such as oxygen, incorporated into the main chain as impurities. Initiation reactions at higher temperatures involve scission of tertiary carbon bonds or ordinary carbon–carbon bonds in the beta position to tertiary carbons. The major products of decomposition are

propane, propene, ethane, ethene, butene, hexene-1, and butene-1. Propene is generated by intramolecular transfer to the second carbon and by scission of the bond beta to terminal $=CH_2$ groups.

The intramolecular transfer route is most important, with molecular coiling effects contributing to its significance. A broad range of activation energies has been reported, depending on the percent conversion, the initial molecular weight, and whether the remaining mass or its molecular weight were monitored. Decomposition is strongly enhanced by the presence of oxygen, with significant effects detectable at 423 K in air.

Polypropylene (PP): In polypropylene, every other carbon atom in the main chain is a tertiary carbon, which is thus prone to attack. This lowers the stability of polypropylene as compared to polyethylene. As with polyethylene, chain scission and chain transfer reactions are important during decomposition. By far, secondary radicals (i.e., radical sites on the secondary carbon) are more important than primary radicals. This is shown by the major products formed, that is, pentane (24 percent), 2 methyl-1-pentene (15 percent), and 2–4 dimethyl-1-heptene (19 percent). These are more easily formed from intramolecular hydrogen transfer involving secondary radicals. Reductions in molecular weight are first observed at 500 to 520 K and volatilization becomes significant above 575 K. Piloted ignition of polypropylene due to radiative heating has been observed at a surface temperature of 610 K. Oxygen drastically affects both the mechanism and rate of decomposition. The decomposition temperature is reduced by about 200 K, and the products of oxidative decomposition include mainly ketones. Unless the polymer samples are very thin (less than 0.25–0.30 mm or 0.010–0.012 in. thick), oxidative pyrolysis can be limited by diffusion of oxygen into the material. At temperatures below the melting point, polypropylene is more resistant to oxidative pyrolysis as oxygen diffusion into the material is inhibited by the higher density and crystallinity of polypropylene. Most authors have assumed that the oxidation mechanism is based on hydrocarbon oxidation, but recent work suggests that it may actually be due to the decomposition of peracids resulting from the oxidation of primary decomposition products.[12]

Polyacrylics

Poly(methyl methacrylate) (PMMA): PMMA is a favorite material for use in fire research since it decomposes almost solely to monomer, and burns at a very steady rate. Methyl groups effectively block intramolecular H transfer as discussed in the General Chemical Mechanisms section, leading to a high monomer yield. The method of polymerization can markedly affect the temperatures at which decomposition begins. Free-radical polymerized PMMA decomposes around 545 K, with initiation occurring at double bonds at chain ends. A second peak between 625 and 675 K in dynamic TGA thermograms is the result of a second initiation reaction. At these temperatures, initiation is by both end-chain and random-chain initiation processes. Anionically produced PMMA decomposes at about 625 K because the end-chain initiation step does not occur due to the lack of double bonds at the chain end when PMMA is polymerized by this method. This may explain the range of observed piloted ignition temperatures (550 to 600 K). Decomposition of PMMA is first order with an activation energy of 120 to 200 kJ/mol, depending on the end group. The rate of decomposition is also dependent on the tacticity of the polymer and on its molecular weight. These effects can also have a profound effect on the flame spread rate.

It is interesting to note that a chemically cross-linked copolymer of PMMA was found to decompose by forming an extensive char, rather than undergoing end-chain scission which resulted in a polymer with greater thermal stability.[53]

Poly(methyl acrylate) (PMA): Poly(methyl acrylate) decomposes by random-chain scission rather than end-chain scission, with almost no monomer formation. This results because of the lack of a methyl group blocking intramolecular hydrogen transfer as occurs in PMMA. Initiation is followed by intra- and intermolecular hydrogen transfer.

Polyacrylonitrile (PAN): PAN begins to decompose exothermically between 525 K and 625 K with the evolution of small amounts of ammonia and hydrogen cyanide. These products accompany cyclization reactions involving the creation of linkages between nitrogen and carbon on adjacent side groups. (See Figure 1-7.8.) The gaseous products are not the result of the cyclization itself, but arise from the splitting off of side or end groups not involved in the cyclization. The ammonia is derived principally from terminal imine groups (NH) while HCN results from side groups that do not participate in the polymerization-like cyclization reactions. When the polymer is not isotactic, the cyclization process is terminated when hydrogen is abstracted by the nitrogen atom. The cyclization process is reinitiated as shown in Figure 1-7.9.

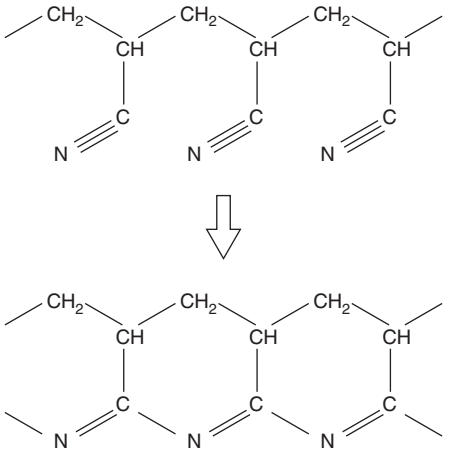


Figure 1-7.8. ***PAN cyclization.***

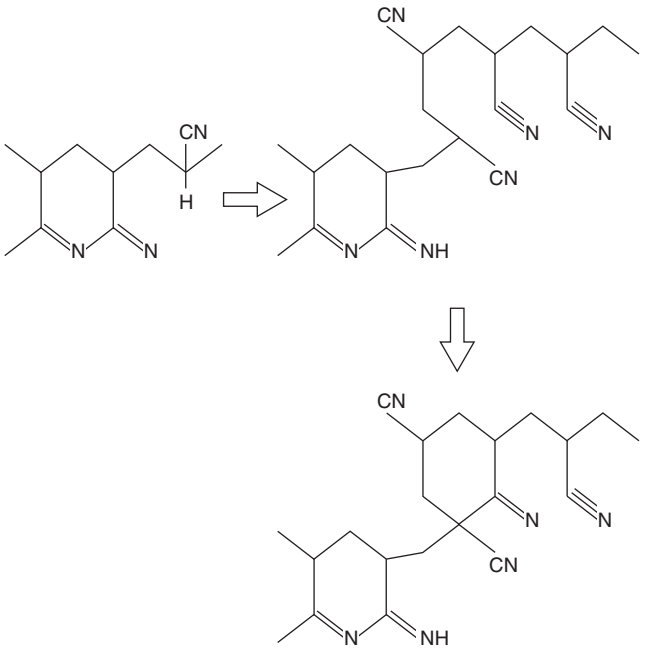

Figure 1-7.9. ***Reinitiation of PAN side-chain cyclization.***

This leaves CN groups not involved in the cyclization which are ultimately removed and appear among the products as HCN. Typically, there are between 0 and 5 chain polymerization steps between each hydrogen abstraction. At temperatures of 625 to 975 K, hydrogen is evolved as the cyclic structures carbonize. At higher temperatures, nitrogen is evolved as the char becomes nearly pure carbon. In fact, with adequate control of the process, this method can be used to produce carbon fibers. Oxygen stabilizes PAN, probably by reacting with initiation sites for the nitrile polymerization. The products of oxidative decomposition are highly conjugated and contain ketonic groups.

Halogenated Polymers

Poly(vinyl chloride) (PVC): The most common halogenated polymer is PVC; it is one of the three most widely used polymers in the world, with polyethylene and polypropylene. Between 500 and 550 K, hydrogen chloride gas is evolved nearly quantitatively, by a chain-stripping mechanism. It is very important to point out, however, that the temperature at which hydrogen chloride starts being evolved in any measurable way is heavily dependent on the stabilization package used. Thus, commercial PVC "compounds" have been shown, in recent work, not to evolve hydrogen chloride until temperatures are in excess of 520 K and to have a dehydrochlorination stage starting at 600 K.[54] Between 700 and 750 K, hydrogen is evolved during carbonization, following cyclization of the species evolved. At higher temperatures, cross-linking between chains results in a fully carbonized residue. The rate of dehydrochlorination depends on the molecular weight, crystallinity, presence of oxygen, hydrogen chloride gas, and stabilizers. The presence of oxygen accelerates the dehydrochlorination process, produces main-chain scissions, and reduces cross-linking. At temperatures above 700 K, the char (resulting from dehydrochlorination and further dehydrogenation) is oxidized, leaving no residue. Lower molecular weight increases the rate of dehydrochlorination. Dehydrochlorination stabilizers include zinc, cadmium, lead, calcium, and barium soaps and organotin derivatives. The stability of model compounds indicates that weak links are important in decomposition. The thermal decomposition of this polymer has been one of the most widely studied ones. It has been the matter of considerable controversy, particularly in terms of explaining the evolution of aromatics in the second decomposition stage. The most recent evidence seems to point to a simultaneous cross-linking and intramolecular decomposition of the polyene segments resulting from dehydrochlorination, via polyene free radicals.[54] Earlier evidence suggested a Diels-Alder cyclization process (which can only be intramolecular if the double bond ends up in a "cis" orientation).[55] Evidence for this was given by the fact that smoke formation (inevitable consequence of the emission of aromatic hydrocarbons) was decreased by introducing cross-linking additives into the polymer.[56] Thus, it has now become clear that formation of any aromatic hydrocarbon occurs intramolecularly. The chemical mechanism for the initiation of dehydrochlorination was also reviewed a few years ago.[57] More recently, a series of papers was published investigating the kinetics of chain stripping, based on PVC.[58]

Chlorinated poly(vinyl chloride) (CPVC): One interesting derivative of PVC is chlorinated PVC (CPVC), resulting from post-polymerization chlorination of PVC. It decomposes at a much higher temperature than PVC, but by the same chain-stripping mechanism. The resulting solid is a polyacetylene, which gives off much less smoke than PVC and is also more difficult to burn.[59]

Poly(tetrafluoroethylene) (PTFE): PTFE is a very stable polymer due to the strength of C–F bonds and shielding by the very electronegative fluorine atoms. Decomposition starts occurring between 750 and 800 K. The principal product of decomposition is the monomer, CF_4, with small amounts of hydrogen fluoride and hexafluoropropene. Decomposition is initiated by random-chain scission, followed by depolymerization. Termination is by disproportionation. It is possible that the actual product of decomposition is CF_2, which immediately forms in the gas phase. The stability of the polymer can be further enhanced by promoting chain transfer reactions that can effectively limit the zip length. Under conditions of oxidative pyrolysis, no monomer is formed. Oxygen reacts with the polymeric radical, releasing carbon monoxide, carbon dioxide, and other products.

Other fluorinated polymers are less stable than PTFE and are generally no more stable than their unfluorinated analogs. However, the fluorinated polymers are more stable in an oxidizing atmosphere. Hydrofluorinated polymers produce hydrogen fluoride directly by chain-stripping reactions, but the source of hydrogen fluoride by perfluorinated polymers, such as PTFE, is less clear. It is

related to the reaction of the decomposition products (including tetrafluoroethylene) with atmospheric humidity.

Other Vinyl Polymers

Several other vinyl polymers decompose by mechanisms similar to that of PVC: all those that have a single substituent other than a hydrogen atom on the basic repeating unit. These include poly(vinyl acetate), poly(vinyl alcohol), and poly(vinyl bromide), and result in gas evolution of acetic acid, water, and hydrogen bromide, respectively. While the chain-stripping reactions of each of these polymers occur at different temperatures, all of them aromatize by hydrogen evolution at roughly 720 K.

Styrenics: *Polystyrene (PS).* Polystyrene shows no appreciable weight loss below 575 K, though there is a decrease in molecular weight due to scission of "weak" links. Above this temperature, the products are primarily monomer with decreasing amounts of dimer, trimer, and tetramer. There is an initial sharp decrease in molecular weight followed by slower rates of molecular weight decrease. The mechanism is thought to be dominated by end-chain initiation, depolymerization, intramolecular hydrogen transfer, and bimolecular termination. The changes in molecular weight are principally due to intermolecular transfer reactions while volatilization is dominated by intramolecular transfer reactions. Depropagation is prevalent despite the lack of steric hindrance due to the stabilizing effect of the electron delocalization associated with the aromatic side group. The addition of an alpha methyl group to form poly(α-methylstyrene) provides additional steric hindrance such that only monomer is produced during decomposition while the thermal stability of the polymer is lessened. Free-radical polymerized polystyrene is less stable than anionic polystyrene with the rate of decomposition dependent on the end group.

Other styrenics tend to be copolymers of polsytyrene with acrylonitrile (SAN), acrylonitrile and butadiene (ABS), or methyl methacrylate and butadiene (MBS), and their decomposition mechanisms are hybrids between those of the individual polymers.

Synthetic Carbon–Oxygen Chain Polymers

Poly(ethylene terephthalate) (PET): PET decomposition is initiated by scission of an alkyl–oxygen bond. The decomposition kinetics suggest a random-chain scission. Principal gaseous products observed are acetaldehyde, water, carbon monoxide, carbon dioxide, and compounds with acid and anhydride end groups. The decomposition is accelerated by the presence of oxygen. Recent evidence indicates that both PET and PBT [poly(butylene terephthalate)] decompose via the formation of cyclic or open-chain oligomers, with olefinic or carboxylic end groups.[60]

Polycarbonates (PC): Polycarbonates yield substantial amounts of char if products of decomposition can be removed (the normal situation). If volatile products are not removed, no cross-linking is observed due to competition between condensation and hydrolysis reactions. The decomposition is initiated by scission of the weak O–CO_2 bond, and the volatile products include 35 percent carbon dioxide. Other major products include bisphenol A and phenol. The decomposition mechanism seems to be a mixture of random-chain scission and cross-linking, initiated intramolecularly.[61] Decomposition begins at 650 to 735 K, depending on the exact structure of the polycarbonate in question.

Blends of polycarbonate and styrenics (such as ABS) make up a set of *engineered thermoplastics.* Their properties are intermediate between those of the forming individual polymers, both in terms of physical properties (and processability) and in terms of their modes of thermal breakdown.

Phenolic resins: Phenolic resin decomposition begins at 575 K and is initiated by the scission of the methylene–benzene ring bond. At 633 K, the major products are C_3 compounds. In continued heating (725 K and higher), char (carbonization), carbon oxides, and water are formed. Above 770 K, a range of aromatic, condensable products are evolved. Above 1075 K, ring breaking yields methane and carbon oxides. In TGA experiments at 3.3°C/min, the char yield is 50 to 60 percent. The weight loss at 700 K is 10 percent. All decomposition is oxidative in nature (oxygen provided by the polymer itself).

Polyoxymethylene (POM): Polyoxymethylene decomposition yields formaldehyde almost quantitatively. The decomposition results from end-chain initiation followed by depolymerization. The presence of oxygen in the chain prevents intramolecular hydrogen transfer quite effectively. With hydroxyl end groups, decomposition may begin at temperatures as low as 360 K while with ester end groups decomposition may be delayed to 525 K. Piloted ignition due to radiative heating has been observed at a surface temperature of 550 K. Acetylation of the chain end group also improves stability. Upon blocking the chain ends, decomposition is by random-chain initiation, followed by depolymerization with the zip length less than the degree of polymerization. Some chain transfer occurs. Amorphous polyoxymethylene decomposes faster than crystalline polyoxymethylene, presumably due to the lack of stabilizing intermolecular forces associated with the crystalline state (below the melting temperature). Incorporating oxyethylene in polyoxymethylene improves stability, presumably due to H transfer reactions that stop unzipping. Oxidative pyrolysis begins at 430 K and leads to formaldehyde, carbon monoxide, carbon dioxide, hydrogen, and water vapor.

Epoxy resins: Epoxy resins are less stable than phenolic resins, polycarbonate, polyphenylene sulphide, and polytetrafluoroethelyne. The decomposition mechanism is complex and varied and usually yields mainly phenolic compounds. A review of epoxy resin decomposition can be found in Lee.[43]

Polyamide Polymers

Nylons: The principal gaseous products of decomposition of nylons are carbon dioxide and water. Nylon 6

produces small amounts of various simple hydrocarbons while Nylon 6–10 produces notable amounts of hexadienes and hexene. As a class, nylons do not notably decompose below 615 K. Nylon 6–6 melts between 529 and 532 K, and decomposition begins at 615 K in air and 695 K in nitrogen. At temperatures in the range 625 to 650 K, random-chain scissions lead to oligomers. The C–N bonds are the weakest in the chain, but the $CO–CH_2$ bond is also quite weak, and both are involved in decomposition. At low temperatures, most of the decomposition products are nonvolatile, though above 660 K main chain scissions lead to monomer and some dimer and trimer production. Nylon 6–6 is less stable than nylon 6–10, due to the ring closure tendency of the adipic acid component. At 675 K, if products are removed, gelation and discoloration begin.

Aromatic polyamides have good thermal stability, as exemplified by Nomex, which is generally stable in air to 725 K. The major gaseous products of decomposition at low temperatures are water and carbon oxides. At higher temperatures, carbon monoxide, benzene, hydrogen cyanide (HCN), toluene, and benzonitrile are produced. Above 825 K, hydrogen and ammonia are formed. The remaining residue is highly cross-linked.

Wool: On decomposition of wool, a natural polyamide, approximately 30 percent is left as a residue. The first step in decomposition is the loss of water. Around 435 K, some cross-linking of amino acids occurs. Between 485 and 565 K, the disulphide bond in the amino acid cystine is cleaved with carbon disulphide and carbon dioxide being evolved. Pyrolysis at higher temperatures (873 to 1198 K) yields large amounts of hydrogen cyanide, benzene, toluene, and carbon oxides.

Polyurethanes

As a class, polyurethanes do not break down below 475 K, and air tends to slow decomposition. The production of hydrogen cyanide and carbon monoxide increases with the pyrolysis temperature. Other toxic products formed include nitrogen oxides, nitriles, and tolylene diisocyanate (TDI) (and other isocyanates). A major breakdown mechanism in urethanes is the scission of the polyol–isocyanate bond formed during polymerization. The isocyanate vaporizes and recondenses as a smoke, and liquid polyol remains to further decompose.

Polydienes and Rubbers

Polyisoprene: Synthetic rubber or polyisoprene decomposes by random-chain scission with intramolecular hydrogen transfer. This, of course, gives small yields of monomer. Other polydienes appear to decompose similarly though the thermal stability can be considerably different. The average size of fragments collected from isoprene decomposition are 8 to 10 monomer units long. This supports the theory that random-chain scission and intermolecular transfer reactions are dominant in the decomposition mechanism. In nitrogen, decomposition begins at 475 K. At temperatures above 675 K, increases in monomer yield are attributable to secondary reaction of volatile products to form monomer. Between 475 and 575 K, low molecular weight material is formed, and the residual material is progressively more insoluble and intractable. Preheating at between 475 and 575 K lowers the monomer yield at higher temperatures. Decomposition at less than 575 K results in a viscous liquid and, ultimately, a dry solid. The monomer is prone to dimerize to dipentene as it cools. There seems to be little significant difference in the decomposition of natural rubber and synthetic polyisoprene.

Polybutadiene: Polybutadiene is more thermally stable than polyisoprene due to the lack of branching. Decomposition at 600 K can lead to monomer yields of up to 60 percent, with lower conversions at higher temperatures. Some cyclization occurs in the products. Decomposition in air at 525 K leads to a dark impermeable crust, which excludes further air. Continued heating hardens the elastomer.

Polychloroprene: Polychloroprene decomposes in a manner similar to PVC, with initial evolution of hydrogen chloride at around 615 K and subsequent breakdown of the residual polyene. The sequences of the polyene are typically around three (trienes), much shorter than PVC. Polychloroprene melts at around 50°C.

Cellulosics

The decomposition of cellulose involves at least four processes in addition to simple desorption of physically bound water. The first is the cross-linking of cellulose chains, with the evolution of water (dehydration). The second concurrent reaction is the unzipping of the cellulose chain. Laevoglucosan is formed from the monomer unit. (See Figure 1-7.10.) The third reaction is the decomposition of the dehydrated product (dehydrocellulose) to yield char and volatile products. Finally, the laevoglucosan can further decompose to yield smaller volatile products, including tars and, eventually, carbon monoxide. Some laevoglucosan may also repolymerize.

Below 550 K, the dehydration reaction and the unzipping reaction proceed at comparable rates, and the basic skeletal structure of the cellulose is retained. At higher temperatures, unzipping is faster, and the original structure of the cellulose begins to disappear. The cross-linked dehydrated cellulose and the repolymerized laevoglucosan begin to yield polynuclear aromatic structures, and graphite carbon structures form at around 770 K. It is well known that the char yield is quite dependent on the rate of heating of the sample. At very high rates of heating, no char is formed. On the other hand, preheating the sample at 520 K will lead to 30 percent char yields. This is due both to the importance of the low-temperature dehydration reactions for ultimate char formation and the increased opportunity for repolymerization of laevoglucosan that accompanies slower heating rates.

Wood is made up of 50 percent cellulose, 25 percent hemicellulose, and 25 percent lignin. The yields of gaseous products and kinetic data indicate that the decomposition may be regarded as the superposition of the

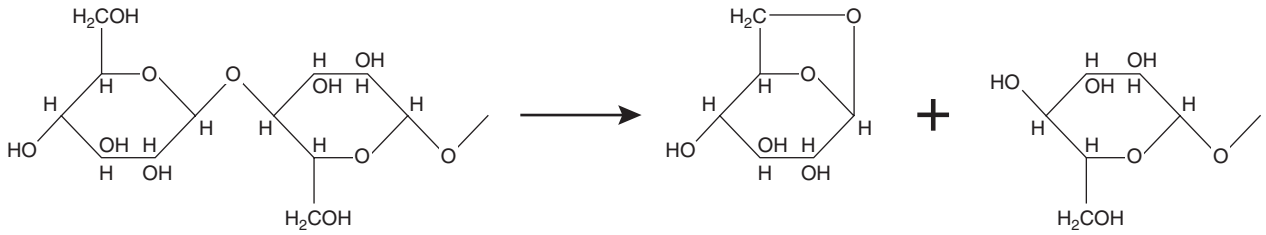

Figure 1-7.10. ***Formation of laevoglucosan from cellulose.***

individual constituent's decomposition mechanisms. On heating, the hemicellulose decomposes first (475 to 535 K), followed by cellulose (525 to 625 K), and lignin (555 to 775 K). The decomposition of lignin contributes significantly to the overall char yield. Piloted ignition of woods due to radiative heating has been observed at a surface temperature of 620 to 650 K.

Polysulfides and Polysulphones

Polysulfides are generally stable to 675 K. Poly(1, 4 phenylene sulfide) decomposes at 775 K. Below this temperature, the principal volatile product is hydrogen sulfide. Above 775 K, hydrogen, evolved in the course of cross-linking, is the major volatile product. In air, the gaseous products include carbon oxides and sulfur dioxide.

The decomposition of polysulphones is analogous to polycarbonates. Below 575 K, decomposition is by heteroatom bridge cleavage, and above 575 K, sulfur dioxide is evolved from the polymer backbone.

Thermally Stable Polymers

The development of thermally stable polymers is an area of extensive ongoing interest. Relative to many other materials, polymers have fairly low use temperatures, which can reduce the utility of the product. This probable improvement in fire properties is, often, counterbalanced by a decrease in processability and in favorable physical properties. Of course, materials that are stable at high temperatures are likely to be better performers as far as fire properties are concerned. The high-temperature physical properties of polymers can be improved by increasing interactions between polymer chains or by chain-stiffening.

Chain interactions can be enhanced by several means. As noted previously, crystalline materials are more stable than their amorphous counterparts as a result of chain interactions. Of course, if a material melts before volatilization occurs, this difference will not affect chemical decomposition. Isotactic polymers are more likely to be crystalline due to increased regularity of structure. Polar side groups can also increase the interaction of polymer chains. The melting point of some crystalline polymers is shown in Table 1-7.1.

The softening temperature can also be increased by chain-stiffening. This is accomplished by the use of aromatic or heterocyclic structures in the polymer backbone. Some aromatic polymers are shown in Figure 1-7.11. Poly(p-phenylene) is quite thermally stable but is brittle, insoluble, and infusible. Thermal decomposition begins at 870 to 920 K; and up to 1170 K, only 20 to 30 percent of the original weight is lost. Introduction of the following groups:

$$–O–,\ –CO–,\ –NH–,\ –CH_2–,\ –O–CO–,\ –O–CO–O–$$

into the chain can improve workability though at the cost of some loss of oxidative resistance. Poly(p-xylene) melts at 675 K and has good mechanical properties though it is insoluble and cannot be thermoprocessed. Substitution of halogen, acetyl, alkyl, or ester groups on aromatic rings can help the solubility of these polymers at the expense of some stability. Several relatively thermostable polymers can be formed by condensation of bisphenol A with a second reagent. Some of these are shown in Figure 1–7.12. The stability of such polymers can be improved if aliphatic groups are not included in the backbone, as the $–C(CH_3)_2–$ groups are weak links.

Other thermostable polymers include ladder polymers and extensively cross-linked polymers. Cyclized PAN is an example of a ladder polymer where two chains are periodically interlinked. Other polymers, such as rigid polyurethanes, are sufficiently cross-linked so that it becomes impossible to speak of a molecular weight or

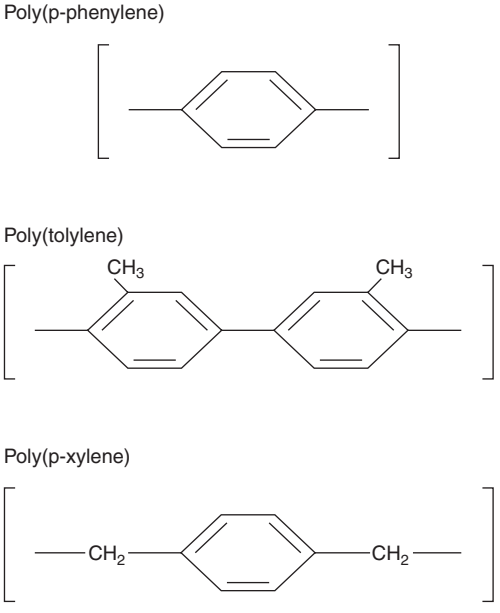

Figure 1-7.11. ***Thermostable aromatic polymers.***

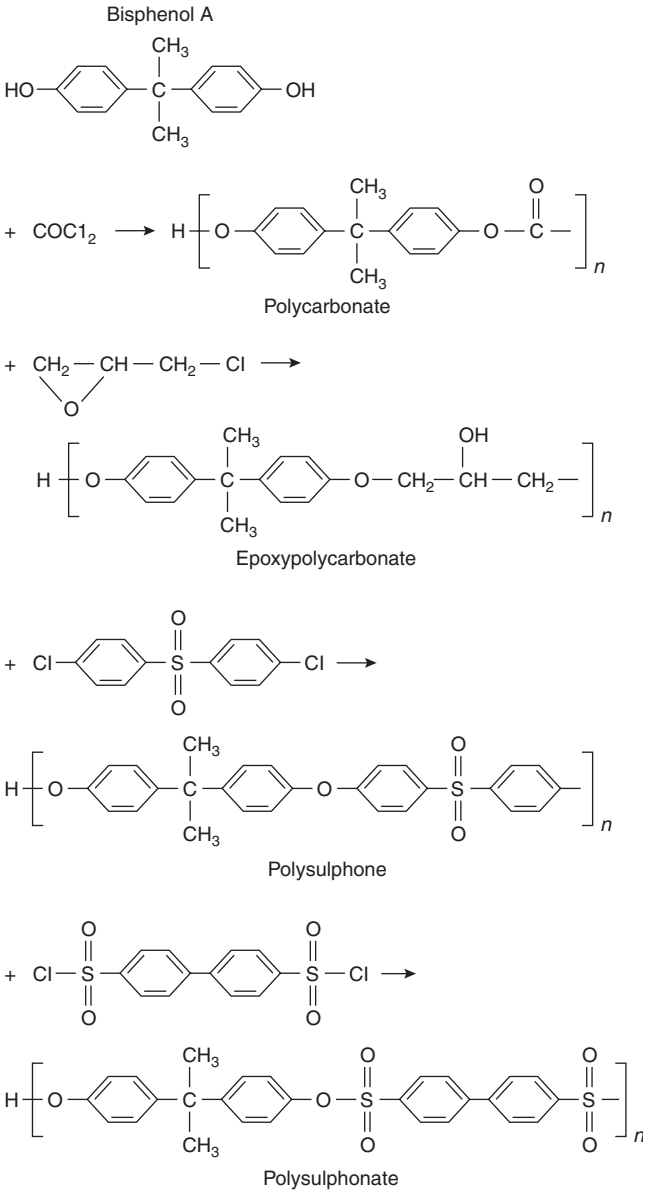

Figure 1-7.12. ***Bisphenol A polymers.***

definitive molecular repeating structure. As in polymers that gel or cross-link during decomposition, cross-linking of the original polymer yields a carbonized char residue upon decomposition, which can be oxidized at temperatures over 775 K.

CHAPTER 8

Structural Mechanics

Robert W. Fitzgerald

Introduction

Structural mechanics is the analysis of the external and internal force systems of structural members, as well as the behavior of those members under loading conditions. Before describing the different types of members and their structural characteristics, it is helpful to describe briefly the structural design process.

Structural design follows roughly the same stages of design as the architectural process. During the schematic stage when the building layout is being created, the structural engineer and the architect identify column locations. Then, a number of different framing schemes utilizing the different structural materials are considered. A design is made for each potential framing alternative for a part of the building that is representative of a major segment of the structure. Economic and functional analyses are made with the different alternatives. The architect and structural engineer select the framing system that is best for the specific building being designed.

After the schematic design has been completed and accepted, the detail design and contract documents stages are undertaken. During these stages, all of the structural members and the important details are designed. Critical design connections, significant construction details, and specifications are developed to ensure a complete and adequate structural system.

The structural design must conform to accepted professional practice at the time. Regardless of materials, this involves three major interrelated considerations. They are

1. The appropriate loading conditions and combinations
2. Structural mechanics
3. Control parameter limits

Dr. Robert W. Fitzgerald is professor of civil and fire protection engineering at Worcester Polytechnic Institute. His major activities are in structural engineering and in building design and technology for fire safety.

The objective of structural design is to select materials and dimensions so that economy is achieved and the building will perform satisfactorily. Performance here means that the structure is compatible with architectural needs and is free from excessive deflection and vibration. Prevention of collapse under expected or reasonably foreseen conditions is included in performance, and safety is a major part of the professional responsibility.

A major aspect of structural engineering is the recognition of conditions that can lead to failure. When these conditions are present, the designer must proportion the members or take other measures to ensure that failure under design conditions will not occur. The identification of loads, selection of engineering calculation models, and the establishment of control parameter limits are all interwoven. Figure 1-8.1 shows a schematic relationship of these components. Although each component may be addressed separately, their interrelationships comprise the unification of the design methodology. Together they allow performance to be monitored.

The loading conditions of Figure 1-8.1 are generally specified in the building code. They include live load values for floor systems, snow and ice, wind, and earthquake. The engineer also will include the dead load for

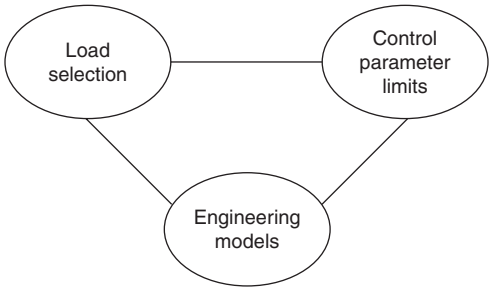

Figure 1-8.1. ***Components of the design methodology.***

the framing system and any special loading that may be expected for the structure being considered.

The engineering models involve two considerations. One is the mechanics of computing the internal forces that result from the loading, dimensions, and support conditions. The other is the relationship between these internal forces and the performance function. This performance function relates the internal forces to control parameters. Stress is the most convenient control parameter, although others, such as deflection, are used also.

Structural mechanics is the engineering science that enables the engineer to calculate the internal shear, moment, and axial force and the related stresses at any location in the structural member for any combination of loads. In addition, it describes the behavior of the member as loads are increased up to failure. This is dependent on the materials involved, the type of loading, and the geometric and support conditions of the member. The behavior includes deformations, vibrations, and failure modes. Structural mechanics may be considered as the "exact" analytical part of the design process.

Another consideration in Figure 1-8.1 involves the specific design requirements for the materials and assembly. These are developed by the different products industries. For example, the American Institute of Steel Construction (AISC) publishes its code of practice,[1] and the American Concrete Institute (ACI) publishes its building code.[2] These publications, often called *codes* by the engineers, give requirements on design and construction that will avoid failure for normal usage. The values for allowable stress are the most common limits. These values are empirically selected considering theoretical mechanical behavior for the material and practical applications. When a designer uses building code loadings with allowable stresses and other control criteria through the mechanism of the engineering models, one can have confidence that the member probably will not fail. The control performance consideration is normally deflection, even though the calculations usually involve stress. Stress and deformation are, of course, related.

The reliability of structural design has evolved through consideration of the entire process. Although individual parts can be examined by in-depth research, the process as a whole is considered in design. Values for loading and codified limits of the parameters are established by the end performance to be achieved.

Professional structural practice integrates the loadings, usually obtained from the local building code or from the conditions that may reasonably be expected by the engineer, with the structural (mechanical) analysis and the design procedures of the structural code. The structural codes are updated periodically, usually about every five to ten years. The literature of the profession can keep the engineer aware of new developments in the field.

With this brief discussion of the structural design process, we will now describe briefly the elements of structural mechanics. In general, this may be grouped as the calculation of external reactions and internal forces and the prediction of failure modes for different materials, geometry, support conditions, and loads.

Statical Analysis for Reactions

The calculation of external reactions of a defined structural element for a given loading condition is the first part of the statical analysis. For planar structures, the available equations of statics are $\sum F_x = 0$, $\sum F_y = 0$, and $\sum M = 0$. For three-dimensional structures, $\sum F_z = 0$, $\sum M = 0$, about the other axes are added. Therefore, for planar structures, one can calculate as many as three unknown reactions on each free body diagram by statical analysis. For three-dimensional structures, one can calculate as many as six unknowns. For this discussion, we will consider only planar structures.

EXAMPLE 1:

To illustrate this process, consider the beam *ABC* of Figure 1-8.2. The supports include a pin at *B* and a roller at *C*. Figure 1-8.2(b) shows the free body of this beam. The reactions are computed as follows:

$$\sum M_B = 0:$$

$$C_y(18) - (1)(24)(6) - \left(\frac{1}{2}\right)(2)(18)(12) + 6(6) = 0$$

$$C_y = 18 \text{ k}$$

$$\sum M_C = 0:$$

$$B_y(18) - (1)(24)(12) - \left(\frac{1}{2}\right)(2)(18)(6) - 6(24) = 0$$

$$B_y = 30 \text{ k}$$

$$\sum F_x = 0: \; B_x = 8 \text{ k}$$

Since there were only three reaction components, one could calculate all three by means of statics alone. The structure would be described as statically determinate. However, if an additional support were introduced, as shown in Figure 1-8.3, four reaction components would exist. Since only three equations of statics are available, all of these reactions cannot be calculated by means of statics alone. The structure of Figure 1-8.3 would be described as statically indeterminate. Means other than statics alone are needed to calculate the reactions. Generally, these techniques involve either superposition or relaxation methods of analysis.

Statical Analysis for Internal Forces

After the external reactions have been calculated, the characteristics of the internal shear, moment, and axial force are determined. This may be computed by cutting the member at the desired location and drawing a free body diagram of one segment.

EXAMPLE 2:

Figure 1-8.4 shows a free body diagram for a section a distance, *x*, between *B* and *C* of the beam of Figure 1-8.2. The internal forces are the shear, *V*; the bending moment,

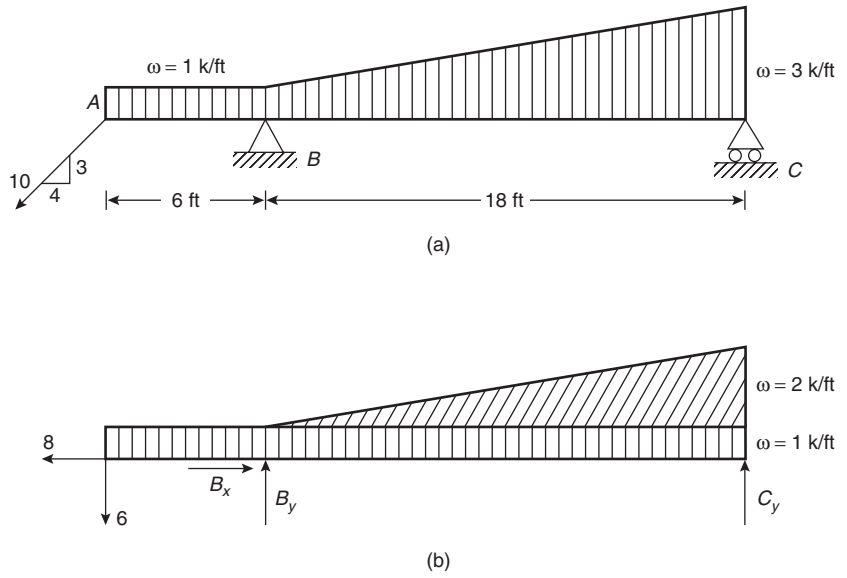

Figure 1-8.2. ***Statically determinate beam.***

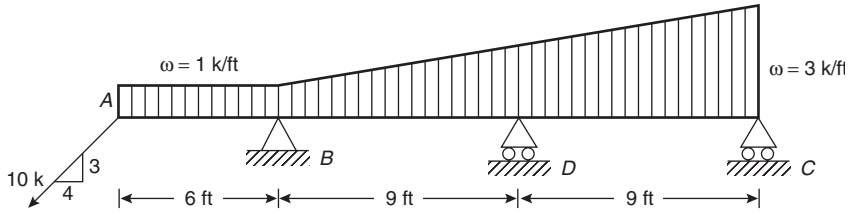

Figure 1-8.3. ***Statically indeterminate beam.***

M; and the normal force, N. These forces are calculated from the free body diagram of Figure 1-8.4 as follows:

$$\sum M_{cut} = 0: \quad M + \frac{1(6+x)(6+x)}{2} + \frac{1}{2}\left(\frac{x}{9}\right)(x)\left(\frac{x}{3}\right) + 6(x+6) - 30(x) = 0$$

$$M = -\frac{x^3}{54} - \frac{x^2}{2} + 18x - 54$$

$$\sum F_y = 0: \quad V + 1(x+6) + \frac{1}{2}\left(\frac{x}{9}\right)(x) + 6 - 30 = 0$$

$$V = -\frac{x^2}{18} - x + 18$$

$$\sum F_x = 0: \quad N = 8$$

The distribution of the internal forces may be plotted on diagrams that show the change in values throughout the length of the beam. Figure 1-8.5 shows the N, V, and M diagrams for the beam of Figure 1-8.2.

Failure Modes

Structural design consists of identifying all of the potential failure modes and providing resistance to avoid failure. Both safety and economy are considerations. A major part of the professional engineering services is the skill in identifying appropriate loading conditions and the associated failure modes for the construction conditions.

The ways in which members fail depend upon the materials, geometry, loading conditions, and support conditions. This section will describe the common structural forms and the failure modes generally associated with those forms.

Tension Members

Figure 1-8.6 illustrates tensile loading on a straight member. The stress in the member is defined as $\sigma = P/A$. The load must be applied through the centroid of the cross section for this equation to be valid. When loads are applied eccentrically to the cross section, a combined bending and axial condition exists. This will be described later.

Figure 1-8.7(a) shows relationship between unit stress, $\sigma = P/A$, and unit strain, $\varepsilon = \delta/L$, for a coupon of mild structural steel. This stress-strain diagram is obtained experimentally and depicts only mild structural steel loaded in tension. Stress-strain diagrams for other materials are also obtained experimentally and show distinctly different load-deformation characteristics.

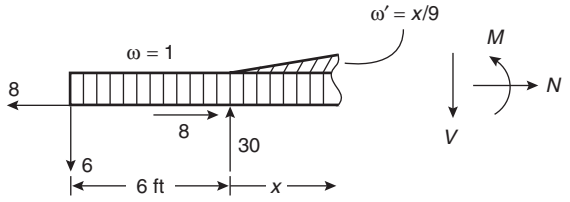

Figure 1-8.4. ***Free body diagram.***

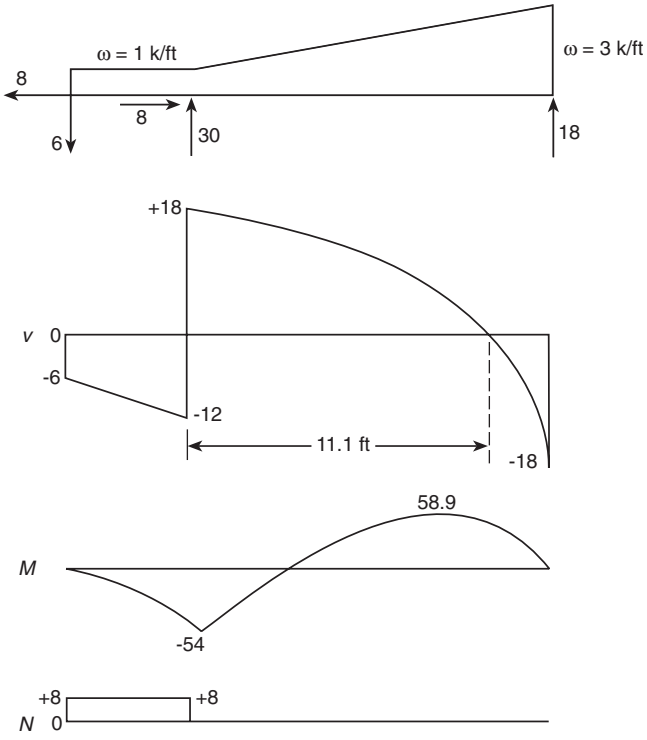

Figure 1-8.5. ***Shear, moment and normal force diagram.***

Figure 1-8.6. ***Tensile loading of a straight member.***

The stress-strain diagram provides an indication of the expected failure mode of the member. A ductile material, such as the mild steel in Figure 1-8.7(a), will elongate significantly under tensile loading. Frequently, the deformations are so great that the structure becomes unusable long before actual rupture. Rupture eventually will occur if loads are increased to the ultimate stress. Brittle materials, such as those shown in Figure 1-8.7(b), will fail by sudden rupture. Little or no warning of impending failure may be present with materials of this type.

There are situations in which a normally ductile material will exhibit a brittle type of failure. This occurs under conditions of low temperature or repeated, fatigue loading conditions.

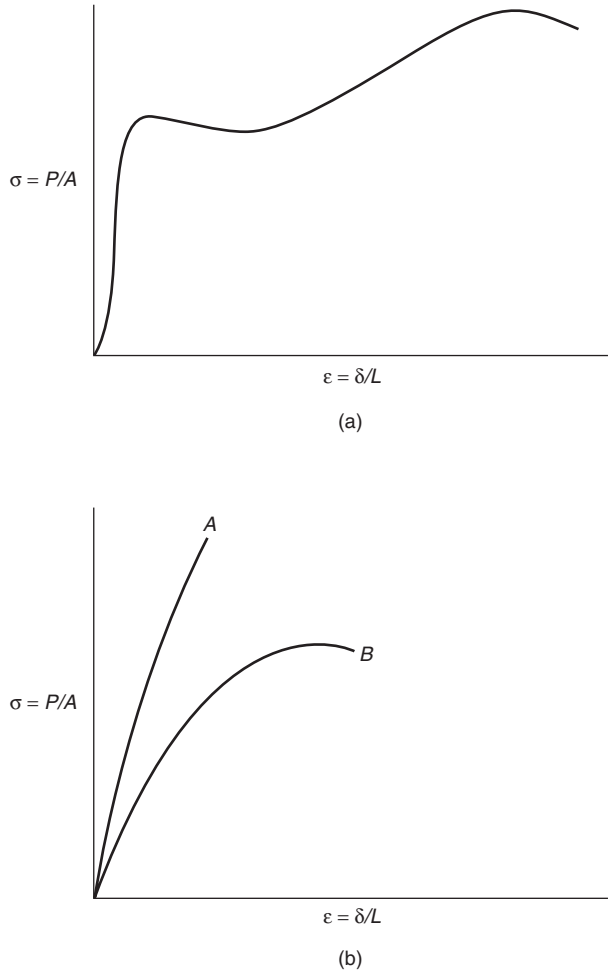

Figure 1-8.7. ***Stress-strain diagram for (a) ductile and (b) brittle materials.***

High temperatures, such as those present in building fires, will cause an increase in the elongation of tension members because of creep. Creep is the phenomenon in which a member will continue to deform after the applied load becomes steady. The magnitude of creep depends upon the material being loaded, the level of stress, the temperature, and the time duration.

Other potential failure modes for tension members include connection failures, excessive stress concentrations due to changes in cross sections, and twisting when unsymmetrical members are excessively long.

Compression Members

Figure 1-8.8 illustrates compressive loading on a member. When the loading is applied along the centroidal axis of the member, the stress may be calculated as $\sigma = P/A$. The importance of centroidal loading is even more critical for compressive forces than for tensile forces because of the magnification effect of eccentricity. This will be discussed more completely later.

Compression members, unlike tension members, have no single general failure mode, regardless of their

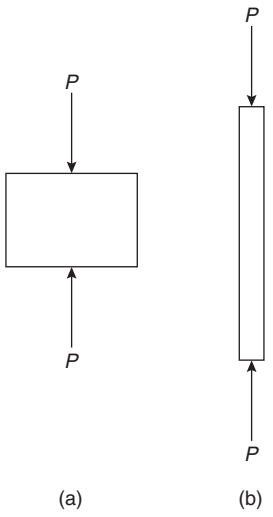

Figure 1-8.8. ***Compressive loading of (a) short and (b) long columns.***

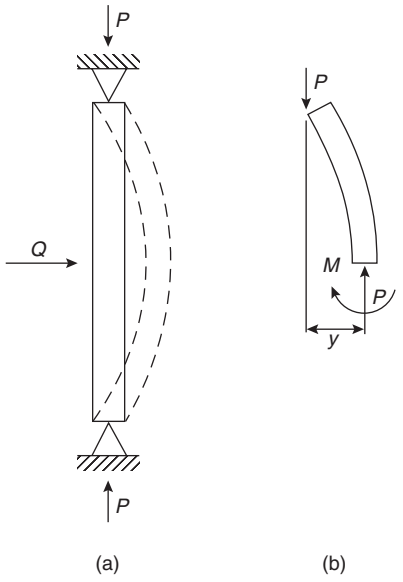

Figure 1-8.9. ***Column buckling.***

length. Short columns, as illustrated by Figure 1-8.8(a), fail by general yielding. Long columns, as illustrated by Figure 1-8.8(b), fail by buckling. Buckling is the rapid collapse of a compression member due to instability. To describe the nature of column behavior, the following discussion may be helpful.

Consider the column shown in Figure 1-8.8(b). Assume that the axial compressive load P starts at a low value and gradually increases in magnitude. Assume a small lateral force is applied, as shown in Figure 1-8.9(a). The bar will deflect laterally by a small amount. When Q is removed, the bar returns to its original position. When a particular value of P is reached, the bar will remain in the deflected position after Q is removed. That load for which the bar is indifferent to its position is defined as the critical buckling load, P_{cr}. If P were increased above P_{cr}, the bar would collapse. If P were decreased below P_{cr}, the bar would return to its straight P position. The critical buckling load is, therefore, the particular load at which neutral equilibrium occurs.

Considering the equilibrium condition when the bar is deformed, we may determine the bending moment from Figure 1-8.9(b), as

$$\sum M_{cut} = 0: \quad M = -Py$$

The equation of the elastic curve of a beam[3] is $d^2y/dx^2 = M/EI$. Substituting this for M above, we obtain

$$\frac{d^2y}{dx^2} + \frac{Py}{EI} = 0$$

Letting $\kappa^2 = P/EI$ and solving this differential equation yields $y = A \cos(\kappa x) + B \sin(\kappa x)$.

Using the boundary conditions of $y = 0$ at $x = 0$ and $y = 0$ at $x = L$, we obtain $A = 0$ and $B \sin(\kappa L) = 0$. Since B cannot be zero, $\sin(\kappa L) = 0$. This eigenvalue equation has solutions of

$$\kappa L = 0, \pi, 2\pi, 3\pi, \ldots, n\pi$$

Taking the general solution we obtain

$$\kappa L = n\pi, \qquad \frac{P}{EI} = \frac{n\pi}{L}$$

$$P = \frac{n^2\pi^2 EI}{L^2}$$

The n-term describes the number of modes of buckling. Since the first mode of buckling will cause failure unless special construction features exist, buckling will occur at $P_{cr} = \pi^2 EI/L^2$.

This column equation was originally described in 1757 by Leonhard Euler, a Swiss mathematician. Controversy about its validity for predicting column loads raged for sixty years. In 1820 it was recognized that the derivation incorporated the bending equation, $\sigma = Mc/I$. Consequently, all assumptions of elastic behavior are intrinsic to the use of the Euler column equation. Therefore, the limit of validity is the proportional limit of the material.

Two clearly identifiable compression failure conditions can exist. One is the yielding condition for short columns where $P = \sigma_y A$, as illustrated in Figure 1-8.8(a). The second is the buckling of long, slender columns, where $P_{cr} = \pi^2 EI/L^2$. This equation may be converted into one involving axial stress by recognizing that $I = Ar^2$, where r is the radius of gyration of the cross-section. Dividing both sides by A gives

$$\sigma_{cr} = \frac{\pi^2 E}{(L/r)^2}$$

The term L/r is defined as the slenderness ratio. Therefore, column slenderness is a function both of the length and the cross-sectional geometry, as described by the radius of gyration, *r.*

If the critical stress versus the slenderness ratio were plotted for columns, the graph of Figure 1-8.10 would result. The segment from *C* to *D* describes long columns in which the critical buckling load may be calculated from Euler's equation. The failure mode is pure buckling, and the limit of validity of the equation is the proportional limit of the material, σ_{PL}. The segment from *A* to *B* identifies short columns, which fail by yielding. The maximum load is $P = \sigma_y A$.

The segment from *B* to *C* is described as the intermediate column range where failure may be considered a combination of buckling and yielding.

Considerable controversy and research has been associated with attempts to relate theory and experimental validation in this intermediate range. While the history of these studies is fascinating, the major interest here relates to design equations. The importance of the intermediate column range is that, from a practical viewpoint, most columns have slenderness ratios within this range. Therefore, the readily derived and theoretically accurate Euler's equation, $P_{cr} = \pi^2 EI/L^2$, is inappropriate for slenderness ratios less than $(L/r)_{PL}$.

From a historical and practical viewpoint, intermediate column formulas have been obtained by curve fitting experimental results. Therefore, one obtains equations that are material dependent, rather than an equation analogous to $\sigma = Mc/I$ that may be valid for a variety of materials. Most column equations have been parabolic or straight-line expressions for ease of design calculations. These expressions may be used because a factor of safety is incorporated for design purposes. The material product industries publish equations appropriate for their materials. Therefore, one must be careful to select column equations that are appropriate to the materials and conditions for the construction.

The most prevalent failure mode for columns is due to general buckling, as described previously. It may be seen from Figure 1-8.10 that the load carrying capacity is reduced significantly as the slenderness ratio increases. Consequently, a long column will buckle at axial loads considerably lower than those for a shorter column of the same cross section. In addition to the slenderness ratio, the strength of columns is dependent upon the modulus of elasticity. In fire conditions, the modulus of elasticity is reduced. This reduction causes a loss in strength of columns.

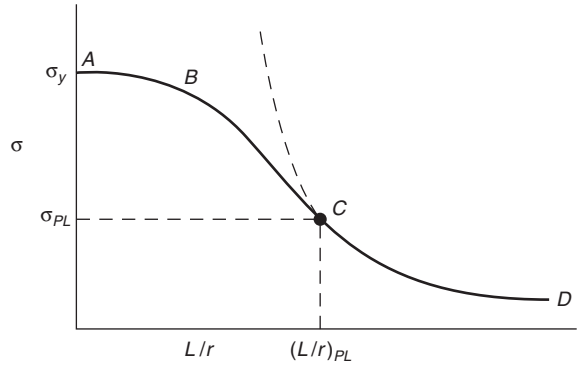

Figure 1-8.10. ***Critical stress of columns as a function of the slenderness ratio, L/r.***

Although general buckling is the most common type of failure, local buckling can occur on platelike elements in compression. This occurs when the plates are too thin for the applied load and premature localized buckling takes place. Because this type of behavior is also related to the modulus of elasticity, fire conditions can cause an earlier localized buckling to members, such as wide-flange steel shapes or angles that are made of thin-plate elements.

Flexural Members

The third type of structural loading is flexural. This occurs when loads are applied perpendicular to the longitudinal axis of the member. These members are described as being in flexure or bending. In structural use they are described as beams, girders, slabs, plates, and rigid frames. Although each of these types of members acts in flexure, their behaviors will differ.

Figure 1-8.11 shows flexural members with couples as the applied load. The top fibers of Figure 1-8.11(a) are in compression, and the bottom fibers are in tension. This is defined as positive bending. The opposite occurs in Figure 1-8.11(b), and this condition is described as negative bending.

Figure 1-8.3 showed a beam supporting transverse loads. The reactions of the beam were calculated in Example 1. The internal shear, moment, and axial forces were computed for a general distance *x* in Example 2. Diagrams that describe the change in vertical shear, *V,* and the change in internal moment, *M,* are constructed to show the distribution of these changes throughout the beam. These are called *shear and moment diagrams.* Every textbook on mechanics of materials and most texts on statics cover procedures for constructing *V* and *M* diagrams for beams. From these shear and moment diagrams the design values for those parameters are selected.

The relationship between the fiber stresses in the member and the internal resisting moment can be obtained in the following manner. Consider a homogeneous beam in pure bending as shown in Figure 1-8.12(a). Two lines, parallel before bending, would assume the position shown after the couples are applied. It is assumed that plane sections before bending remain plane after bending. Figure 1-8.12(b) shows the strain distribution of the fibers throughout the cross section. The top fibers have

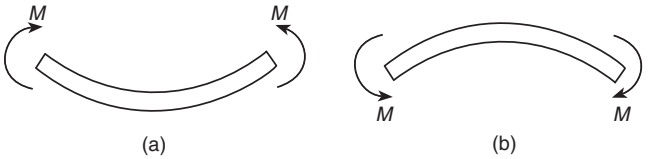

Figure 1-8.11. ***Deflection of flexural members under load.***

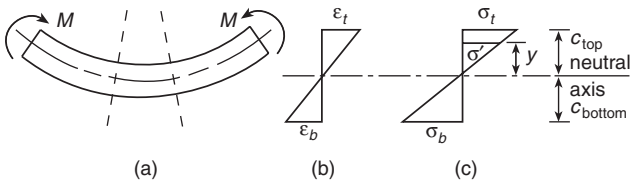

Figure 1-8.12. ***Homogeneous beam in (a) pure bending, and the resulting (b) strain distribution, and (c) stress distribution.***

shortened, and the bottom fibers have elongated. One layer of fibers has not changed in length. This plane is called the neutral plane of the member.

Hooke's law states that stress is proportional to strain. When the proportionality is linear, the stress distribution is as shown in Figure 1-8.12(c). The maximum stress, σ, will occur at the fibers located farthest from the neutral axis. The stress at the neutral axis is zero.

If we consider the stress, σ_1, in a single fiber of area, dA, at a distance, y, above the neutral axis, the force exerted by that fiber due to the stress is $dP = \sigma' dA$. This stress may be related to the stress, σ, in the extreme fibers, by the similar triangles of Figure 1-8.12(c).

$$\frac{\sigma'}{y} = \frac{\sigma'}{c}, \quad \text{or} \quad \sigma' = \sigma\left(\frac{y}{c}\right)$$

The force, dP, exerted by this fiber may be expressed as

$$dP = \sigma' dA = \sigma\left(\frac{y}{c}\right) dA$$

The moment of this force about the neutral axis is

$$dM = dPy = \sigma\left(\frac{y}{c}\right) dA(y)$$

$$dM = \frac{\sigma}{c} y^2\, dA$$

Summing the moments of each of the fibers of the member yields

$$\int_0^M dM = \int_{-c}^{+c} \frac{\sigma}{c} y^2\, dA = \frac{\sigma}{c} \int_{-c}^{+c} y^2\, dA$$

The moment of inertia, I, of the cross section is defined as

$$I = \int_{-c}^{+c} y^2\, dA$$

The flexure formula, therefore, may be expressed as

$$\sigma = \frac{Mc}{I} \tag{1}$$

where

σ = flexural stress at the extreme fibers

M = bending moment at the section of the beam being considered

c = distance from the neutral axis to the extreme fibers

I = moment of inertia of the cross section

Equation 1 has several limitations that have been incorporated into the assumptions of its derivation. These include (1) the beam is initially straight and of constant cross section; (2) all stresses are below the proportional limit, and Hooke's law applies; (3) the modulus of elasticity in compression is equal to that in tension; (4) loads are applied through the shear center so that torsion will not occur; and (5) the compression fibers are laterally restrained.

The design of flexural members for bending loads involves (1) determining the dead and live loading for the member; (2) calculating the maximum moment in the beam; (3) selecting the materials and obtaining the allowable stresses; (4) calculating a required section modulus; and (5) selecting a beam to provide for that section modulus efficiently and economically; and (6) ensuring that all other failure modes will not occur.

Because many beams have common loading and support conditions, it is possible to develop standard conditions to obtain the maximum shear and moment by formula. Figures 1-8.13 and 1-8.14 illustrate two common conditions. Most handbooks and mechanics of materials textbooks provide several additional cases. The maximum moment from Figure 1-8.13 is $M = 1/8\omega L^2$, and that from Figure 1-8.14 is $M = Pab/L$. Loading conditions may be combined by superposition. However, it is important to conform with the conditions where superposition is valid. For example, Figure 1-8.15 shows a beam with a uniformly distributed load, ω, and a concentrated load, P, at the center. Because the maximum moment of each load occurs at the same location, it is possible to compute the maximum moment as $M = \omega L^2/8 + PL/4$. However, if the concentrated load were at another location, as in Figure 1-8.16, superposition would not be valid. In those cases, the engineer must compute the maximum V and M by using the basic principles of statics. Example 2 illustrated that technique.

Statically Indeterminate Beams

It is common to construct beams with more reactions than are necessary for statical stability alone. These members are statically indeterminate because the calculation of reactions requires means in addition to statics alone. Figure 1-8.17 illustrates some statically indeterminate

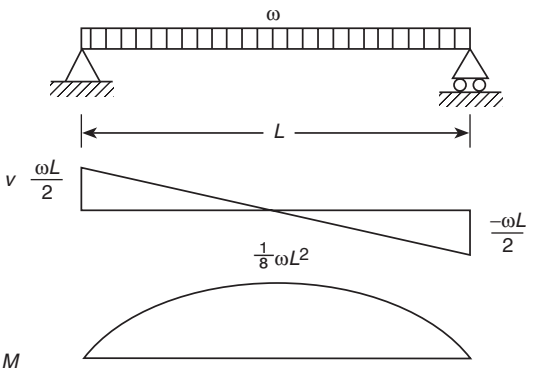

Figure 1-8.13. ***Shear and moment diagram for a simply supported beam under uniform loading.***

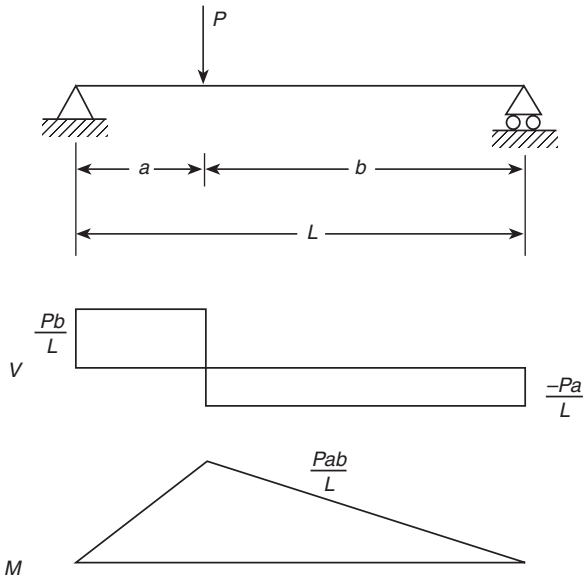

Figure 1-8.14. ***Shear and moment diagram for a simply supported beam under concentrated loading.***

beams, and Figure 1-8.18 shows some statically indeterminate frames.

The procedure for designing statically indeterminate beams is similar to that described for statically determinate beams. An increased complication arises, however, when determining the maximum shear and moment for a beam such as that shown in Figure 1-8.17(c). The dead load is applied over the entire span and is fixed. The live load is movable and may be applied to any or all spans. An integral part of the computation of the design shear and moment is to place the movable live load at positions that produce the most severe values. This may be done by constructing influence lines for the design functions. An influence line is a graph of the function as a unit load moves across the structure. The influence line shows where loads must be placed to produce the most severe conditions. To illustrate this concept, the loading condition shown in Figure 1-8.17(c) would be used to determine the maximum negative moment over support *E*, while the loading condition shown in Figure 1-8.17(d) would be used to determine the maximum positive moment at the midpoint of span *DE*.

Statically indeterminate structures are inherently stronger than statically determinate structures. This occurs because of the additional load-carrying capacity due to the redistribution of moments. The amount of this increased load capacity depends upon the type and location of load, the support conditions, the material properties, and the geometry and dimensions of the cross section.

To illustrate this concept, consider the simply supported beam of Figure 1-8.19. The maximum moment is $M = 1/8\omega L^2$. The stress may be computed as $\sigma = Mc/I$ as long as the fibers are stressed below the proportional limit. Figure 1-8.20(a) shows a wide flange cross section. Figure 1-8.20(b) shows a stress variation that is valid up to the value where the extreme fibers reach σ_y. The moment that causes that stress is M_y, the bending moment that will just cause yielding to be imminent at the extreme fibers. That value is the limit of validity for the flexure formula, $\sigma = Mc/I$.

The beam, however, has an increased load-bearing capacity beyond that value. Excessive deformation (i.e., collapse) will not occur until the entire cross section has yielded. The stress distribution for this condition is shown in Figure 1-8.20(c). The moment capacity at that point is called the fully plastic moment, M_p. The increase in moment is dependent upon the geometry of the cross section. The ratio of M_p/M_y is the shape factor. For steel wide-flange beams, the shape factor averages 1.14. The shape factor will be different for other geometrical shapes and dimensions.

If the simply supported beam of Figure 1-8.19 were a steel wide-flange shape, we would expect the collapse load to be 14 percent higher than the yield load. The design load usually has a factor of safety of 1.5 over the yield load. Therefore, the factor of safety for collapse above the design value is $1.50 \times 1.14 = 1.71$ for normal design conditions.

If the support conditions are fixed, as shown in Figure 1-8.21, the maximum moment occurs at the support. For elastic conditions, the moment at the support is $M = (1/12)\omega L^2$, and the moment at the center is $M' = (1/24)\omega L^2$. As the load is increased to the point where σ_y is first reached (at the ends), the value of $M_y = (1/12)\omega_y L^2$.

As the load continues to increase, the location of greatest stress (the ends) will reach their fully plastic value, M_p. However, the beam still has additional carrying capacity because a collapse mechanism will not occur until three hinges form. At the time M_p occurs at the ends, the other location of maximum moment, the center, is still

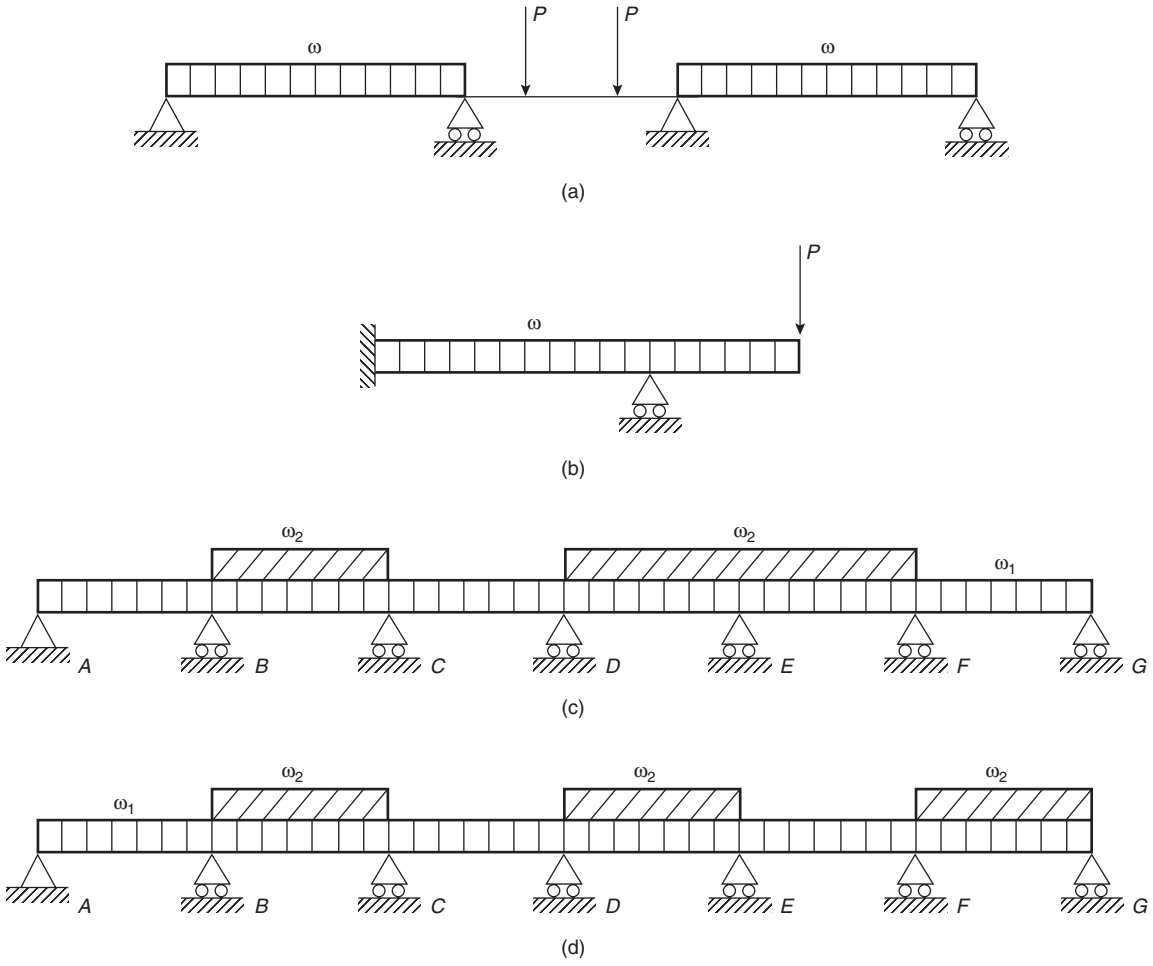

Figure 1-8.17. ***Statically indeterminate beams.***

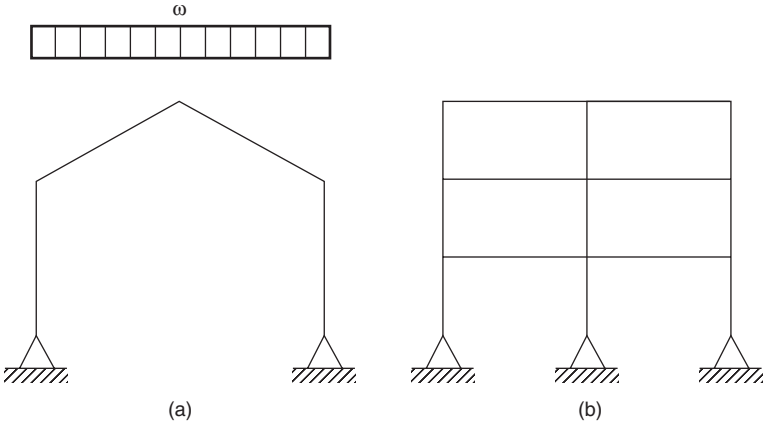

Figure 1-8.18. ***Statically indeterminate frames.***

in the elastic range. The value of M_p at the ends cannot increase. Therefore, any increase in load must be carried by the elastic portion. The moments redistribute, as illustrated by the dashed line of Figure 1-8.21(c). They will increase until M_p occurs at the center. At that time, collapse is imminent.

The collapse moment for the beam of Figure 1-8.21 is $2M_p = 1/8\omega_u L^2$; therefore $\omega_u = 16\ M_p/L^2$. The collapse

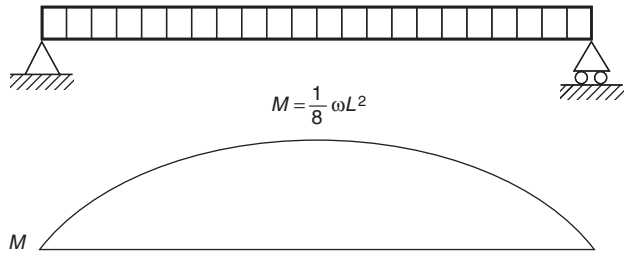

Figure 1-8.19. ***Uniformly loaded simply supported beam.***

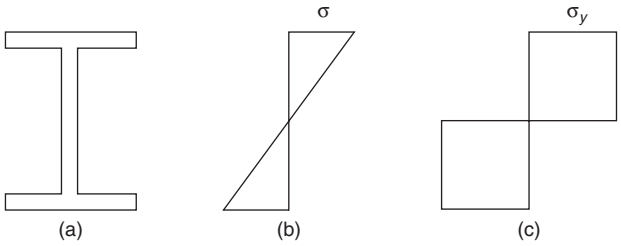

Figure 1-8.20. ***(a) Wide flange cross section and stress distributions, (b) prior to yielding of extreme fibers, and (c) after complete yielding.***

moment for the simply supported beam of Figure 1-8.19 is $M_p = 1/8\omega_u L^2$; therefore $\omega_u = 8\ M_p/L^2$. Therefore, the ultimate load-carrying capacity of the beam with fixed ends is twice that of a beam with simply supported ends.

This concept is sometimes described as limit state design, ultimate design, inelastic design, or plastic design. Limit state design seems more appropriate to a variety of materials.

The concept of ductility and its behavior is intrinsic to safe structural design because a ductile structure will deform considerably before collapse. This deformation warns occupants of impending danger before failure. Brittle design and elastic instability are not as desirable because failure can occur with relatively little warning. Therefore, structural engineers attempt to incorporate ductility into their designs as much as possible. This ductility is evident in most structural building materials.

Flexural Failure Modes

Depending upon the magnitude, type of loading, and support conditions, flexural members may exhibit different types of failure modes. The most evident type of failure is the overstress that contributes to the development of a plastic hinge. This was described in the previous section. A statically determinate structure will collapse when the first plastic hinge forms. A statically indeterminate structure requires two or three hinges to form before collapse. The support conditions determine the number of hinges needed for collapse.

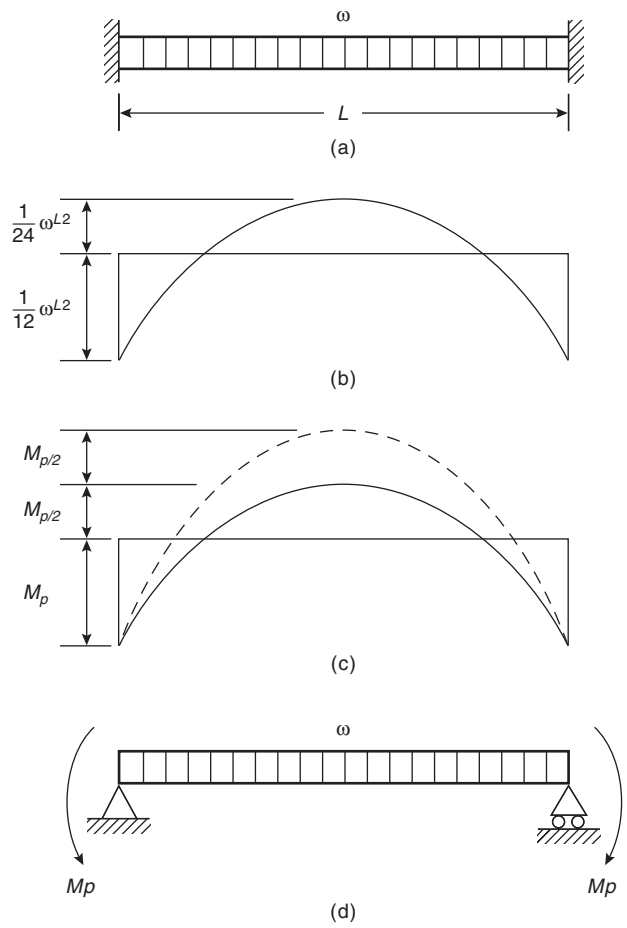

Figure 1-8.21. ***Moment redistribution in a fixed-ended beam.***

Another common mode of failure is lateral instability. The compression flange of the beam must be supported laterally at sufficient intervals to prevent lateral buckling. Lateral buckling is similar to column buckling, and it can occur when supports are spaced too far apart. When lateral supports are spaced farther apart than the distance needed to avoid lateral buckling, the allowable stress is reduced to compensate for the reduction in local carrying capacity.

A third mode of beam failure is through torsional loading. An open cross section is particularly weak when subjected to torsional loads. A torsional load exists whenever the line of action of the applied loads does not intersect the shear center of a beam. The shear center is a particular location on the cross section. For symmetrical members, such as that of Figure 1-8.22(a), the shear center coincides with the centroid. For unsymmetrical members, the shear center may be calculated. Figure 1-8.22(b) and (c) illustrate the location of the shear center for this type of cross section. Whenever loads do not pass through the shear center, construction features must be introduced to counterbalance the rotational effect of the loads.

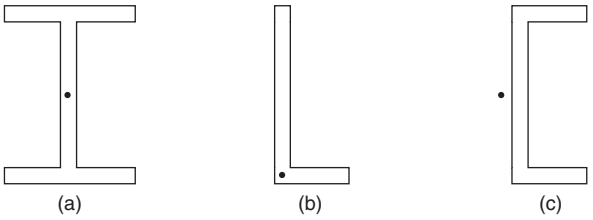

Figure 1-8.22. ***Location of shear center for (a) symmetrical and (b,c) unsymmetrical sections.***

Another mode of failure is excessive deflection. This can occur when the stiffness is insufficient and can occur at relatively low stresses. In addition to excessive deflection, unwanted vibrations or sway, such as wind loads on tall buildings, may occur.

It is not uncommon for members to be loaded with both axial and flexural forces. Rigid frames and chord members of trusses, where the load is applied directly to a chord, are common examples of this condition. Depending upon the construction conditions, failure may occur due to premature formation of plastic hinges or buckling of the compression flange.

Structural Design for Fire Conditions

The theory and procedures for structural analysis and design at normal temperatures have been well studied. Understanding of theoretical and empirical relationships, and the ability to predict performance for practical applications and conditions, is relatively clear to most practitioners. However, the understanding of the structural behavior for fire conditions becomes theoretically and practically a far more complex problem.

Structural analysis and design for fire conditions can take one of several forms. The simplest application can be described by the procedures used in most conventional building codes. In this case, a representative sample is tested in a standard fire endurance test, such as ISO 834 or ASTM E119, *Standard Test Methods for Fire Tests of Building Construction and Materials.* The length of time in the laboratory test before failure occurs produces a fire endurance time. Building codes specify the fire endurance required for structural members and barriers in identified occupancies and classifications of construction. The engineer or architect need only incorporate the standard construction features identified by the test results and published documentation to satisfy the code requirements.

This procedure requires no knowledge of fire or structural engineering by the practitioner. A catalog of construction assemblies and their fire endurance ratings are the only data needed to satisfy code compliance. Unfortunately, the actual structural performance in fires is not known or investigated. The sophisticated knowledge of the interrelationships that lead to an understanding of structural performance and economical design is submerged in the process. The increased structural strength achieved by continuity in construction is not a consideration in this procedure. The rated fire endurance of a beam and its value from the building code viewpoint is the same whether it is constructed as a statically determinate structure or as continuous construction, even though the performance may vary quite significantly.

Another procedure involves the calculation of structural fire endurance based on the standard ASTM E119 or ISO 834 fire test. Empirical and theoretical relationships are used to predict the fire endurance, based on the standard fire time-temperature relationship. Two advantages of this procedure are that (1) it allows the building codes to retain their present form and (2) it leaves undisturbed the interrelationship between construction classifications and other fire defense measures. Also, it provides more flexibility: fire endurance of different types of assemblies can be obtained by calculation rather than by test. However, the same limitations present in the traditional test procedure and code format remain.

A third procedure can be described as a rational approach to structural design for fire conditions. This approach is exemplified by the procedures for (1) structural steel design and (2) reinforced concrete design developed in Sweden. In these procedures, the design incorporates the structural performance at elevated temperatures in a manner analogous to design at normal temperatures. The mechanical properties of the structural materials at elevated temperatures are incorporated into the traditional structural theory to develop a rational analytical procedure for predicting structural behavior. Further, the natural room fire temperature-time relationship is used instead of the standard test time-temperature relationship, and the thermal properties and heat transfer through the insulating materials are incorporated into the analysis. The procedures follow more closely the traditional structural engineering methods for predicting structural behavior.

Summary

The ability of structural members to withstand failure of excessive deflection, insufficient strength, and instability is a major requirement of any structure. While the analysis and design process for normal loads and conditions is not particularly difficult, it does require care in application. The care relates to the type and validity of the assumptions made and to the form of construction used.

The anatomy of the entire structural system is an important aspect of the analysis and design process. Unless care is taken to specify clearly the construction details, inappropriate design calculations can result. To the lay person, one form of construction often appears to be the same as another. To the student who often has insufficient opportunity and training to recognize the construction details, analysis and design may appear to be an academic exercise. Normally, much of the ability to recognize the essential details is obtained through engineering practice with a professional engineer.

Fires in buildings create an added dimension of complexity to the analysis of the behavior of structural members at elevated temperatures. The fire design of structural members must include the same attention to details as the design of members at normal temperatures.

Nomenclature

A = area
c = distance from neutral axis to extreme fibers
E = modulus of elasticity
F = force
I = moment of inertia
L = length of beam or member
M = moment
P = concentrated or point load
r = radius of gyration
V = shear
x = space coordinate along the beam
y = space coordinate normal to the beam
ε = strain
δ = deformation
σ = stress
ω = uniform load density

CHAPTER 9

Premixed Burning

Robert F. Simmons

Introduction[1]

When a mixture of fuel vapor and oxidant burns on a cylindrical tube, as with a Bunsen burner, the resulting premixed flame has the characteristic structure of a luminous inner cone and an outer sheath of hot combustion gases.[1] This inner cone depicts the end of the primary reaction zone of the flame, in which a fast oxidation reaction occurs, so that in this part of the flame the temperature rises very rapidly. When the initial mixture of fuel and oxidant is fuel rich, that is, there is a deficiency of oxidant in terms of the stoichiometric conversion of the fuel to its oxidation products, the outer sheath is essentially a diffusion flame in which the hot combustion products from the primary reaction zone burn in the surrounding atmosphere. In contrast, with lean flames this outer sheath is indistinct as there is sufficient oxidant in the initial mixture for the complete combustion of the fuel, and the surrounding atmosphere is entrained into the burnt gases.

A stable premixed flame can only be obtained over a limited range of mixture compositions and flow rates, and the flow conditions for a given initial mixture can be seen from a consideration of an idealized flat flame, as shown in Figure 1-9.1. For such a flame, the flow of the initial combustible mixture is normal to the flame front. If the flow is too fast the flame is "blown off," while if it is too slow the flame "flashes back." A stable flame is only obtained when the flow velocity of the incident mixture is just equal to the *burning velocity* of the mixture. This fundamental parameter is defined as the velocity with which a premixed flame moves normal to its surface through the adjacent unburnt mixture. While a flat flame can only be stabilized over a narrow range of flow velocities, a conical flame can be established over a much wider range of flows, as the area of the inner cone can change to maintain the balance between the burning velocity and the flow velocity normal to the flame front. A typical flow pattern and temperature distribution in such a flame is shown in Figure 1-9.2.[2]

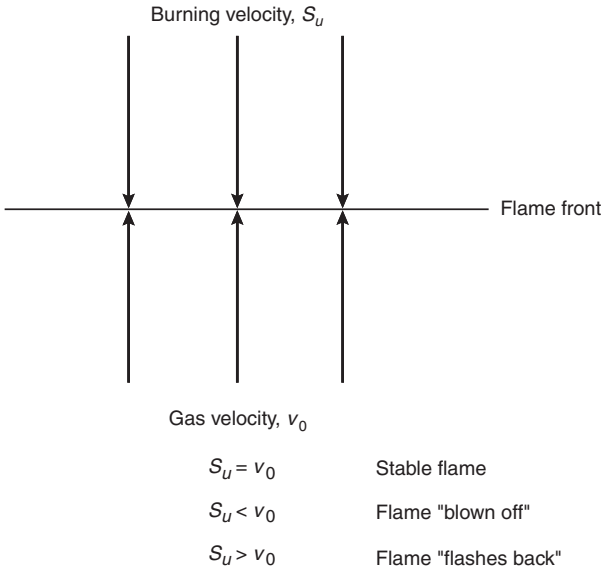

Figure 1-9.1. ***Diagrammatic representation of a flat premixed flame.***

The maximum temperature in the flame is usually reached a little downstream of the inner cone. If the flame is sufficiently large, the adiabatic flame temperature is reached in the middle part of the gas stream; thus, with the temperature distribution given in Figure 1-9.2, the calculated adiabatic flame temperature is nearly reached just

Dr. Robert F. Simmons has a Ph.D. in physical chemistry and his major research interests have centered around flame propagation, the chemistry of combustion reactions, and industrial safety. Until his retirement, he was a senior lecturer in chemistry at the University of Manchester Institute of Science and Technology, and he served as deputy editor of *Combustion and Flame.*

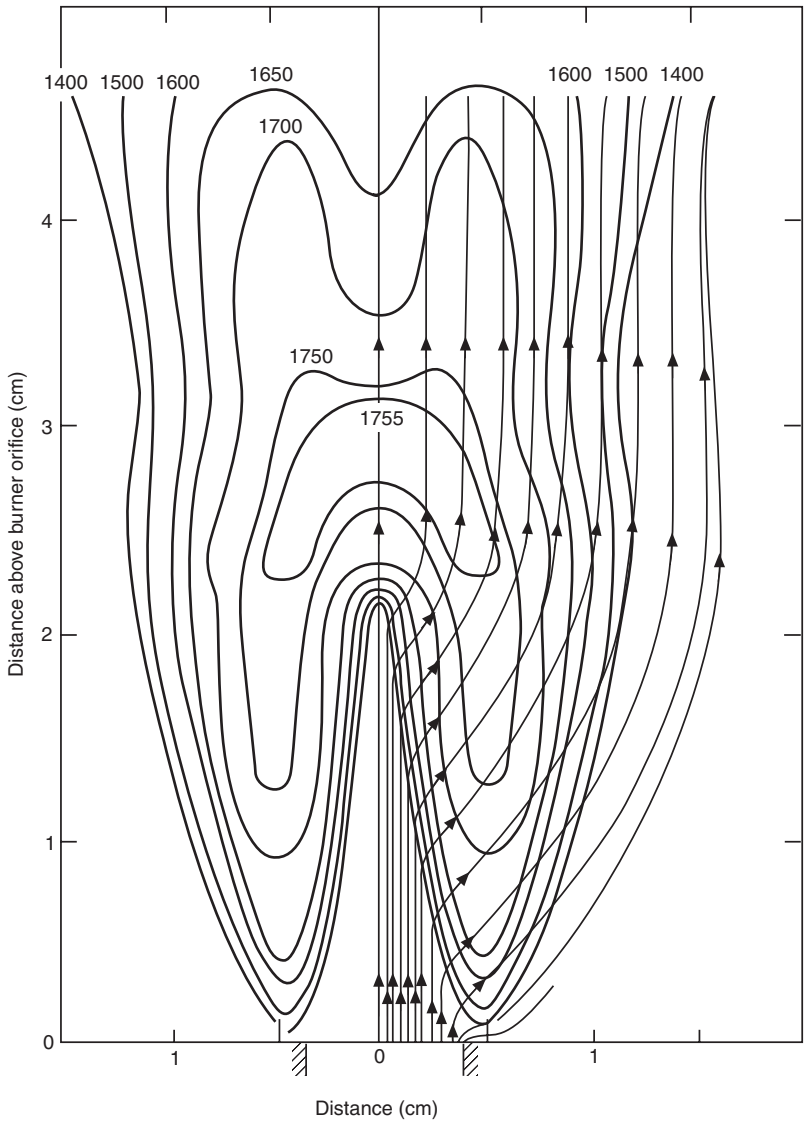

Figure 1-9.2. ***Temperature distribution and flow pattern in a premixed flame (7.5 percent natural gas and air burning on a rectangular burner 0.755 × 2.19 cm). The quoted temperatures are °C.[2]***

above the inner cone of the flame. Toward the outside of the flame, however, heat losses lead to a steep temperature gradient between the combustion products and surroundings. This *adiabatic flame temperature* is given by the balance between the heat released in the combustion reaction (ΔH_r^θ) at the initial temperature of the reactants (T_i) and the heat required to raise the temperature of the products to the final flame temperature (T_f), that is,

$$\Delta H_r^\theta = \int_{T_i}^{T_f} C_p \, dT$$

where C_p is the heat capacity of the combustion products. This calculation assumes that heat losses from the flame by radiation, thermal conduction, or diffusion to a wall can be neglected. Thus, small premixed flames and turbulent flames of all kinds normally fail to reach their adiabatic flame temperature as the heat loss from such flames is appreciable.

Calculation of the adiabatic flame temperature always assumes chemical equilibrium has been reached in the burnt gas. For lean flames with a relatively low adiabatic flame temperature, the calculation is relatively straightforward, in that the combustion products are given by the simple stoichiometry for the overall combustion process, but for temperatures above 1800 K allowance must be made for the heat used up in the dissociation of carbon dioxide, steam, oxygen, and so

forth. However, the composition of the products can only be calculated if the temperature is known, and the temperature depends on this composition. As a result, a method of successive approximations must be employed in the calculation, and this can most conveniently be done using a computer program, such as NASA SP-273.[3] Although the adiabatic flame temperature is only reached in a restricted region of a large premixed flame, it is a useful combustion parameter and especially useful in the calculation of limits of flammability. (See Section 1, Chapter 5, "Thermochemistry.")

All experimental determinations of burning velocity involve measuring the area of the flame front for a particular flow of unburnt mixture. Much of the discrepancy between different determinations can be ascribed to the method used to specify the position of the flame front; further, when burner flames have been used there is also the complication of quenching near the burner rim and the increase in burning velocity near the tip of the cone (because the heat flow in this region is strongly convergent). For example, the maximum values reported for the laminar burning velocity of propane-air mixtures mainly lie between 37 and 45 $cm \cdot s^{-1}$, but the majority of the values lie in the range of 41 ± 2 $cm \cdot s^{-1}$. All the saturated hydrocarbons have about the same maximum burning velocity, and Table 1-9.1 lists the maximum values for some other fuel-oxidant combinations.

The values in Table 1-9.1 refer to initial conditions of room temperature and atmospheric pressure. In general, hotter flames have higher burning velocities, and thus increasing the initial temperature of the mixture increases the burning velocity. For example, when the initial temperature of propane-air mixtures is increased from 300 to 480 K, the maximum burning velocity doubles.[4] The effect of pressure on burning velocity is simple and is frequently expressed as a simple power law

$$\frac{S_{u,a}}{S_{u,b}} = \left(\frac{p_a}{p_b}\right)^n \tag{1}$$

where $S_{u,a}$ and $S_{u,b}$ are the burning velocities with respect to the unburnt gas at pressures p_a and p_b, respectively, and n is a constant for the flame. Values of n have been reported for a number of flames ranging from 0.25 (for hot flames with oxygen as the oxidant) to -0.33 (for cooler flames supported by air).[5]

Table 1-9.1 ***Maximum Burning Velocities for Laminar Fuel-Oxidant Mixtures***

Mixture	Maximum Burning Velocity S_u/cm·s^{-1}	Reference
Propane-air	41	1
Ethene-air	68	1
Acetylene-air	175	1
Hydrogen-air	320	6
Propane-oxygen	360	7
Acetylene-oxygen	1120	6
Hydrogen-oxygen	1180	6

Another factor that affects the burning velocity is the degree of turbulence in the flame. In laminar flames the flow lines in any given volume are parallel, but for turbulent flow the velocities have components normal to the average flow direction. The state of flow is usually characterized in terms of the Reynolds number (Re) which is the dimensionless quantity

$$\mathrm{Re} = \frac{vd\rho}{\eta} \tag{2}$$

where

v = average gas velocity

d = diameter of the tube

ρ = density of the gas stream

η = viscosity of the gas stream

For $\mathrm{Re} < 2300$ the flow is always laminar, and for $\mathrm{Re} > 3200$ it is usually turbulent.[8] In the intermediate region the flow alternates between laminar and turbulent flow, the periods of each depending on whether Re is nearer the lower or higher value.

When the flow is laminar the flame front is sharply defined, but as the Reynolds number of the flow increases the flame front becomes progressively more and more blurred, so that the whole volume in which the primary reaction occurs has the appearance of a "brush." This arises because of the fluctuations in the local gas velocity. At points where the velocity is high the flame front moves away from the burner, while in regions of low velocity it moves toward the burner. Thus, the net effect of turbulence is to increase the effective area of the flame front, with a resulting increase in burning velocity. For example, with propane-air, ethene-air, and acetylene-air flames, the burning velocity approximately doubles as the Reynolds number is increased to 40,000.[9] A theoretical treatment of turbulent combustion suggests that the burning velocity can increase by a factor of five when the degree of turbulence in the flow is very high.[10]

The above discussion has been concerned with stationary flames burning on a burner; but if the local flow velocity in a tube or duct is too low to sustain a stationary flame, the flame propagates through the incident mixture provided it is flammable, that is, its composition lies within the *limits of flammability.* These are the limits of composition over which a self-sustaining flame can propagate and, as such, they are important parameters in any consideration of the fire and explosion risk associated with a particular fuel-oxidant system. They are normally measured for upward propagation of the flame (since this gives the widest limits) in a tube sufficiently wide to minimize quenching effects and sufficiently long to ensure that it is the self-propagation of the flame that is being studied, that is, the measured limits are independent of the energy input from the ignition source. The dimensions of the tube are typically 100-cm long × 5-cm inside diameter (ID); this is quite satisfactory for hydrocarbon fuels, but a larger diameter is necessary for fuels, such as ethyl chloride, that have a large quenching distance.[11]

It should be noted that if burning occurs in a closed vessel, the resulting temperature rise produces a corre-

sponding rise in pressure. For example, a stoichiometric hydrocarbon-air mixture at an initial temperature of 300 K has an adiabatic flame temperature of about 2200 K, so that the pressure can reach a little over 7 bar under adiabatic conditions. In practice, the maximum pressure is likely to be somewhat lower because of heat loss to the walls of the vessel; but unless the vessel has been designed to withstand such pressures it will rupture explosively. The situation is further complicated if connected vessels are involved, as burning in one vessel leads to an increased pressure in the connected vessel; if the flame then propagates into this second vessel, a correspondingly higher pressure is produced.

These limits of flammability widen as the temperature increases, but at sufficiently low temperatures the flammable range is limited by the vapor pressure of the liquid fuel, as shown in Figure 1-9.3. It follows that the *flash point* is the temperature at which the vapor pressure is just sufficient to give a lean limit mixture of the fuel vapor in air. However, a somewhat higher temperature (the *fire point*) is needed before the fuel is ignited by the burning gas above the surface of the material. At sufficiently high temperatures autoignition occurs and the minimum temperature at which this can happen is termed the *autoignition temperature.* (See Section 2, Chapter 8, "Ignition of Liquid Fuels.") Although the flame in a real fire is essentially a diffusion flame (addressed later in this chapter), the initial ignition of the combustible material, whether liquid or solid, involves the ignition of a mixture of fuel vapor and air in the boundary layer above its surface.

If the flame tries to propagate through a gap that is too small it is quenched. These limiting distances are usually measured using spark ignition at the center of a pair of parallel plates[12] or a rectangular burner,[13] and the *quenching distance* is the maximum distance that will just prevent the propagation of a flame through any mixture of the fuel-oxidant mixture. The quenching is probably due to a combination of heat loss to the walls and the removal of free radicals which are important for the propagation of the flame. These quenching effects are utilized in flame traps, but here it is also necessary that any hot gas forced through the trap must be sufficiently cooled so that it does not ignite any flammable mixture present on the other side.

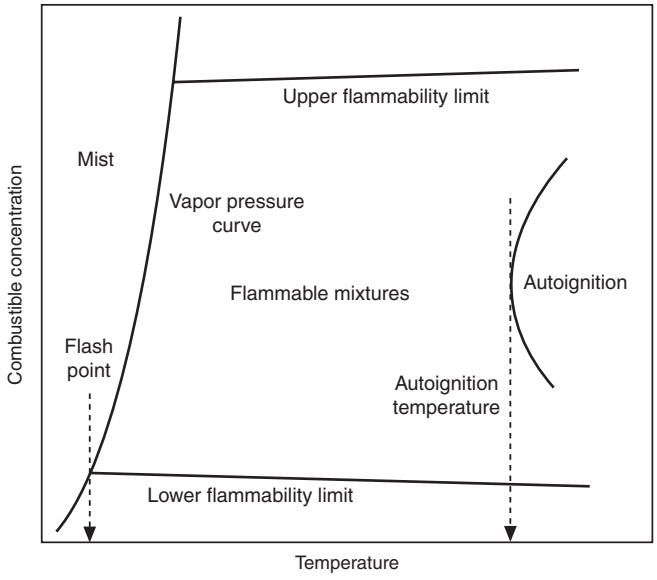

Figure 1-9.3. ***Effect of temperature on the limits of flammability of a combustible vapor in air at a constant initial pressure.[14]***

A flame propagating along a duct away from an opening usually proceeds, at first, at a fairly uniform speed which is controlled by the burning velocity of the mixture and the area of the flame front. This linear velocity, *V,* is related to the burning velocity through the relation

$$V = \frac{S_u A_f}{A_d} \tag{3}$$

where A_f and A_d are the areas of the flame front and the cross section of the duct, respectively. Since A_f is always greater than A_d (typically by a factor of two or three), it follows that the linear velocity of the flame is correspondingly larger than the burning velocity. This distinction is important when the design of automatic protection is considered.

If the hot combustion products cannot vent to maintain an approximately constant pressure in the system, they force the flame and the unburnt gases forward with increasing velocity. In turn, this induces increased turbulence ahead of the flame front with a consequential further increase in burning velocity. If the duct is sufficiently long and the resulting acceleration is sufficiently rapid, the flame front acts as an accelerating piston and a shock wave is formed ahead of the flame front. Under such conditions, the flame becomes a detonation propagating at supersonic velocity, typically between 1500 and 3000 m s^{-1}.[15] For gases initially at atmospheric pressure, the pressure immediately behind the detonation can be up to 20 bar, and up to 100 bar if it is reflected from the end of the duct. As a result, detonations are much more destructive than a propagating premixed flame.

Mechanism of Flame Propagation

The preceding discussion has been concerned with phenomena associated with the propagation of the flame and, while these are important from the practical viewpoint, they give no insight into how the flame propagates from one layer of gaseous mixture to the next. Such insight comes from using the continuity equations for flame propagation in a laminar flow[16] and, for convenience and simplicity, the following discussion is based on the equations for a flat flame.

First, there must be *conservation of mass* through the flame, so that

$$\rho v A = \rho_0 v_0 A_0 = M \tag{4}$$

where

ρ = density
v = gas velocity
A = cross-sectional area of the gas flow
M = mass burning rate (mass per unit time)

Conservation of energy requires that the heat conducted into a gaseous element of the flame plus the heat liberated by chemical reaction within the element is used up in raising its temperature, that is,

$$\frac{d(k \cdot dT/dz)}{dz} + Q \cdot R - \frac{d(c_p \cdot T \cdot \rho \cdot v)}{dz} = 0 \qquad (5)$$

where

k = thermal conductivity of the mixture
c_p = heat capacity
T = temperature at distance z
Q = heat of reaction
R = rate of reaction

There must also be *conservation of the individual atomic species* through the flame; that is, for a given chemical species i there must be a balance between its rate of production (or removal) in a given element of the flame and its transport by diffusion and convection. Thus,

$$R_i + \frac{d(D_i \cdot dn_i/dz)}{dz} - \frac{d(n_i \cdot v)}{dz} = 0 \qquad (6)$$

where D_i is its diffusion coefficient, and n_i its concentration. Equation 6 leads to the following expression for the rate of reaction of species i

$$R_i = \left(\frac{\rho_0 v_0}{M_i}\right)\left(\frac{dG_i}{dz}\right) \qquad (7)$$

where

M_i = molecular weight of species i
V_i = diffusion velocity
G_i = mass flux fraction

The latter is given by

$$G_i = \frac{M_i(v + V_i)}{v}$$

where the diffusion velocity, V_i is given by

$$V_i = \frac{-D_i}{X_i}\left(\frac{dX_i}{dz}\right) \qquad (8)$$

In principle, Equations 4 through 6 can be solved to give the burning velocity (v_0), plus the composition and temperature profiles through the flame, but it will be obvious that a detailed reaction mechanism is needed before this can be done. Dixon-Lewis has used the established mechanism for the hydrogen-oxygen reaction to do this for hydrogen-air flames,[17] and similar calculations have been carried out for other hydrocarbon-air flames, such as those presented by Warnatz[18]; such numerical computations for the structure of one-dimensional flames have now become quite commonplace.[19]

The present detailed understanding of the important chemical processes occurring in a premixed flame has come from an analysis of the experimental temperature and concentration profiles through a flat flame; some typical results for a lean propane-oxygen-argon flame are given in Figure 1-9.4.[20] Such analyses show that the flame can be divided up into a number of distinct regions, as shown at the top of Figure 1-9.4. In the initial *pre-heating zone* the temperature rise is that expected from conduction of heat back from the hotter parts of the flame, and chemical reaction does not start until the temperature has reached about 700 K. There is some depletion of fuel at lower temperatures than this, but it is the result of its forward diffusion to a higher temperature region of the flame and not chemical reaction. Similarly, there is back-diffusion of carbon monoxide, carbon dioxide, and water vapor into this region of the flame.

The reaction in the *primary reaction zone* is induced by the diffusion of free radical species, X, back from the hotter parts of the flame. These react with the fuel to give alkyl radicals in reaction (1). At the start of the primary reaction zone in lean flames, X is probably mainly the hydroxyl radical,[20] but in rich flames the hydrogen atom is likely to be the predominant species. It should be noted that the reaction of these alkyl radicals with oxygen is not important in flames,[21] and there is direct experimental evidence that octyl radicals (for example) break down into smaller fragments (mainly C_1 and C_2) in this region of the flame.[22] In the case of propane, both n-propyl and sec-propyl radicals are formed in reaction (1), and these react by reactions (2) and (3), respectively.

$$X + C_3H_8 = HX + C_3H_7 \qquad (R1)$$

$$n - C_3H_7 = C_3H_6 + H \qquad (R2)$$

$$sec - C_3H_7 = CH_3 + C_2H_4 \qquad (R3)$$

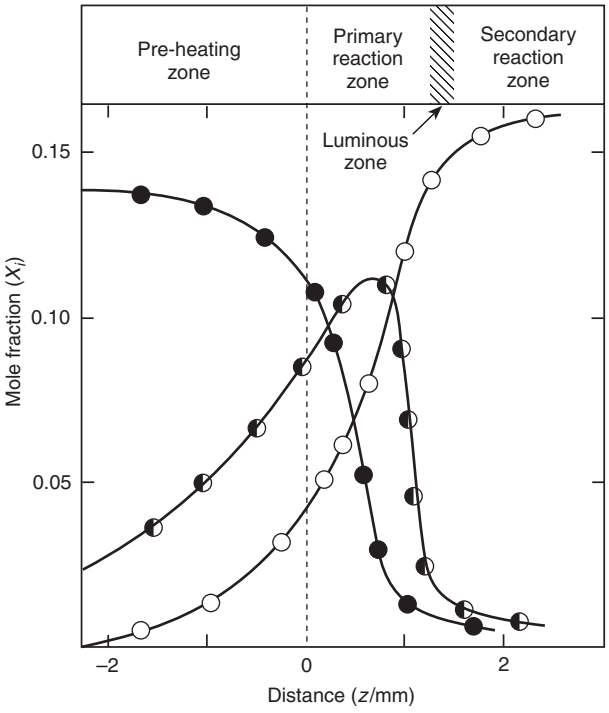

Figure 1-9.4. ***Typical composition profiles through a flat propane-oxygen-argon flame (1.38 percent propane; O_2:Ar = 15.85). Note: ⊙ 4 × CO_2; ● 10 × C_3H_8; ◐ 10 × CO.***[20]

Typical reaction rate profiles are given in Figure 1-9.5. This shows that the maximum rate of removal of propane and the maximum rate of formation of carbon monoxide both occur at about the same temperature (1160 K), and, at this temperature, about 90 percent of the original propane has been consumed. In this region of the flame, the ratio $R_{CO} + R_{CO_2}/-R_{C_3H_8}$ has a value of 3.1, which is reasonably close to the expected value of 3.0; such simple checks give confidence that the analysis of the experimental data is essentially correct. A detailed discussion of the chemistry involved in the formation of carbon monoxide from the hydrocarbon fragments is inappropriate for the present purposes, but it is generally agreed that one very important route is *via* the reaction of methyl radicals with oxygen atoms. This produces formaldehyde, which subsequently gives carbon monoxide by reactions such as (5) and (6).

$$CH_3 + O = HCHO + H \quad \text{(R4)}$$

$$X + HCHO = HX + CHO \quad \text{(R5)}$$

$$CHO = H + CO \quad \text{(R6)}$$

$$OH + CO = CO_2 + H \quad \text{(R7)}$$

Figure 1-9.5 shows that there is significant conversion of carbon monoxide to carbon dioxide in the primary reaction zone of lean flames, and this arises through reaction (7). Many researchers have used the experimentally measured rate of this formation in conjunction with the experimental local concentration and temperature (and, hence, known rate constant),[23] to derive a mole fraction profile for hydroxyl radicals. Such a profile is shown in Figure 1-9.6, together with the profile obtained for lower temperatures, assuming the removal of propane is due solely to its reaction with hydroxyl radicals. While the two profiles cover different parts of the flame, they are in excellent agreement where they overlap. A further indication that the removal of propane is *via* reaction with hydroxyl radicals comes from the temperature dependence of the rate of heat release in the early part of the flame; this is about 10 kJ mol^{-1}, which is close to that expected for the reaction of propane and hydroxyl radicals and much less than that expected for the reaction of propane with either hydrogen atoms or HO_2 radicals (37 and 78 kJ mol^{-1}, respectively). It must be stressed, however, that this conclusion comes from the analysis of data for very lean flames and that reaction with hydrogen atoms will become increasingly important as the mole fraction of propane in the initial mixture increases.

$$H + O_2 = OH + O \quad \text{(R8)}$$

$$H + O_2 + M = HO_2 + M \quad \text{(R9)}$$

Figure 1-9.5 shows that the maximum rate of removal of oxygen occurs somewhat later in the flame (at 1280 K) than the maximum rate of removal of propane (1160 K). It is instructive to examine the relative rates of reaction of hydrogen atoms with oxygen through the preheating and primary reaction zones of the flame. (See Table 1-9.2.) It can

Table 1-9.2 ***Relative Rates of Reaction of Hydrogen Atoms with Oxygen and Propane through a Premixed Propane-Oxygen-Argon Flame***

Initial mixture composition: 1.38 percent C_3H_8, 14.8 percent O_2, 83.82 percent Ar

Temp (K)	R_{H+O_2+M}/R_{H+O_2}	$R_{H+C_3H_8}/R_{H+O_2}$
600	450	38
800	12	7.5
1000	1.2	1.5
1200	0.25	0.4

k_{H+O_2} and k_{H+O_2+M} have been taken from Baulch et al.[24]
$k_{H+C_3H_8}$ has been taken from Walker.[25]

be seen that, at the lower temperatures, the termolecular reaction (9) predominates over the branching reaction (8); however, as the temperature rises above 1000 K, reaction (8) becomes increasingly important. Similarly, Table 1-9.2 also shows that, between 1000 and 1200 K, reaction (8) becomes faster than the removal of hydrogen atoms by reaction with propane. As a result, there is a rapid increase in the concentration of free atoms and radicals, that is, chain centers, toward the end of the primary reaction zone, so that the expected thermal equilibrium level can be exceeded by more than an order of magnitude.[26]

This rapid increase is in accordance with chain reaction theory.[27] This shows that, with a reaction involving linearly branched chains and linear chain termination, there is an exponential increase in the concentration of chain centers, even under isothermal conditions, as soon as the rate of chain branching exceeds the rate of chain termination. The situation is more complicated in the case of a hydrocarbon-air flame, as there has already been a major consumption of reactants by the time the branching reaction (8) becomes important. This consumption limits the concentration of chain centers, as shown in Figure A-1-9.1. In principle, another limiting factor to the growth in the concentration of chain centers in the flame is the occurrence of quadratic termination processes, such as reaction (10), which are known to be important in the secondary reaction zone of the flame. A combination of linearly branched chains and quadratic termination must lead to a stationary-state concentration.

$$H + OH + M = H_2O + M \qquad \text{(R10)}$$

This high concentration of chain centers produces the luminous flame front, that is, the characteristic inner cone of the Bunsen burner flame. The radiation from this region of the flame includes that from electronically excited hydroxyl radicals, which are believed to be formed partly by radical-radical reactions, such as reactions (11) and (12), and partly by reaction (13).[1]

$$O + H = OH^* \qquad \text{(R11)}$$

$$H + OH + OH = OH^* + H_2O \qquad \text{(R12)}$$

$$CH + O_2 = CO + OH^* \qquad \text{(R13)}$$

At this point in the flame all the fuel has effectively been consumed, some of the resulting carbon monoxide has been converted to carbon dioxide, and the radical concentration exceeds the corresponding thermal equilibrium level. Thus, in the *secondary reaction zone,* the important processes are the conversion of the major part of the carbon monoxide to carbon dioxide plus the decay in the concentration of radical species by recombination reactions. This leads to a further, but slower, rise in temperature until the final thermodynamic equilibrium has been reached with the burnt gas at the final flame temperature.

$$CH_4 + 2O_2 = CO_2 + H_2 + H_2O \qquad \text{(R14)}$$

$$CO + H_2O = CO_2 + H_2 \qquad \text{(R15)}$$

$$O_2 + 2H_2 = 2H_2O \qquad \text{(R16)}$$

The detailed computations for a one-dimensional laminar flame structure typically involve more than 120 elementary reaction steps for even simple hydrocarbon fuels; with more realistic fuels, the potential number can become very large. While this is practicable for such systems, it is out of the question for many engineering applications where three-dimensional and time-dependent effects arise (e.g., turbulent flames). Here, a substantial reduction in the number of reaction steps is needed before inclusion of the chemistry in the computations becomes practicable. The early attempts at producing a simplified global reaction scheme involved adjusting rate coefficients and reaction orders to fit the experimental observations, but this has too many unsatisfactory aspects. A much more satisfactory approach involves the systematic use of steady-state and partial-equilibrium approximations to reduce the number of independent reaction steps.[28] Under these circumstances, the rate constants for these global reaction steps can be expressed as a combination of the known rate constants of elementary reactions. For example, Peters and Williams have shown that the three-step mechanism comprising reactions (14) through (16) gives a good representation of a stoichiometric methane-air flame burning at atmospheric pressure and above.[28] Similar mechanisms have also been derived for methanol and propane flames.[29]

Effect of Additives on Flame Propagation

When inert diluents such as nitrogen, argon, and carbon dioxide are introduced into a premixed flame, they reduce the final flame temperature and, if the corresponding reduction in burning velocity is sufficiently large, the flame is extinguished. The limits of flammability data for propane[30] in Figure 1-9.7 show that the "peak" concentration of nitrogen is quite high [about 43 percent (by vol)], so that the oxygen content of an air-nitrogen mixture must be reduced to below 12 percent to ensure that no mixture of propane and air will burn. For such systems, the adiabatic flame temperature at the limit of flammability is not only remarkably constant, but this temperature is effectively the same all around the limit curve, so that the additive must act only as a diluent.

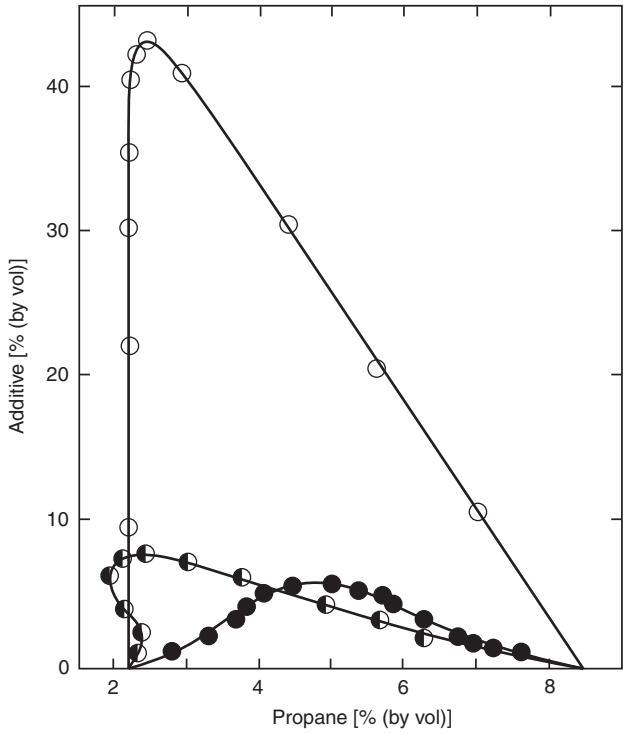

Figure 1-9.7. ***Effect of nitrogen, hydrogen bromide, and methyl bromide on the limits of flammability of propane in air (pressure 380 mmHg). Note: ⊙ N_2; ● HBr; ◐ CH_3Br.***

Hydrogen chloride must also act predominantly as an inert diluent as its effect on the limits of flammability of hydrogen-air mixtures is almost identical to that of nitrogen.[31] This arises because although the formation of chlorine atoms by reaction (17) is fast, the subsequent abstraction of a hydrogen atom by reaction (18) is also fast. However, the effective equilibrium position lies over on the side of hydrogen chloride, so that even though the additive is involved chemically, it has no overall chemical effect on the combustion process.

$$X + HCl = HX + Cl \quad \text{(R17)}$$

$$Cl + RH = HCl + R \quad \text{(R18)}$$

In contrast, bromine compounds are much more effective than the inert diluents in preventing flame propagation as they act as chemical inhibitors.[32,33] (See Figure 1-9.7.) Even a trace amount of such compounds in a premixed flame markedly reduces its burning velocity, and it is particularly striking that when sufficient compound has been added to extinguish a stoichiometric hydrocarbon-air flame, the adiabatic flame temperature of the resulting limit mixture is only slightly lower than that in its absence.[32] The action of such inhibitors can be illustrated by considering the action of hydrogen bromide in a hydrogen flame.[34] In this case, hydrogen atoms are removed by reaction (19) in preference to reacting in the chain branching reaction (8), so that the reactive hydrogen atoms are converted into relatively unreactive bromine atoms. Computations show that apart from in the very early stages of the flame, reactions (19) and (20) are effectively in equilibrium locally, with the equilibrium lying over on the side of bromine atoms. This produces some reduction in burning velocity, but it does not explain quantitatively the observed results. The inclusion of an additional chain-termination step, such as reaction (21), is required so that the rate of chain termination is increased relative to the rate of chain branching, in accord with the theory of chain reactions. (See Appendix A to this chapter.)

$$H + O_2 = OH + O \quad \text{(R8)}$$

$$H + HBr = H_2 + Br \quad \text{(R19)}$$

$$H + Br_2 = HBr + Br \quad \text{(R20)}$$

$$Br + Br + M = Br_2 + M \quad \text{(R21)}$$

Application to "Real" Fires

A basic understanding of premixed burning is an important prerequisite in a number of applications concerning "real fires," even though the latter are essentially diffusion flames by nature. In such systems, the rate-controlling process is normally the diffusion of fuel and oxygen from their respective sides of the flame and not the rate of chemical reaction (1) and, in the case of a jet of fuel gas burning in air, the stability of the flame depends on the burning of a pocket of premixed gas at the base of the flame. Immediately above the burner rim there is a region where the gas velocity is low and where the fuel and air mix; it is a combination of the burning velocity of this mixture and the local gas velocity that determines whether the diffusion flame is stable or is "blown off." Similarly, diffusion flames can be stabilized behind an obstruction in a gas stream, since the recirculation zone behind the obstruction produces a region of low gas velocity. Such stabilization has important practical implications concerning the extinction of fires where the source of the fuel lies behind an obstruction, since such flames can be highly stable.[35]

In a diffusion flame, the fuel and oxidant react overall in stoichiometric proportions, but the local stoichiometric ratio ranges from very fuel rich in the yellow carbon zone to excess oxygen in the hot blue zone on the air side of the flame. The basic chemistry of the combustion process in a hydrocarbon-air diffusion flame is essentially the same as in a premixed flame, but the detailed mechanism reflects the change in local conditions across the flame. Thus, on the fuel side of the flame, thermal decomposition reactions are the most important processes and, owing to the lack of oxygen in this region, this leads to carbon formation and the characteristic yellow color associated with such flames. The maximum temperature is reached in the main reaction zone on the air side of the flame. The oxygen consumption occurs mainly on the air side of this zone by reaction (8),[36] and diffusion of the resulting hydroxyl radicals toward the rich side of the flame leads to the conversion of carbon monoxide to carbon

dioxide by reaction (7). Since this latter reaction produces hydrogen atoms, reactions (7) and (8) constitute a self-sustaining sequence for this part of the combustion process. In addition, reaction (8) is also the source of the oxygen atoms required for the formation of carbon monoxide by reactions (4) through (6).

$$OH + CO = CO_2 + H \quad (R7)$$

$$H + O_2 = OH + O \quad (R8)$$

$$H + H_2O = H_2 + OH \quad (R22)$$

Many researchers have assumed that a state of quasi-equilibrium exists in the main reaction zone of a diffusion flame, but this is strictly true only for a limited region of the flame. For example, Mitchell et al. have shown that the water-gas reaction ($CO + H_2 = CO_2 + H_2$) approaches equilibrium on the fuel side of the main reaction zone of a methane-air flame, which implies that reactions (7) and (22) are effectively balanced in this part of the flame.[37] Similarly, comparison of experimental data for a propane flame with that expected from thermodynamic equilibrium shows that the situation is close to equilibrium around the stoichiometric plane of the flame.[36] On the rich side of the flame, however, the carbon dioxide and water vapor levels exceed their thermodynamic equilibrium values while the carbon monoxide level is much lower. On the air side, the conversion of carbon monoxide to carbon dioxide has not reached complete equilibrium. The final "burnout" of carbon monoxide to carbon dioxide on the air side of the flame is effectively stopped when the temperature falls below 1250 K provided a critical temperature gradient is also exceeded.[38] Since this conversion occurs by reaction (7), this quenching must reflect a correspondingly sharp drop in the concentration of hydroxyl radicals, as it has a low-temperature dependence with an activation energy of only 3 kJ mol^{-1}.[23]

As far as the elementary reactions are concerned, Bilger et al. has shown that reactions (23) and (24) are effectively balanced on the fuel side of a methane-air diffusion flame, and that reactions (8), (25), and (26) only approach equilibrium in a very narrow region of the flame.[39]

$$CH_4 + H = CH_3 + H_2 \quad (R23)$$

$$H + H_2O = H_2 + OH \quad (R24)$$

$$O + H_2O = 2OH \quad (R25)$$

$$O + H_2 = OH + H \quad (R26)$$

This lack of equilibrium is much more pronounced in turbulent diffusion flames, where it has long been recognized as a problem in the modeling of such systems from first principles. With "real fires" there is the added complication of the feedback mechanism responsible for the growth of the fire. Such modeling involves a highly complex interaction of chemistry, heat transfer, and fluid dynamics and, to date, such simulations have effectively ignored the chemistry by either concentrating on the steady-state situation or assuming an exponential rate of growth for the fire as observed experimentally. Since the flow is usually dominated by buoyancy, the rate of mixing (and, hence, chemical reaction) is controlled by the resulting turbulent motion. If it is also assumed that chemical equilibrium exists through the flame, the problem reduces to the solution of the classical equations for conservation of mass, momentum, heat, and species to obtain gas velocities and temperatures for discrete points in space and moments in time.

One promising way of avoiding the equilibrium assumption is the use of laminar flamelets, in which a given microscopic element in the turbulent flow is assumed to have the same composition as an element of the same overall stoichiometry in a laminar flame.[40,41] The advantage of this approach can be seen from the predictions for carbon monoxide for a turbulent methane-air diffusion flame; when thermodynamic equilibrium was assumed the peak mole fraction of carbon monoxide was about 2.5 times that observed experimentally, whereas when the laminar flamelet approach was used the agreement was within 10 percent.[42] Lack of appropriate experimental data may restrict the use of this approach, however, unless it can be shown experimentally that essentially the same variation in composition with stoichiometry is obtained for a range of fuels.

$$CH_4 + 2H + H_2O = CO + 4H_2 \quad (R27)$$

$$CO + H_2O = CO_2 + H_2 \quad (R15)$$

$$O_2 + 2H_2 = 2H_2O \quad (R16)$$

$$O_2 + 3H_2 = 2H + 2H_2O \quad (R28)$$

An alternative approach is to simplify the chemical component of the computation by using a reduced reaction mechanism.[38,43] Full calculations for a laminar methane-air diffusion flame shows that the steady-state approximation can be applied to the species

$$OH, O, HO_2, CH_3, CH_2O, \text{ and } CHO$$

Using this approximation enables the full mechanism to be reduced to four global reaction steps, for example,[39] reactions (27), (15), (16), and (28), whose rate can be represented by a combination of the rates of individual elementary reactions. The computational advantage of this approach comes from reducing the number of chemical species, since it is the number of species rather than the number of reaction steps that determines the complexity of the calculations.

Appendix A
Mathematical Treatment of Branching Chain Reactions

Linearly Branched Chains with Linear Gas-Phase Termination under Isothermal Conditions

With such a system, the rate of change of radical concentration can be represented by an equation of the form

$$\frac{dn}{dt} = \theta + fn - gn \quad \text{(A1)}$$

where

n = radical concentration
θ = rate of chain initiation
f = coefficient of linear branching
g = coefficient of linear termination

The classic example of such a system is the thermal reaction between hydrogen and oxygen, where the second explosion limit is controlled by a competition between the reactions

$$H + O_2 = OH + O \quad \text{(R8)}$$

$$H + O_2 + M = HO_2 + M \quad \text{(R9)}$$

In this case: $n = [H]$, $f = k_2[O_2]$, and $g = k_3[O_2][M]$, where i represents the concentration of species i.

Three cases can be distinguished:

1. $g > f$

In this case the rate of chain termination is greater than the rate of chain branching, and integration of Equation A1 gives

$$n = \frac{\theta}{(f-g)} \cdot [1 - \exp^{-(g-f)\cdot t}] \quad \text{(A2)}$$

When t is large $\exp^{-(g-f)\cdot t}$ approaches zero, so that n tends to the stationary state value

$$n = \frac{\theta}{(g-f)} \quad \text{(A3)}$$

2. $f = g$

In this case n increases linearly with time, that is,

$$n = \theta \cdot t \quad \text{(A4)}$$

3. $f > g$

In this case the rate of chain branching is always greater than the rate of chain termination, and so n grows exponentially with time. Integration of Equation A1 gives

$$n = \frac{\theta}{(f-g)} \cdot [\exp^{(f-g)\cdot t} - 1]$$

These three cases are represented graphically in Figure A-1-9.1 and, in the latter case, the exponential increase in the radical concentration must lead to explosion unless this is prevented by consumption of reactants.

In the case of the hydrogen-oxygen reaction, where the hydrogen atom is the slowest reacting species, it has been shown that the ratios [H]/[OH] and [H]/[O] maintain their stationary-state values even during the exponential growth in radical concentration which leads to explosion. As a result, with such systems the usual practice is to consider the change in concentration of the slowest reacting species and assume that the concentration of all other species is the corresponding stationary-state value.

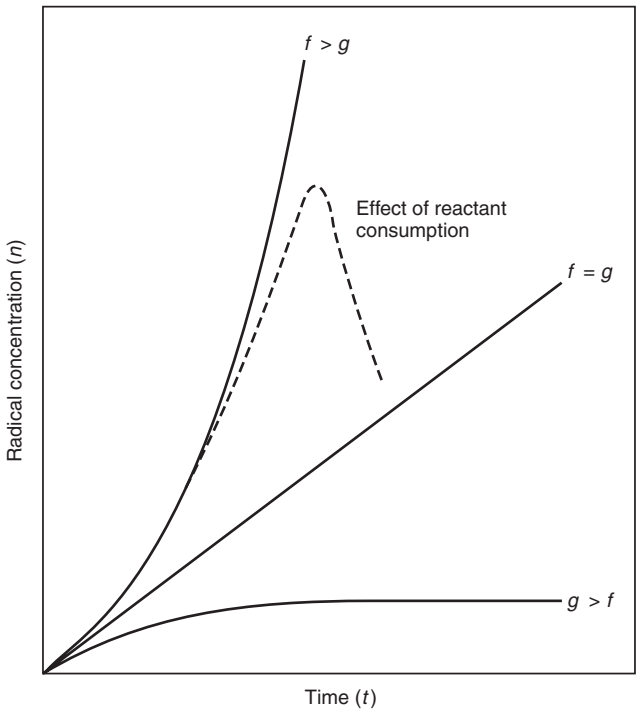

Figure A-1-9.1. ***Growth of free radical concentration, n, with time, t, in a linearly branched and terminated reaction. Boundary condition between a steady-state and exponential growth is f = g.***

CHAPTER 10

Properties of Building Materials

V. K. R. Kodur and T. Z. Harmathy

Introduction

Building components are to be designed to satisfy the requirements of serviceability and safety limit states. One of the major safety requirements in building design is the provision of appropriate fire resistance to various building components. The basis for this requirement can be attributed to the fact that, when other measures of containing the fire fail, structural integrity is the last line of defense. In this chapter, the term *structural member* is used to refer to both load bearing (e.g., columns, beams, slabs) and non–load-bearing (e.g., partition walls, floors) building components.

Fire resistance is the duration during which a structural member exhibits resistance with respect to structural integrity, stability, and temperature transmission. Typical fire resistance rating requirements for different building components are specified in building codes.

In the past, the fire resistance of structural members could be determined only by testing. In recent years however, the use of numerical methods for the calculation of the fire resistance of various structural members is gaining acceptance since these calculation methods are far less costly and time consuming.

The fire performance of a structural member depends, in part, on the properties of the materials the building component is composed of. The availability of material properties at high temperature and temperature distributions permits a mathematical approach to predicting the performance of building components exposed to fire. When a structural member is subjected to a defined temperature-time exposure during a fire, this exposure will cause a predictable temperature distribution in the member. Increased temperatures cause deformations and property changes in the materials. With knowledge of the deformations and property changes, the usual methods of structural mechanics can be applied to predict fire resistance performance.

In recent years, significant effort has been undertaken to develop material properties of various construction materials at elevated temperatures. In this chapter, the characteristics of materials are outlined. The various properties that influence fire resistance performance, together with the methods used to develop these properties, is discussed. The trends on the variation of thermal, mechanical, and other material-specific properties with temperature of commonly used construction materials are presented.

Dr. V. K. R. Kodur is Research Officer at the Institute for Research in Construction, National Research Council of Canada. He has published over 75 papers in the structural and fire resistance areas. He is a member of the ACI 216 Committee and the ASCE Committee on Structural Fire Protection. His research interests are in the fire resistance of structural members, material behavior, and on the nonlinear design and analysis of structures.

Dr. T. Z. Harmathy was head of the Fire Research Section, Institute of Research in Construction, National Research Council of Canada, until his retirement in 1988. His research centered on materials science and the spread potential of compartment fires.

Material Characteristics

Classification

Materials, based on composition, can be classified as either a homogeneous or heterogeneous type. *Homogeneous* materials have the same composition and properties throughout their volume, and are rarely found in nature. *Heterogeneous* materials have different composition and properties. Most construction materials are heterogeneous, yet their heterogeneity is often glossed over when dealing with practical problems.

The heterogeneity of concrete is easily noticeable. Other heterogeneities related to the microstructure of materials, that is, their grain and pore structures, are rarely detectable by the naked eye. The microstructure depends greatly on the way the materials are formed. In general,

materials formed by solidification from a melt show the highest degree of homogeneity. The result of the solidification is normally a *polycrystalline* material, comprising polyhedral grains of crystals which, in general, are equiaxial and randomly oriented. Severe cold-working in metals may produce an elongated grain structure and crystals with preferred orientations.

Noncrystalline solids are called *amorphous* materials. Gels and glasses are amorphous materials. Gels are formed by the coagulation of a colloidal solution. Glasses (vitreous materials) are solids with a liquid-like, grainless submicroscopic structure with low crystalline order. On heating, they will go through a series of phases of decreasing viscosity.

Synthetic polymers (plastics) are made up of long macromolecules created by polymerization from smaller repeating units (monomers). In the case of *thermoplastic* materials, the mobility of the molecular chains increases on heating. Such materials soften, much like glass. In some other types of plastics, called *thermosetting* materials, polymerization also produces cross-bonds between the molecular chains. These cross-bonds prevent the loosening of the molecular structure and the transition of the material into a liquid-like state.

Some building materials (e.g., gypsum, brick) are formed from a wet, plastic mass or from compacted powders by firing. The resulting product is a polycrystalline solid with a well-developed pore structure.

Two important building materials, concrete and gypsum, are formed by mixing finely ground powders (and aggregates) with water. The mixture solidifies by hydration. The cement paste in a concrete has a highly complex microstructure, interspersed with very fine, elaborate pores.

Most building materials can be treated as *isotropic* materials, that is, as though they possessed the same properties in all directions. An exception to this is some of the advanced composite materials, such as fiber-reinforced polymers (FRP), which might possess varying properties in different directions and are classifed as *anisotropic* materials.

Among the material properties, those that are unambiguously defined by the current composition and phase are referred to as *structure-insensitive.* Some others depend on the microstructure of the solid or on its previous history. These properties are *structure-sensitive.*

Porosity and Moisture Sorption

The fire performance of a material is dependent on the chemical composition and atomic structure of the material. The presence of water in the material composition influences the properties of materials at elevated temperatures. The two commonly associated terms to describe the composition and the extent of water present in a material are porosity and moisture sorption.

What is commonly referred to as a solid object is actually all the material within its visible boundaries. Clearly, if the solid is porous—and most building materials are—the so-called solid consists of at least two phases: (1) a solid-phase matrix, and (2) a gaseous phase (namely, air) in the pores within the matrix. Usually, however, there is also a liquid or liquid-like phase present: moisture either absorbed from the atmosphere to the pore surfaces, or held in the pores by capillary condensation. This third phase is always present if the pore structure is continuous; discontinuous pores (like the pores of some foamed plastics) are not readily accessible to atmospheric moisture.

The pore structure of materials is characterized by two properties: *porosity, P* ($m^3 \cdot m^{-3}$), the volume fraction of pores within the visible boundaries of the solid; and *specific surface, S* ($m^2 \cdot m^{-3}$), the surface area of the pores per unit volume of the material. For a solid with continuous pore structure, the porosity is a measure of the maximum amount of water the solid can hold when saturated. The specific surface and (to a lesser degree) porosity together determine the moisture content the solid holds in equilibrium with given atmospheric conditions.

The *sorption isotherm* shows the relationship at constant temperature between the equilibrium moisture content of a porous material and the relative humidity of the atmosphere. A sorption isotherm usually has two branches: (1) an *adsorption branch,* obtained by monotonically increasing the relative humidity of the atmosphere from 0 to 100 percent through very small equilibrium steps; and (2) a *desorption branch,* obtained by monotonically lowering the relative humidity from 100 to 0 percent. Derived experimentally, the sorption isotherms offer some insight into the nature of the material's pore structure.[1,2]

For heterogeneous materials consisting of solids of different sorption characteristics (e.g., concrete, consisting of cement paste and aggregates), the sorption isotherms can be estimated using the simple mixture rule (with $m = 1$; see Equation 1).

Building materials, such as concrete (or more accurately, the cement paste in the concrete) and wood, because of their large specific surfaces, can hold water in amounts substantial enough to be taken into consideration in fire performance assessments.

Mixture Rules

Some properties of materials of mixed composition or mixed phase can be calculated by simple rules if the material properties for the constituents are known. The simplest mixture rule is[3]

$$\pi^m = \sum_i \nu_i \pi_i^m \tag{1}$$

where

π = material property for the composite

π_i = material property for the composite's ith constituent

ν_i ($m^3 \cdot m^{-3}$) = volume fraction of the ith constituent

m (dimensionless) = constant that has a value between -1 and $+1$

Hamilton and Crosser recommended the following rather versatile formula for two-phase solids:[4]

$$\pi = \frac{\nu_1 \pi_1 + \gamma \nu_2 \pi_2}{\nu_1 + \gamma \nu_2} \tag{2}$$

where

$$\gamma = \frac{n\pi_1}{(n-1)\pi_1 + \pi_2} \quad (3)$$

Here phase 1 must always be the principal continuous phase. n (dimensionless) is a function of the geometry of phase distribution. With $n \rightarrow \infty$ and $n = 1$, Equations 2 and 3 convert into Equation 1 with $m = 1$ and $m = -1$, respectively. With $n = 3$, a relation is obtained for a two-phase system where the discontinuous phase consists of spherical inclusions.[5]

By repeated application, Equations 2 and 3 can be extended to a three-phase system,[6] for example, to a moist, porous solid that consists of three essentially continuous phases (the solid matrix, with moisture and air in its pores).

Survey of Building Materials

There are burnable (combustible) and nonburnable (noncombustible) building materials. The reason for preferring the use of the words *burnable* and *nonburnable* has been discussed by Harmathy.[2] To a designer concerned with the structural performance of a building during a fire, the mechanical and thermal properties of these materials are of principal interest. Yet burnable building materials may become ignited, and thereby the positive role assigned to these materials by design (i.e., functioning as structural elements of the building) may change into a negative role—that is, becoming fuel and adding to the severity of fire. Those properties of burnable building materials that are related to the latter role are discussed in other chapters of this handbook.

From the point of view of their performance in fire, building materials can be divided into the following groups:

1. *Group L (load-bearing) materials.* Materials capable of carrying high stresses, usually in tension or compression. With these materials, the mechanical properties related to behavior in tension and/or compression are of principal interest.
2. *Group L/I (load-bearing/insulating) materials.* Materials capable of carrying moderate stresses and, in fire, providing thermal protection to Group L materials. With Group L/I materials, the mechanical properties (related mainly to behavior in compression) and the thermal properties are of equal interest.
3. *Group I (insulating) materials.* Materials not designed to carry load. Their role in fire is to resist the transmission of heat through building elements and/or to provide insulation to Group L or Group L/I materials. With Group I materials, only the thermal properties are of interest.
4. *Group L/I/F (load-bearing/insulating/fuel) materials.* Group L/I materials that may become fuel in fire.
5. *Group I/F (insulating/fuel) materials.* Group I materials that may become fuel in fire.

The number of building materials has been increasing dramatically during the past few decades. In the last decade or so, a number of high-performing materials, such as FRP and high-strength concrete (HSC), have been developed to achieve cost-effectiveness in construction. While many of these high-performing materials possess superior properties at ambient temperatures, the same cannot be said of their performance at elevated temperatures. In materials such as HSC, additional complexities such as spalling arise, which might severely impact the fire performance of a structural member.

By necessity, only a few of those materials that are commonly used will be discussed in this chapter in some detail. These materials are as follows: in Group L—structural steel, lightguage steel, and reinforcing/prestressing steel; Group L/I—concrete and brick (including fiber-reinforced concrete); Group L/I/F (or Group I/F and L/F)—wood and FRP; and Group I—gypsum and insulation.

Material Properties at Elevated Temperatures

The behavior of a structural member exposed to fire is dependent, in part, on the thermal and mechanical properties of the material of which the member is composed. While calculation techniques for predicting the process of deterioration of building components in fire have developed rapidly in recent years, research related to supplying input information into these calculations has not kept pace. The designer of the fire safety features of buildings will find that information on the properties of building materials in the temperature range of interest, 20 to 800°C, is not easy to come by. Most building materials are not stable throughout this temperature range. On heating, they undergo physicochemical changes ("reactions" in a generalized sense), accompanied by transformations in their microstructure and changes in their properties. For example concrete at 500°C is completely different from the material at room temperature.

The thermophysical and mechanical properties of most materials change substantially within the temperature range associated with building fires. In the field of fire science, applied materials research faces numerous difficulties. At elevated temperatures, many building materials undergo physicochemical changes. Most of the properties are temperature dependent and sensitive to testing method parameters such as heating rate, strain rate, temperature gradient, and so on. Harmathy[7] cited the lack of adequate knowledge of the behavior of building materials at elevated temperatures as the most disturbing trend in fire safety engineering. There has been a tendency to use "notional" (also called "typical," "proprietary," "empirical," etc.) values for material properties in numerical computations—in other words, values that ensure agreement between experimental and analytical results. Harmathy warned that this practice might lead to a proliferation of theories that lack general validity.

Clearly, the generic information available on the properties of building materials at room temperature is seldom applicable in fire safety design. It is imperative, therefore, that the fire safety practitioner know how to extend, based on a priori considerations, the utility of the scanty data that can be gathered from the technical literature. Also, knowledge of unique material-specific characteristics at

elevated temperatures, such as spalling in concrete or charring in wood, is critical to determine the fire performance of a structural member. These properties are discussed in the following sections.

Reference Condition

Most building materials are porous and therefore capable of holding moisture, the amount of which depends on the atmospheric conditions. Since the presence of moisture may have a significant and often unpredictable effect on the properties of materials at any temperature below 100°C, it is imperative to conduct all property tests on specimens brought into a moistureless "reference condition" by some drying technique prior to the test. The reference condition is normally interpreted as that attained by heating the test specimen in an oven at 105°C until its weight shows no change. A few building materials however, among them all gypsum products, may undergo irreversible physicochemical changes when held at that temperature for an extended period. To bring them to a reference condition, specimens of these materials should be heated in a vacuum oven at some lower temperature level (e.g., at 40°C in the case of gypsum products).

Mechanical Properties

The mechanical properties that determine the fire performance of structural members are strength, modulus of elasticity, and creep of the component materials at elevated temperatures.

Stress-Strain Relationships

The mechanical properties of solids are usually derived from conventional tensile or compressive tests. The strength properties are usually expressed in stress-strain relations, which are often used as input data in mathematical models calculating the fire resistance. Figure 1–10.1 shows, for a metallic material, the variation of stress, σ (Pa), with increasing strain (deformation), ε ($m \cdot m^{-1}$), while the material is strained (deformed) in a tensile test at a more or less constant rate (i.e., constant crosshead speed), usually of the order of 1 $mm \cdot min^{-1}$. Generally, because of a decrease in the strength and ductility of the material, the slope of the stress-strain curves decreases with increasing temperature.

Modulus of Elasticity, Yield Strength, Ultimate Strength

The modulus of elasticity is a measure of the ability of the material to resist deformation, and is expressed as the ratio of the deforming stress to the strain in the material. Generally, the modulus of elasticity of a material decreases gradually with increasing temperature.

The tensile or compressive strength of the material is generally expressed by means of yield strength and ultimate strength. Often the strength at elevated temperature is expressed as a percentage of the compressive (tensile) strength at room temperature. Figure 1-10.2 shows the variation of strength with temperature (ratio of strength at elevated temperature to that at room temperature) for concrete, steel, and wood. For all four materials, the strength decreases with increasing temperature; however, the rate of strength loss is different.

For materials such as concrete, compressive strength is of main interest since it has very limited tensile strength at higher temperatures. However, for materials such as steel, both compressive and tensile strengths are of equal interest.

Section 0-*e* of the curve in Figure1-10.1 represents the elastic deformation of the material, which is instantaneous and reversible. The modulus of elasticity, *E* (Pa), is the slope of that section. Between points *e* and *u* the deforma-

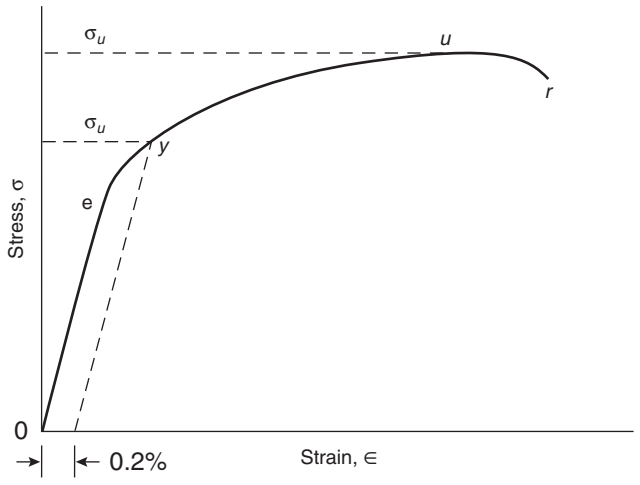

Figure 1-10.1. ***Stress-strain curve (strain rate is roughly constant).***

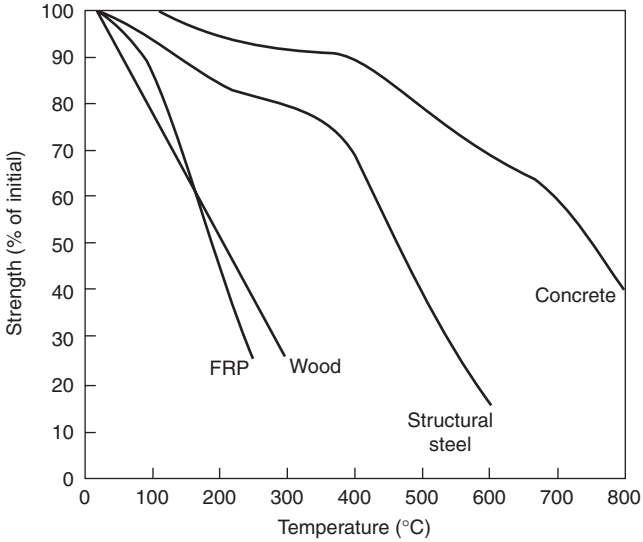

Figure 1-10.2. ***Variation of strength with temperature for different materials.***

tion is plastic, nonrecoverable, and quasi-instantaneous. The plastic behavior of the material is characterized by the yield strength at 0.2 percent offset, σ_y (Pa), and the ultimate strength, σ_u (Pa). After some localized necking (i.e., reduction of cross-sectional area), the test specimen ruptures at point *r*. The modulus of elasticity is more or less a structure-insensitive property.

For metals of similar metallurgical characteristics, the stress-strain curve can be reproduced at room temperature at a reasonable tolerance, and the shape of the curve does not depend significantly on the crosshead speed. At sufficiently high temperatures, however, the material undergoes plastic deformation even at constant stress, and the *e*-*r* section of the stress-strain curve will depend markedly on the crosshead speed.

Creep

Creep, often referred to as creep strain, is defined as the time-dependent plastic deformation of the material and is denoted by ε_t (m·m^{-1}). At normal stresses and ambient temperatures, the deformation due to creep is not significant. At higher stress levels and at elevated temperatures, however, the rate of deformation caused by creep can be substantial. Hence, the main factors that influence creep are the temperatures, the stress level, and their duration.

In a creep test the variation of ε_t is recorded against time, *t* (h), at constant stress (more accurately, at constant load) and at constant temperature *T* (K). A typical strain-time curve is shown in Figure 1-10.3(a). The total strain, ε (m·m^{-1}), is

$$\varepsilon = \frac{\sigma}{E} + \varepsilon_t \tag{4}$$

The 0-*e* section of the strain-time curve represents the instantaneous elastic (and reversible) part of the curve; the rest is creep, which is essentially nonrecoverable. The creep is fast at first [primary creep, section *e*-s_1 in Figure 1-10.3(a)], then proceeds for a long time at an approximately constant rate (secondary creep, section s_1-s_2), and finally accelerates until rupture occurs (tertiary creep, section s_2-*r*). The curve becomes steeper if the test is conducted either at a higher load (stress) or at a higher temperature.

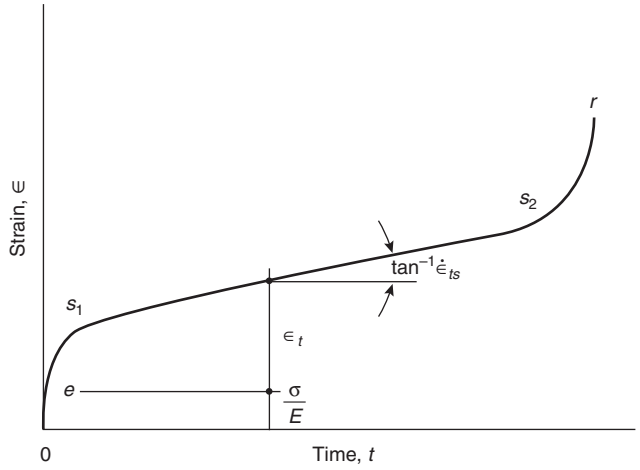
Dorn's concept is particularly suitable for dealing with deformation processes developing at varying temperatures.[8] Dorn eliminated the temperature as a separate variable by the introduction of a new variable: the "temperature-compensated time," θ (h), defined as

$$\theta = \int_0^t e^{-\Delta H_c/RT}\, dt \tag{5}$$

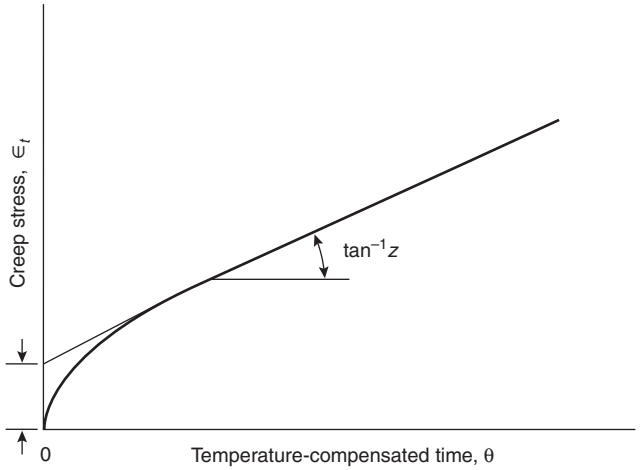
where ΔH_c (J·kmol^{-1}) is the activation energy of creep, and *R* (J·kmol^{-1}·K^{-1}) is the gas constant.

From a practical point of view, only the primary and the secondary creeps are of importance. It has been shown that the creep strain in these two regimes can be satisfactorily described by the following equation[9]

$$\varepsilon_t = \frac{\varepsilon_{t0}}{\ln 2} \cosh^{-1}(2^{Z\theta/\varepsilon_{t0}}) \qquad (\sigma \simeq \text{constant}) \tag{6}$$



(a)



(b)

Figure 1-10.3. ***(a) Creep strain vs. time curve (T = constant; σ ≈ constant); (b) creep strain vs temperature-compensated time curve (σ ≈ constant).***

or approximated by the simple formula[10]

$$\varepsilon_t \approx \varepsilon_{t0} + Z\theta \qquad (\sigma \simeq \text{constant}) \tag{7}$$

where *Z* (h^{-1}) is the Zener-Hollomon parameter, and ε_{t0} (mm^{-1}) is another creep parameter, the meaning of which is explained in Figure 1-10.3(b). The Zener-Hollomon parameter is defined as[11]

$$Z = \dot{\varepsilon}_{ts} e^{\Delta H/RT} \tag{8}$$

where $\dot{\varepsilon}_{ts}$ (mm^{-1}·h^{-1}) is the rate of secondary creep at a temperature, *T*. The two creep parameters, *Z* and ε_{t0}, are functions of the applied stress only (i.e., they are independent of the temperature).

For most materials, creep becomes noticeable only if the temperature is higher than about one-third of the melting temperature (on the absolute scale).

The creep of concrete is due to the presence of water in its microstructure.[12] There is no satisfactory explanation for the creep of concrete at elevated temperatures. Anderberg and Thelandersson,[13] and Schneider[14] suggested techniques for the calculation of the deformation of concrete under conditions characteristic of fire exposure.

Thermal Properties

The material properties that influence the temperature rise and distribution in a member are its thermal conductivity, thermal expansion, specific heat, thermal diffusivity, and mass loss. These properties depend on the composition and characteristics of the constituent materials.

Thermal Expansion

The thermal expansion characterizes the expansion (or shrinkage) of a material caused by heating and is defined as the expansion (shrinkage) of unit length of a material when it is raised one degree in temperature. The expansion is considered to be positive when the material elongates and is considered negative when it shortens. In general, the thermal expansion of a material is dependent on the temperature. The dilatometric curve is a record of the fractional change of a linear dimension of a solid at a steadily increasing or decreasing temperature. With mathematical symbolism, the dilatometric curve is a plot of

$$\frac{\Delta \ell}{\ell_0} \quad \text{against} \quad T$$

where $\Delta \ell = \ell - \ell_0$ and ℓ (m) and ℓ_0 (m) are the changed and original dimensions of the solid, respectively, the latter usually taken at room temperature. $\Delta \ell$ reflects not only the linear expansion or shrinkage of the material, but also the dimensional effects brought on by possible physicochemical changes (i.e., "reactions").

The heating of the solid usually takes place at a predetermined rate, 5°C·min^{-1} as a rule. Because the physicochemical changes proceed at a finite rate and some of them are irreversible, a dilatometric curve obtained by heating rarely coincides with that obtained during the cooling cycle. Sluggish reactions may bring about a steady rise or decline in the slope of the dilatometric curve. Discontinuities in the slope indicate very fast reactions. Heating the material at a rate higher than 5°C·min^{-1} usually causes the reactions to shift to higher temperatures and to develop faster.

The coefficient of linear thermal expansion, β (m·m^{-1}·K^{-1}), is defined as

$$\beta = \frac{1}{\ell} \frac{d\ell}{dT} \tag{9}$$

Since $\ell = \ell_0$, the coefficient of linear thermal expansion is, for all intents, the tangent to the dilatometric curve. For solids that are isotropic in a macroscopic sense, the coefficient of volume expansion is approximately equal to 3β.

The thermal expansion is measured with a dilatometric apparatus, capable of producing curves that show the expansion of the materials with temperature in the range from 20°C to 1000°C. Harmathy,[7,15] using a horizontal dilatometric apparatus, recorded dilametric curves for various types of concrete and brick, some of which are presented in later sections. The sample was 76.2-mm-long and about 13 by 13 mm in cross section. It was subjected to a small spring load that varied during the test. Unfortunately, even this small load caused creep shrinkage with those materials that tended to soften at higher temperatures. Furthermore, since the apparatus did not provide a means for placing the sample in a nitrogen atmosphere, in certain cases oxidation may also have had some effect on the shape of the curves.

Mass Loss

The mass loss is often used to express the loss of mass at elevated temperatures. The thermogravimetric curve is a record of the fractional variation of the mass of a solid at steadily increasing or decreasing temperature. Again, with mathematical symbolism, a thermogravimetric curve is a plot of

$$\frac{M}{M_0} \quad \text{against} \quad T$$

where M and M_0 (kg) are the changed and original masses of the solid, respectively, the latter usually taken at room temperature. Generally a heating rate of 5°C·min^{-1} is used in the measurements.

A thermogravimetric curve reflects reactions accompanied by loss or gain of mass but, naturally, it does not reflect changes in the materials' microstructure or crystalline order. $M/M_0 = 1$ is the thermogravimetric curve for a chemically inert material. Again, an increase in the rate of heating usually causes those features of the curve that are related to chemical reactions to shift to higher temperatures and to develop faster.

The thermogravimetric curves to be shown were obtained by a DuPont 951 thermogravimetric analyzer,[16] using specimens of 10 to 30 mg in mass, placed in a nitrogen atmosphere.[7] The rate of temperature rise was 5°C·min^{-1}. Figure 1-10.4 shows the variation of mass loss for concrete in the temperature range from 20°C to 1000°C.

Density, Porosity

The density, ρ (kg·m^{-3}), in an oven-dry condition, is the mass of a unit volume of the material, comprising the solid itself and the air-filled pores. Assuming that the material is isotropic with respect to its dilatometric behavior, its density at any temperature can be calculated from the thermogravimetric and dilatometric curves.

$$\rho = \rho_0 \frac{(M/M_0)_T}{[1 + ((\Delta \ell)/(\ell_0))_T]^3} \tag{10}$$

where ρ_0 (kg·m^{-3}) is the density of the solid at the reference temperature (usually room temperature), and the T subscript indicates values pertaining to temperature T in the thermogravimetric and dilatometric records.

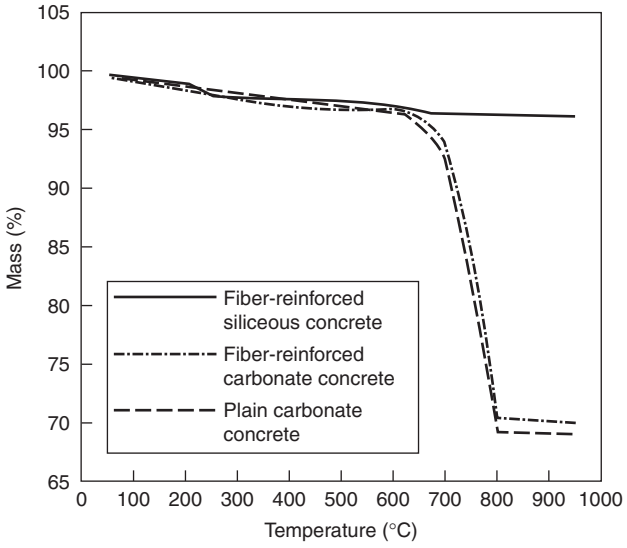


Figure 1-10.4. ***Mass loss of various concrete types as a function of temperature.[17]***

The density of composite solids at room temperature can be calculated by means of the mixture rule in its simplest form (Equation 1 with $m = 1$).

$$p = \sum_i \nu_i p_i \tag{11}$$

where the i subscript relates to information on the ith component. At elevated temperatures, the expansion of the components is subject to constraints, and therefore the mixture rule can only yield a crude approximation.

If, as usual, the composition is given in mass fractions rather than in volume fractions, the volume fractions can be obtained as

$$\nu_i = \frac{w_i/p_i}{\sum_i w_i/p_i} \tag{12}$$

where w_i is the mass fraction of the ith component (kg·kg^{-1}).

True density, ρ_t (kg·m^{-3}), is the density of the solid in a poreless condition. Such a condition is nonexistent for many building materials, and, therefore, ρ_t may be a theoretical value derived on crystallographic considerations, or determined by some standard technique, for example, ASTM C135.[18] The relationship between the porosity and density is

$$P = \frac{\rho_t - \rho}{\rho_t} \tag{13}$$

The overall porosity of a composite material consisting of porous components is

$$P = \sum_i \nu_i P_i \tag{14}$$

where, again, the i subscript relates to the ith component of the material.

Specific Heat

The specific heat of a material is the characteristic that describes the amount of heat required to raise a unit mass of the material at unit temperature. A calorimetric curve describes the variation with temperature of the apparent specific heat of a material at constant pressure, c_p (J·kg^{-1}·K^{-1}). The apparent specific heat is defined as

$$c_p = \frac{\delta h}{\delta T_p} \tag{15}$$

where h is enthalpy (J·kg^{-1}), and the p subscripts indicate the constancy of pressure. If the heating of the solid is accompanied by physicochemical changes (i.e., "reactions"), the enthalpy becomes a function of the reaction progress variable, ξ (dimensionless), that is, the degree of conversion at a particular temperature from reactant(s) into product(s). For any temperature interval where physicochemical change takes place,[2,6,19] $0 \le \xi \le 1$, and

$$c_p = \bar{c}_p + \Delta h \frac{d\xi}{dT} \tag{16}$$

where c_p (J·kg^{-1}·K^{-1}) is the specific heat for that mixture of reactants and (solid) products that the material consists of at a given stage of the conversion (as characterized by ξ), and Δh_p (J·kg^{-1}) is the latent heat associated with the physicochemical change.

As Equation 16 and Figure 1-10.5 show, in temperature intervals of physicochemical instability, the apparent specific heat consists of sensible heat and latent heat contributions. The latter contribution will result in extremities in the calorimetric curve: a maximum if the reaction is endothermic, a minimum if it is exothermic.

In heat flow studies, it is usually the ρc_p product (J·m^{-3}·K^{-1}) rather than c_p that is needed as input information. This product is referred to as volume specific heat.

Until the eighties, adiabatic calorimetry was the principal method to study the shape of the c_p versus T relationship. Since the eighties, differential scanning calorimetry

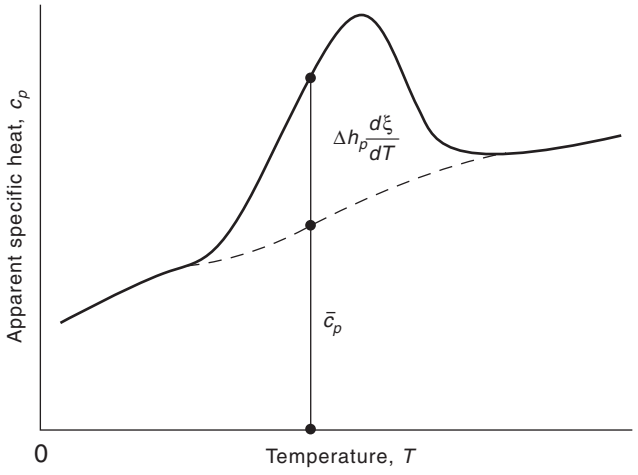

Figure 1-10.5. ***The apparent specific heat.***

(DSC) is the most commonly used technique for mapping the curve in a single temperature sweep at a desired rate of heating. Unfortunately, the accuracy of the DSC technique in determining the sensible heat contribution to the apparent specific heat may not be particularly good (sometimes it may be as low as ±20 percent). The rate of temperature rise was usually 5°C·min^{-1}. At higher heating rates, the peaks in the DSC curves tend to shift to higher temperatures and become sharper. For temperatures above 600°C, a high-temperature differential thermal analyzer (DTA) is also used. Harmathy, with the aid of a DuPont 910 differential scanning calorimeter, developed calorimetric curves for a number of materials by placing the samples, 10 to 30 mg in mass, in a nitrogen atmosphere.[7,20]

Materials that undergo exothermic reactions may yield negative values in the calorimetric curve. A negative value for c_p indicates that, at the applied (and enforced) rate of heating, the rate of evolution of reaction heat exceeds the rate of absorption of sensible heat by the material. In natural processes, the apparent specific heat can never be negative, because the heat evolving from the reaction is either scattered to the surroundings or, if absorbed by the material, causes a very fast temperature rise. If the heat of reaction is not very high, obtaining nonnegative values for c_p can be achieved by suitably raising the scanning rate. For this reason, some materials undergoing exothermic reactions must be tested at rates of heating higher than 5°C·min^{-1}, often as high as 50°C·min^{-1}.

If experimental information is not available, the c_p versus T relationship can be calculated from data on heat capacity and heat of formation for all the components of the material (including reactants and products), tabulated in a number of handbooks.[21,22] Examples of calculations are presented in References 2 and 6, where information is developed for the apparent specific heat versus temperature relation for a cement paste and four kinds of concrete.

Thermal Conductivity

The temperature rise in a member, as a result of heat flow, is a function of the thermal conductivity of the material. Heat transmission solely by conduction can occur only in poreless, nontransparent solids. In porous solids (most building materials), the mechanism of heat transmission is a combination of conduction, radiation, and convection. (If pore size is less than that about 5 mm, the contribution of pores to convective heat transmission is negligible.) The thermal conductivity of porous materials is, in a strict sense, merely a convenient empirical factor that makes it possible to describe the heat transmission process with the aid of the Fourier law. That empirical factor will depend not only on the conductivity of the solid matrix, but also on the porosity of the solid and the size and shape of the pores. At elevated temperatures, because of the increasing importance of radiant heat transmission through the pores, conductivity becomes sensitive to the temperature gradient.

Since measured values of the thermal conductivity depend to some extent on the temperature gradient employed in the test, great discrepancies may be found in thermal conductivity data reported by various laboratories. A thermal conductivity value yielded by a particular technique is, in a strict sense, applicable only to heat flow patterns similar to that characteristic of the technique employed.

Experimental data indicate that porosity is not a greatly complicating factor as long as it is not larger than about 0.1. With insulating materials, however, the porosity may be 0.8 or higher. Conduction through the solid matrix may be an insignificant part of the overall heat transmission process; therefore, using the Fourier law of heat conduction in analyzing heat transmission may lead to deceptive conclusions.

If the solid is not oven-dry, a temperature gradient will induce migration of moisture, mainly by an evaporation condensation mechanism.[23] The migration of moisture is usually, but not necessarily, in the direction of heat flow, and manifests itself as an increase in the apparent thermal conductivity of the solid. Furthermore, even oven-dry solids may undergo decomposition (mainly dehydration) reactions at elevated temperatures. The sensible heat carried by the gaseous decomposition products as they move in the pores adds to the complexity of the heat flow process. At present there is no way of satisfactorily accounting for the effect of simultaneous mass transfer on heat flow processes occurring under fire conditions.

The thermal conductivity of layered, multiphase solid mixtures depends on whether the phases lie in the direction of, or normal to, the direction of heat flow and is determined using the simple mixture rule.[4,24] At higher temperatures, because of radiative heat transfer through the pores, the contribution of the pores to the thermal conductivity of the solid must not be disregarded.[25]

The thermal conductivity of solids is a structure-sensitive property. For crystalline solids, the thermal conductivity is relatively high at room temperature, and gradually decreases as the temperature rises. For predominantly amorphous solids, on the other hand, the conductivity is low at room temperature and increases slightly with the rise of temperature. The conductivity of porous crystalline materials may also increase at very high temperatures because of the radiant conductivity of the pores.

The thermal conductivity of materials such as concrete or brick can be measured, in the temperature range between 20°C and 800°C, using a non-steady-state hot wire method.[26,27] The thermal conductivity values at discrete temperature levels can be plotted to obtain a curve. Unfortunately, no scanning technique exists for acquiring a continuous thermal conductivity versus temperature curve from a single temperature sweep.

Special problems arise with the estimation of the thermal conductivity for temperature intervals of physicochemical instability. Both the steady-state and variable-state techniques of measuring thermal conductivity require the stabilization of a pattern of temperature distribution (and thereby a certain microstructural pattern) in the test sample prior to the test. The test results can be viewed as points on a continuous thermal conductivity versus temperature curve obtained by an imaginary scanning technique performed at an extremely slow scanning rate. Since each point pertains to a more or less stabilized microstructural pattern, there is no way of knowing how the thermal conductivity would vary in the course of a

physicochemical process developing at a finite rate and varying microstructure.

On account of the nonreversible microstructural changes brought about by heating, the thermal conductivity of building materials (and perhaps most other materials) is usually different in the heating and cooling cycles. Open and solid circles are used in the figures to identify thermal conductivity values obtained by stepwise increasing and stepwise decreasing the temperature of the sample, respectively. Also, often the thermal conductivity of a material is taken as invariant with respect to the direction of heat flow.

Thermal Diffusivity

The thermal diffusivity of a material is defined as the ratio of thermal conductivity to the volumetric specific heat of the material. It measures the rate of heat transfer from an exposed surface of a material to the inside. The larger the diffusivity, the faster the temperature rise at a certain depth in the material. Similar to thermal conductivity and specific heat, thermal diffusivity varies with temperature rise in the material. Thermal diffusivity, α, can be calculated using the relation:

$$\alpha = \frac{k}{\rho c_p} \tag{17}$$

where

k = thermal conductivity
ρ = density
c_p = specific heat of the material

Special (Material-Specific) Properties

In addition to thermal and mechanical properties, certain other properties, such as spalling in concrete and charring in wood, influence the performance of a material at elevated temperature. These properties are unique to specific materials and are critical for predicting the fire performance of a structural member.

Critical Temperature

In building materials, such as steel and FRP, the determination of failure in a structural member exposed to fire is simplified to the calculation of critical temperature. The critical temperature is defined as the temperature at which the material loses much of its strength and can no longer support the applied load. When this temperature is reached, the safety factor against failure becomes less than 1.

North American standards (ASTM E119) assume a critical or failure temperature of 538°C (1000°F) for structural steel. It is a typical failure temperature for columns under full design load. This temperature is also regarded as the failure temperature in the calculation of fire resistance of steel members. If a load is applied to the member, the test is continued until the member actually fails, which, depending on the load intensity, may occur at a higher or lower steel temperature.

This concept of critical temperature is also used for reinforced and prestressed steel in concrete structural members for evaluating the fire resistance ratings. These ratings are generally obtained through the provision of minimum member dimensions and minimum thickness of concrete cover. The minimum concrete cover thickness requirements are intended to ensure that the temperature in the reinforcement does not reach its critical temperature for the required duration. For reinforcing steel, the critical temperature is 593°C, while for prestressing steel the critical temperature is 426°C.[28]

Spalling

Spalling is defined as the breaking of layers (pieces) of concrete from the surface of the concrete elements when the concrete elements are exposed to high and rapidly rising temperatures, such as those experienced in fires. Spalling can occur soon after exposure to heat and can be accompanied by violent explosions, or it may happen when concrete has become so weak after heating that, when cracking develops, pieces fall off the surface. The consequences may be limited as long as the extent of the damage is small, but extensive spalling may lead to early loss of stability and integrity due to exposed reinforcement and penetration of partitions.

While spalling might occur in all concretes, high-strength concrete (HSC) is believed to be more susceptible than normal-strength concrete (NSC) because of its low permeability and low water-cement ratio. In a number of test observations on HSC specimens, it has been found that spalling is often of an explosive nature.[29,30] Hence, spalling is one of the major concerns in the use of HSC and should be properly accounted for in evaluating fire performance. Spalling in NSC and HSC columns is compared in Figure 1-10.6 using the data obtained from full-scale fire tests on loaded columns.[31] It can be seen that the spalling is quite significant in the HSC column.

Spalling is believed to be caused by the buildup of pore pressure during heating. The extremely high water vapor pressure, generated during exposure to fire, cannot escape due to the high density (and low permeability) of HSC, and this pressure buildup often reaches the saturation vapor pressure. At 300°C, the pressure reaches approximately 8 MPa; such internal pressures are often too high to be resisted by the HSC mix having a tensile strength of approximately 5 MPa.[32] The drained conditions at the heated surface, and the low permeability of concrete, lead to strong pressure gradients close to the surface in the form of the so-called "moisture clog."[2,33] When the vapor pressure exceeds the tensile strength of concrete, chunks of concrete fall off from the structural member. The pore pressure is considered to drive progressive failure; that is, the greater the spalling, the lower the permeability of concrete. This falling off can often be explosive in nature, depending on the fire and concrete characteristics.

However, other researchers explain the occurrence of spalling on the basis of fracture mechanics and argue that the spalling results from restrained thermal dilatation close to the heated surface.[34] This leads to compressive stresses parallel to the heated surface, which are released by brittle fractures of concrete, in other words, spalling.

(a) (b)

Figure 1-10.6. ***Spalling in NSC and HSC columns after exposure to fire:[31] (a) normal-strength concrete column, and (b) high-strength concrete column.***

Spalling, which often results in the rapid loss of concrete during a fire, exposes deeper layers of concrete to fire temperatures, thereby increasing the rate of transmission of heat to the inner layers of the member, including the reinforcement. When the reinforcement is directly exposed to fire, the temperatures in the reinforcement rise at a very high rate, leading to a faster decrease in strength of the structural member. The loss of strength in the reinforcement, added to the loss of concrete due to spalling, significantly decreases the fire resistance of a structural member.

In addition to strength and porosity of concrete mix, density, load intensity, fire intensity, aggregate type, and relative humidity are the primary parameters that influence spalling in HSC. The variation of porosity with temperature is an important property needed for predicting spalling performance of HSC. Noumowe et al. carried out porosity measurements on NSC and HSC specimens, using a mercury porosimeter, at various temperatures.[35]

Charring

Charring is the process of formation of a layer of char at the exposed surface of wood members during exposure to fire. The charring process also occurs in other members, such as FRP and some types of plastics. When exposed to heat, wood undergoes thermal degradation (pyrolysis), the conversion of wood to char and gas, resulting in a reduction of the density of the wood. Studies have shown that the charring temperature for wood lies in the range of 280°C to 300°C.[28]

The charred layer is considered to have practically no strength. The fire resistance of the member depends on the extent of charring and the remaining strength of the uncharred portion.

The charring rate, a critical parameter in determining the fire resistance of a structural wood member, is defined as the rate at which wood is converted to char. In the standard fire resistance test, it has been noted that the average rate of charring transverse to the grain is approximately 0.6 mm/min.[28] The charring rate parallel to the grain of wood is approximately twice the rate when it is transverse to the grain. Detailed studies on the charring rates for several specimen and timber types are reported by various researchers[36–38] and are summarized in a report.[39] These charring rates were constant (in each study) and ranged from 0.137 to 0.85 mm/min. The assumption of a constant rate of charring is reasonable for thick wood members.

Charring is influenced by a number of parameters, the most important ones being density, moisture content, and contraction of wood. The influence of the moisture content and density of the wood on the charring rate is illustrated in Figure 1-10.7 for Douglas fir exposed to the standard fire.[28] It can be seen that the charring rate decreases with increasing density of the wood and also with increasing moisture content.

It is important to recognize that the charring rate in real fires depends on the severity of fire to which the wood is exposed. This depends on the fuel load and the ventilation factor of the compartment (for full details see Section 4, Chapter 8, "Fire Temperature-Time Relations" in this book). Detailed information on the charring of untreated wood—with expressions for charring rate in terms of the influencing factors of density, moisture con-

tent, external heat flux, and oxygen concentration—when exposed to real fires is given by Hadvig[40] and Mikkola.[41]

Sources of Information

Information on the properties of building materials at elevated temperatures is scattered throughout the literature. There are a few publications, however, that may be particularly valuable for fire safety practitioners. A book by Harmathy[2] and the ASCE manual on structural fire protection[28] present a wealth of information on concrete, steel, wood, brick, gypsum, and various plastics. The thermal properties of 31 building materials are surveyed in an NRCC report.[7] The mechanical and thermal properties of concrete are discussed in an ACI guide,[42] and in reports by Bennetts[43] and Schneider.[44] Those of steel are surveyed in the ACI guide, in Bennetts's report, and in a report by Anderberg.[45] Information on the thermal conductivity of more than 50 rocks (potential concrete aggregates) is presented in a paper by Birch and Clark.[46] The relationships for thermal and mechanical properties, at elevated temperatures, for some building materials are listed in the ASCE structural fire protection manual.[28] In most cases these properties are expressed, in the temperature range of 0 to 1000°C, as a function of temperature and other properties at ambient temperature. These values can be used as input data in mathematical models for predicting the temperatures and fire performance of structural members.

Steel

Steel is a Group L material. The steels most often used in the building industry are either hot-rolled or cold-drawn. The structural steels and concrete-reinforcing bars are hot-rolled, low-carbon, ferrite-pearlite steels. They have a randomly oriented grain structure, and their strength depends mainly on their carbon content. The prestressing steel wires and strands for concrete are usually made from cold-drawn, high-carbon, pearlitic steels with an elongated grain structure, oriented in the direction of the cold work. In addition, light-gauge steel, made from cold-formed steel, finds wide applications in lightweight framing, such as walls and floors.

Information on the mechanical properties of two typical steels [a structural steel (ASTM A36) and a prestressing wire (ASTM A421)] is presented in Figures 1-10.8 through 1-10.10, and in Table 1-10.1.[47] Figures 1-10.8 and 1-10.9 are stress-strain curves at room temperature (24°C and 21°C, respectively) and at a number of elevated temperature levels. Figure 1-10.10 shows the effect of temperature on the yield and ultimate strengths of the two steels.

Table 1-10.1 presents information on the effect of stress on the two creep parameters, Z and ε_{t0} (see Equation 7). Since creep is a very structure-sensitive property, the creep parameters may show a substantial spread, even for steels with similar characteristics at room temperature. The application of the creep parameters to the calculation of the time of structural failure in fire is discussed in Reference 4.

The modulus of elasticity (E) is about 210×10^3 MPa for a variety of common steels at room temperature. Figure 1-10.11 shows its variation with temperature for struc-

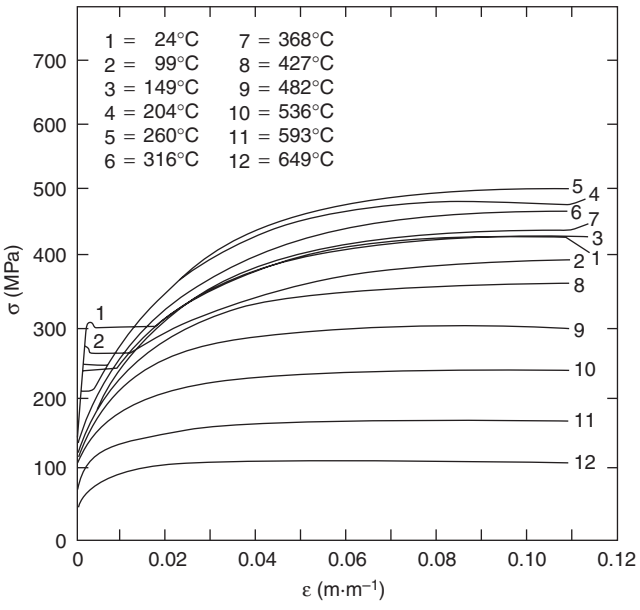

Figure 1-10.8. ***Stress-strain curves for a structural steel (ASTM A36) at room temperature and elevated temperatures.[47]***

tural steels[48] and steel reinforcing bars.[49] (E_0 in Figure 1-10.11 is the modulus of elasticity at room temperature.)

The density (ρ) of steel is about 7850 kg·m^{-3}. Its coefficient of thermal expansion (β) is a structure-insensitive property. For an average carbon steel, β is 11.4×10^{-6} m·m^{-1}·K^{-1} at room temperature. The dilatometric curve shown in Figure 1-10.12 is applicable to most of the common steels. The curve reveals substantial contraction of the material at about 700°C, which is associated with the transformation of the ferrite-pearlite structure into austenite.

Being a structure-sensitive property, the thermal conductivity of steel is not easy to define. For carbon steels it usually varies within the range of 46 to 65 W·m^{-1}·K^{-1}.

Equations for various properties of steel, as functions of temperature, are available in the ASCE structural fire protection manual[28] and in Eurocode 3.[50,51] In the ASCE manual, the same set of relationships is applicable for thermal properties of both structural and reinforcing steel. However, separate relationships for stress-strain and elasticity are given for the two steels with slightly conservative values for stuctural steel. Recently, Poh proposed a general stress-strain equation that expreses stress explicitly in terms of strain in a single continuous curve.[52]

The critical temperature of steel is often used as a bench mark for determining the failure of structural members exposed to fire. This ensures that the yield strength is not reduced to less than that of 50 percent of ambient value. The critical temperature for various types of steels is given in Table 1-10.2.

The properties of cold-formed light-gauge steel are slightly different from those of hot-rolled structural steel. Gerlich[53] and Makelainen and Miller,[54] based on steady-

the proposed relationships and on the relationship in BS 5950.[56] The BS 5950 curves represent a conservative 95 percent confidence limit (i.e., a 5 percent chance that strength would fall below the curve), while the other two curves are representative of mean test data. Figure 1-10.14 shows the variation of modulus of elasticity of light-gauge steel at elevated temperatures. The modulus E_T represents the tangent modulus at low stress levels (or initial tangent modulus), because steel stress-strain relationships become increasingly nonlinear at elevated temperatures. The effect of zinc coating on the mechanical properties of steel is of little significance.

The light-gauge steel has somewhat lower thermal expansion when compared to similar expressions for other steels.[54] The other thermal properties of steel, such as specific heat and thermal conductivity, are of little importance for the thermal modeling of light-gauge steel because steel framing plays a minor role in the heat transfer mechanism. A review of some of these properties is presented in a review paper.[57]

The critical temperature of light-gauge steel is much lower than for other types of steels. While Eurocode 3 limits this to a conservative value of 350°C, in other cases a critical temperature of 400°C is used (see Table 1-10.2).

Concrete

Concrete is a Group L/I material. The word *concrete* covers a large number of different materials, with the single common feature that they are formed by the hydration of cement. Since the hydrated cement paste amounts to only 24 to 43 volume percent of the materials present, the properties of concrete may vary widely with the aggregates used.

Traditionally, the compressive strength of concrete used to be around 20 to 50 MPa, which is referred to as normal-strength concrete (NSC). In recent years, concrete with a compressive strength in the range 50 to 100 MPa has become widely used and is refered to as high-strength concrete (HSC). Depending on the density, concretes are usually subdivided into two major groups: (1) normal-weight concretes with densities in the 2150- to 2450-kg·m^{-3} range, and (2) lightweight concretes with densities between 1350 and 1850 kg·m^{-3}. Fire safety practitioners again subdivide the normal-weight concretes into silicate (siliceous) and carbonate aggregate concrete, according to the composition of the principal aggregate. Also, a small amount of discontinuous fibers are often added to the concrete mix to achieve superior performance; this concrete is referred to as fiber-reinforced concrete (FRC). In this section, the properties of concrete are discussed under three groups: namely, NSC, FRC, and HSC.

Normal-Strength Concrete

A great deal of information is available in the literature on the mechanical properties of various types of normal-strength concrete. This information is summarized in reports by Bennetts[43] and Schneider,[44] the ACI guide,[42] the ASCE fire protection manual,[28] and in Harmathy's book.[2] Figure 1-10.15 shows the stress-strain curves for a lightweight concrete with expanded shale aggregate at room temperature (24°C) and a few elevated temperature levels.[58] The shape of the curves may depend on the time of holding the test specimen at the target temperature level before the compression test.

The modulus of elasticity (E) of various concretes at room temperature may fall within a very wide range, 5.0×10^3 to 35.0×10^3 MPa, dependent mainly on the water-cement ratio in the mixture, the age of concrete, the method of conditioning, and the amount and nature of the aggregates. Cruz found that the modulus of elasticity decreases rapidly with the rise of temperature, and the fractional decline does not depend significantly on the type of aggregate.[59] (See Figure 1-10.16; E_0 in the figure is the modulus of elasticity at room temperature.) From other surveys,[2,43] it appears, however, that the modulus of elasticity of normal-weight concretes decreases faster with the rise of temperature than that of lightweight concretes.

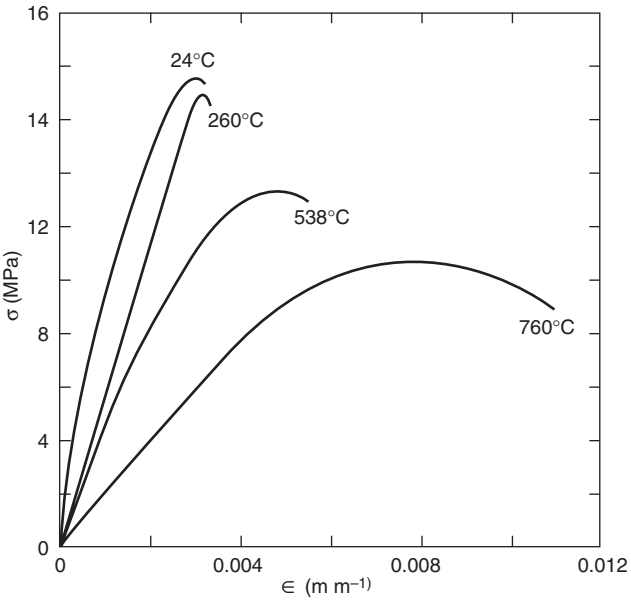

Figure 1-10.15. ***Stress-strain curves for a lightweight masonry concrete at room and elevated temperatures.[58]***

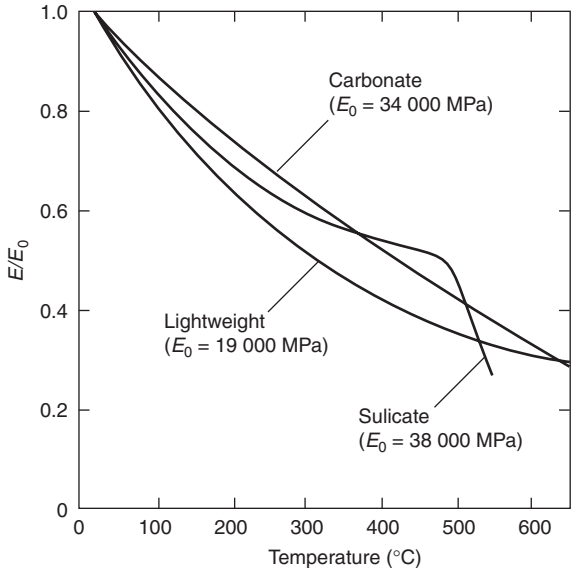

Figure 1-10.16. ***The effect of temperature on the modulus of elasticity of concretes with various aggregates.[59]***

The compressive strength (σ_u) of NSC may also vary within a wide range. Compressive strength is influenced by the same factors as the modulus of elasticity. For conventionally produced normal-weight concretes, the strength at room temperature is usually between 20 and 50 MPa. For lightweight concretes, the strength is usually between 20 and 40 MPa.

Information on the variation of the compressive strength with temperature is presented in Figure 1-10.17 (for a silicate aggregate concrete), Figure 1-10.18 (for a carbonate aggregate concrete), and Figure 1-10.19 (for two lightweight aggregate concretes, one made with the addition of natural sand).[60] [$(\sigma_u)_0$ in the figures stands for the compressive strengths of concrete at room temperature.] In some experiments, the specimens were heated to the test temperature without load (see curves labeled "unstressed"). In others they were heated under a load amounting to 40 percent of the ultimate strength (see curves labeled "stressed"). Again, in others they were heated to the target temperature without load, then cooled to room temperature and stored at 75 percent relative humidity for six days, and finally tested at room temperature (see curves labeled "unstressed residual").

Some information on the creep of concrete at elevated temperatures is available from the work of Cruz,[61] Mare-

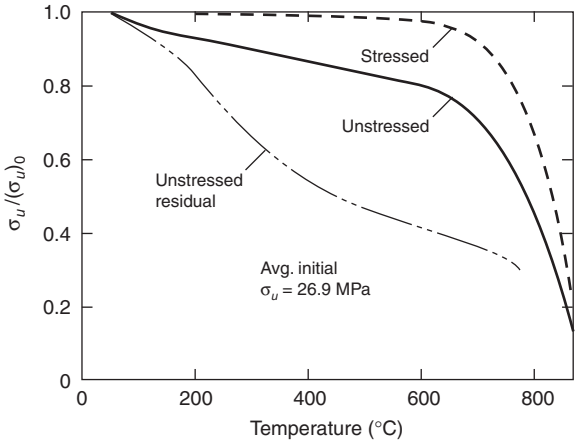

Figure 1-10.17. ***The effect of temperature on the compressive strength of a normal-weight concrete with silicate aggregate.[60]***

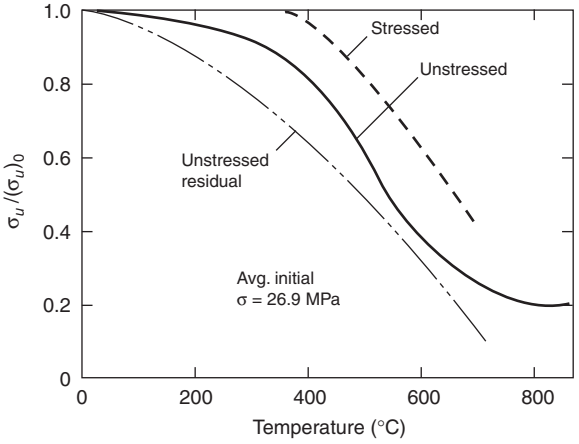

Figure 1-10.18. ***The effect of temperature on the compressive strength of a normal-weight concrete with carbonate aggregate.[60]***

Âchal,[62] Gross,[63] and Schneider et al.[64] The creep curves shown in Figure 1-10.20 are those recorded by Cruz for a normal-weight concrete with carbonate aggregates.

Since the aggregates amount to 60 to 75 percent of the volume of concrete, the dilatometric curve usually resembles that of the principal aggregate. However, some lightweight aggregates, for example, pearlite and vermiculite,

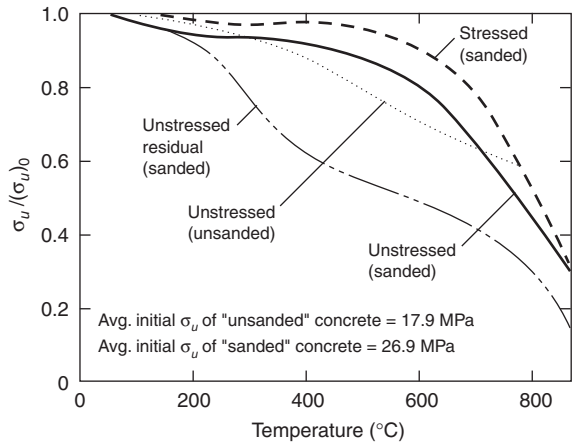

Figure 1-10.19. ***The effect of temperature on the compressive strength of two lightweight concretes (one with natural sand).[60]***

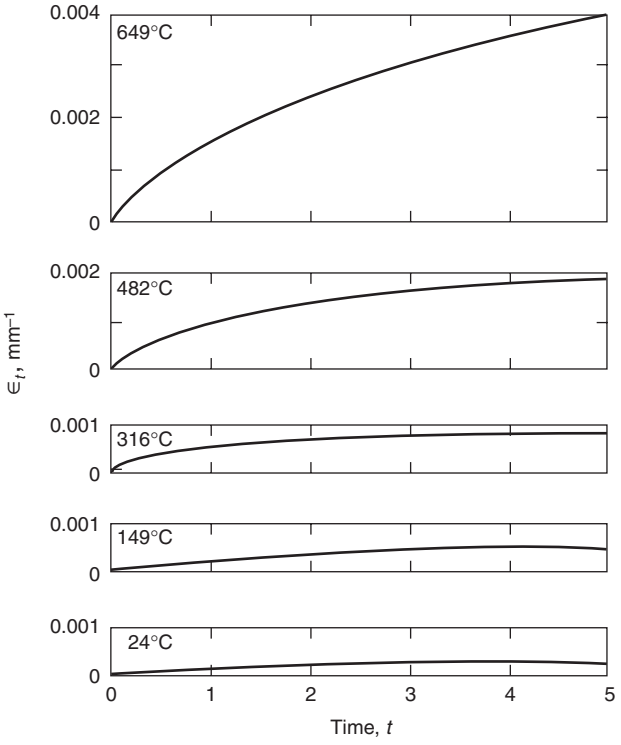

Figure 1-10.20. ***Creep of a carbonate aggregate concrete at various temperature levels (applied stress:12.4 MPa; compressive strength of the material at room temperature: 27.6 MPa).[61]***

are unable to resist the almost continuous shrinkage of the cement paste on heating, and therefore their dilatometric curves bear the characteristic features of the curve for the paste.

The dilatometric curves of two normal-weight concretes (with silicate and carbonate aggregates) and two lightweight concretes (with expanded shale and pumice aggregates) are shown in Figure 1-10.21.[19] These curves were obtained in the course of a comprehensive study performed on 16 concretes.

The results of dilatometric and thermogravimetric tests were combined to calculate the density (ρc_p) versus temperature relation for these four concretes, as shown in Figure 1-10.22. The partial decomposition of the aggregate is responsible for a substantial drop (above 700°C) in the density of concretes made with carbonate aggregate.

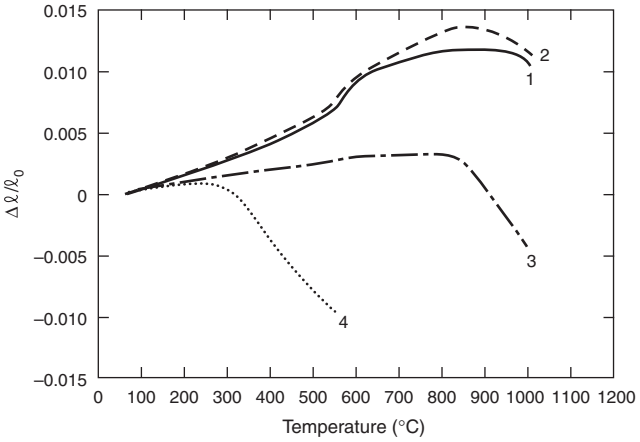

Figure 1-10.21. ***Dilatometric curves for two normal-weight and two lightweight concretes.[19] (1) normal-weight concrete with silicate aggregate, (2) normal-weight concrete with carbonate aggregate, (3) lightweight concrete with expanded shale aggregate, (4) lightweight concrete with pumice aggregate.***

The aggregate type and moisture content have significant influence on the specific heat of concrete. The usual ranges of variation of the volume-specific heat (i.e., the product ρc_p) for normal-weight and lightweight concretes is shown in Figure 1-10.23. This information, derived by combining thermodynamic data with thermogravimetric observations,[2,6] has since been confirmed by differential scanning calorimetry.[7] Experimental data are also available on a few concretes and some of their constituents.[2,7]

The thermal conductivity (k) of concrete depends mainly on the nature of its aggregates. In general, concretes made with dense, crystalline aggregates show higher conductivities than those made with amorphous or porous aggregates. Among common aggregates, quartz has the highest conductivity; therefore, concretes made with siliceous aggregates are on the whole more conductive than those made with other silicate and carbonate aggregates.

Derived from theoretical considerations,[6] the solid curves in Figure 1-10.24 describe the variation with temperature of the thermal conductivity of four concretes. In deriving these curves, two concretes (see curves 1 and 2) were visualized to represent limiting cases among normal-weight concretes, and the other two (see curves 3 and 4), limiting cases among lightweight concretes. The points in Figure 1-10.24 stand for experimental data. They reveal that the upper limiting case is probably never reached with aggregates in common use, and that the thermal conductivity of lightweight concretes may be somewhat higher than predicted on theoretical considerations.

Further experimental information on the thermal conductivity of some normal-weight and many lightweight concretes is available from the literature.[6,7,19]

Fiber-Reinforced Concrete

Steel and polypropylene discontinuous fibers are the two most common fibers used in the concrete mix to im-

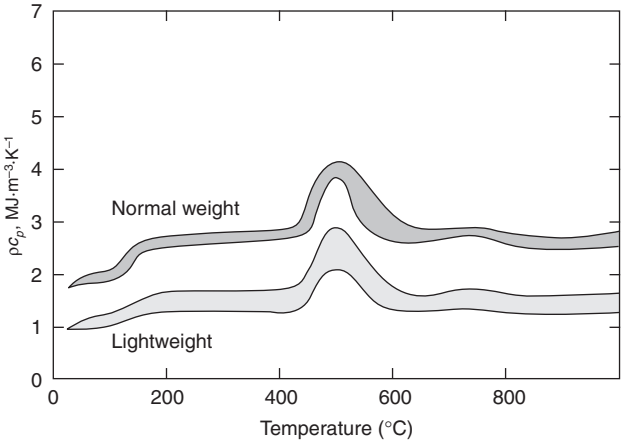

Figure 1-10.23. ***Usual ranges of variation for the volume-specific heat of normal-weight and lightweight concretes.[6]***

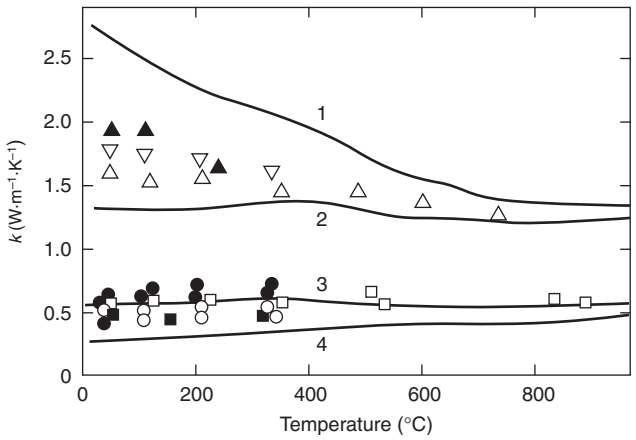

Figure 1-10.24. ***Thermal conductivity of four "limiting" concretes and some experimental thermal conductivity data.[6,19] Symbols: ▲, ▽—various gravel concretes; ●—expanded slag concretes; ■, □—expanded shale concretes; ○—pumice concrete.***

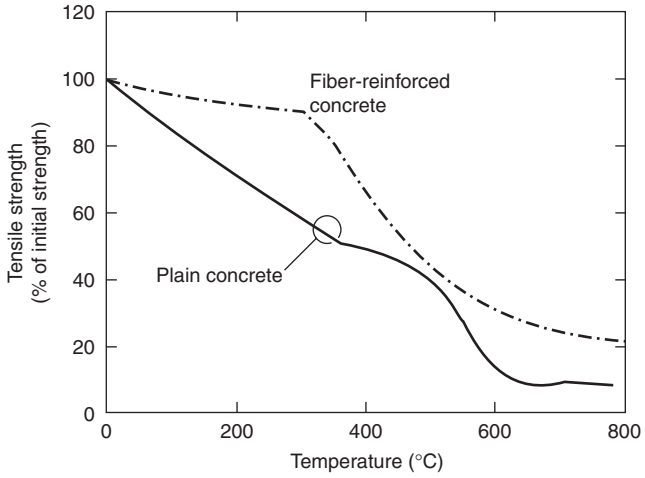

Figure 1-10.26. ***Effect of temperature on tensile strength of steel fiber–reinforced concrete.***

prove structural properties of concrete. Studies have shown that polypropylene fibers in a concrete mix are quite effective in minimizing spalling in concrete under fire conditions.[65,66] The polypropylene fibers melt at a relatively low temperature of about 170°C and create channels for the steam pressure in concrete to escape. This prevents the small explosions that cause the spalling of the concrete. Based on these studies, the amount of polypropylene fibers needed to minimize spalling is about 0.1 to 0.25 percent (by volume). The polypropylene fibers were found to be most effective for HSC made with normal-weight aggregate.

The addition of fibers improves certain mechanical properties, such as tensile strength, ductility, and ultimate strain, at room temperature. However, there is very little information on the high-temperature properties of this type of concrete.[67]

Steel fiber–reinforced concrete (SFRC) exhibits, at elevated temperatures, mechanical properties that are more beneficial to fire resistance than those of plain concrete. There is some information available on SFRC's material properties at elevated temperatures. The effect of temperature on the compressive strength for two types of SFRC is shown in Figure 1-10.25. The strength of both types of SFRC exceeds the initial strength of the concretes up to about 400°C. This is in contrast to the strength of plain concrete, which decreases slightly with temperatures up to 400°C. Above approximately 400°C, the strength of SFRC decreases at an accelerated rate.[68]

The effect of temperature on the tensile strength of steel fiber–reinforced carbonate concretes is compared to that of plain concrete in Figure 1-10.26.[69] The strength of SFRC decreases at a lower rate than that of plain concrete throughout the temperature range, with the strength being significantly higher than that of plain concrete up to about 350°C. The increased tensile strength delays the propagation of cracks in fiber-reinforced concrete structural members and is highly beneficial when the member is subjected to bending stresses.

The type of aggregate has a significant influence on the tensile strength of steel fiber–reinforced concrete. The decrease in tensile strength for carbonate aggregate concrete is higher than that for siliceous aggregate concrete.[69]

The thermal properties of SFRC, at elevated temperatures, are similar to those of plain concrete. Kodur and Lie[26,67] have carried out detailed experimental studies and developed dilatometric and thermogravimetric curves for various types of SFRC. Based on these studies, they have also developed expressions for thermal and mechanical properties of steel fiber–reinforced concrete, in the temperature range 0 to 1000°C.[70]

High-Strength Concrete

The strength of concrete has significant influence on the properties of HSC. The material properties of HSC vary differently with temperature than those of NSC. This

variation is more pronounced for mechanical properties, which is affected by these factors: compressive strength, moisture content, density, heating rate, percentage of silica fume, and porosity. The available information on the mechanical properties of HSC at elevated temperatures is presented in a review report by Phan.[29]

The loss in compressive strength with temperature is higher for HSC than that for NSC up to about 450°C. Figure 1-10.27 shows the comparison of strengths for NSC and HSC types, together with CEB and European design curves for NSC. The difference between compressive strength versus temperature relationships of normal-weight and lightweight aggregate concrete is not significant. However, HSC mixture with silica fume have higher strength loss with increasing temperature than HSC mixture without silica fume. The variation, with temperature, of modulus of elasticity and tensile strength of HSC is similar to that of NSC.

Kodur and Sultan have presented detailed experimental data on the thermal properties of HSC (for both plain and steel fiber–reinforced concrete types).[71] The type of aggregate has significant influence on the thermal properties of HSC at elevated temperatures. Figure 1-10.28 shows the thermal conductivity and specific heat of HSC, with siliceous and carbonate aggregates, as a function of temperature.

The variation of thermal expansion with concrete temperature for siliceous and carbonate aggregate HSC is similar to that of NSC, with the aggregate having a strong influence. Overall, the thermal properties of HSC, at elevated temperatures, are similar to those of NSC.

HSC, due to low porosity, is more susceptible to spalling than NSC, and explosive spalling may occur when HSC is exposed to severe fire conditions. Hence, one of the major concerns for the use of HSC is regarding its behavior in fire, in particular, the occurrence of spalling at elevated temperatures. For predicting spalling performance, knowledge of the variation of porosity with temperature is essential. Figure 1-10.29 shows the variation of porosity with temperature for NSC and HSC. The data in this figure are taken from the measurements of porosity after exposure to different temperatures.[35]

The spalling in HSC can be minimized by creating pores through which water vapor can be relieved before vapor pressure reaches critical values. This is usually done by adding polypropylene fibers to the HSC.[65,66,72]

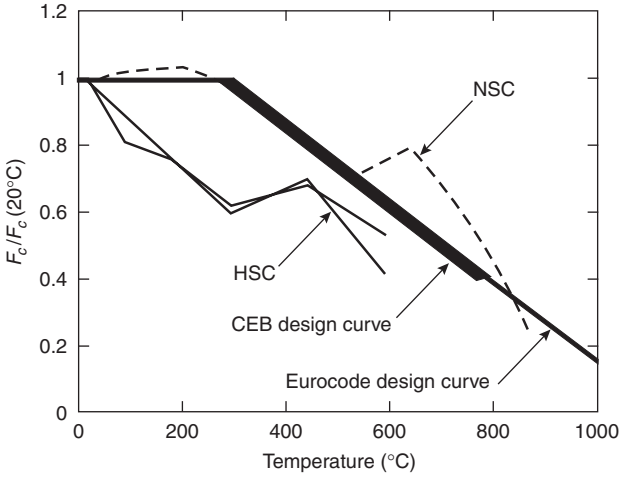

Figure 1-10.27. ***Comparison of design compressive strength and results of unstressed tests of lightweight aggregate concrete.[29]***

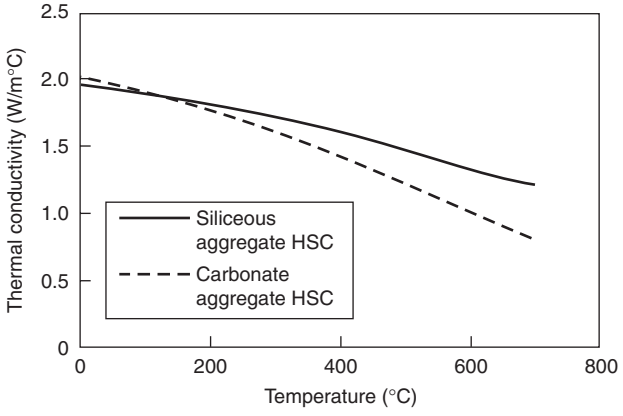
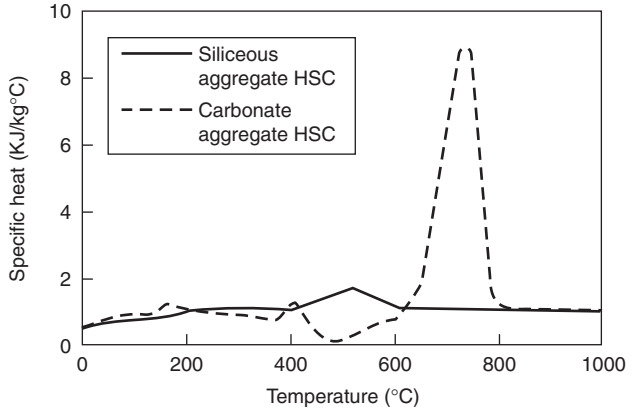
Brick

Building brick belongs in the L/I group of materials. The density (ρ) of bricks ranges from 1660 to 2270 kg·m^{-3}, depending on the raw materials used in the manufacture, and on the molding and firing technique. The true density



(a)



(b)

Figure 1-10.28. ***Thermal conductivity and specific heat capacity of HSC as a function of temperature:[71] (a) thermal conductivity of high-strength concrete, and (b) specific heat of high-strength concrete.***

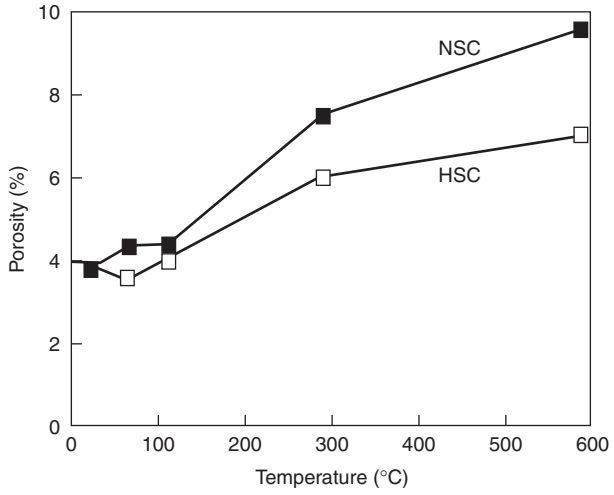


Figure 1-10.29. ***Porosity of HSC and NSC as a function of temperature.[35]***

of the material (ρ_t) is somewhere between 2600 and 2800 kg·m^{-3}.

The modulus of elasticity of brick (E) is usually between 10×10^3 and 20×10^3 MPa. Its compressive strength (σ_u) varies in a very wide range, from 9 to 110 MPa—50 MPa may be regarded as average.[73] This value is an order of magnitude greater than the stresses allowed in the design of grouted brickwork. Since brick is rarely considered for important load-bearing roles in buildings, there has been little interest in the mechanical properties of bricks at elevated temperatures.

At room temperature, the coefficient of thermal expansion (α) for clay bricks is about 5.5×10^{-6} m·m^{-1}·K^{-1}. The dilatometric and thermogravimetric curves for a clay brick of 2180 kg·m^{-3} density are shown in Figure 1-10.30.[7] The variation with temperature of the specific heat and the thermal conductivity of this brick is shown in Figures 1-10.31 and 1-10.32, respectively.[7]

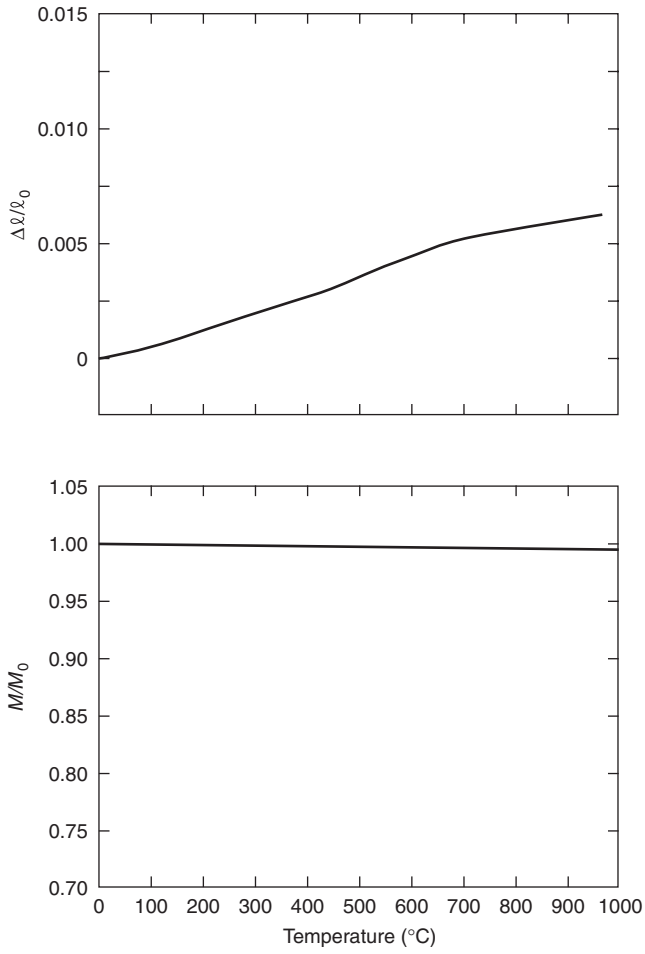

Figure 1-10.30. ***Dilatometric and thermogravimetric curves for a clay brick.[7]***

Wood

Wood is a Group L/I/F or I/F material. As structural members, wood is widely used in residential and low-rise constructions. Although about 180 wood species are commercially grown in the United States, only about 25 species have been assigned working stresses. The two groups most extensively used as structural lumber are the Douglas firs and the southern pines.

The oven-dry density (ρ) of commercially important woods ranges from 300 kg·m^{-3} (white cedar) to 700 kg·m^{-3} (hickory, black locust). The density of Douglas firs varies from 430 to 480 kg·m^{-3}, and that of southern pines, from 510 to 580 kg·m^{-3}. The true density of the solid material that forms the walls of wood cells (α_t) is about 1500 kg·m^{-3} for all kinds of wood. The density of wood decreases with temperature; the density ratio (ratio of density at room temperature to that at elevated temperature) drops to

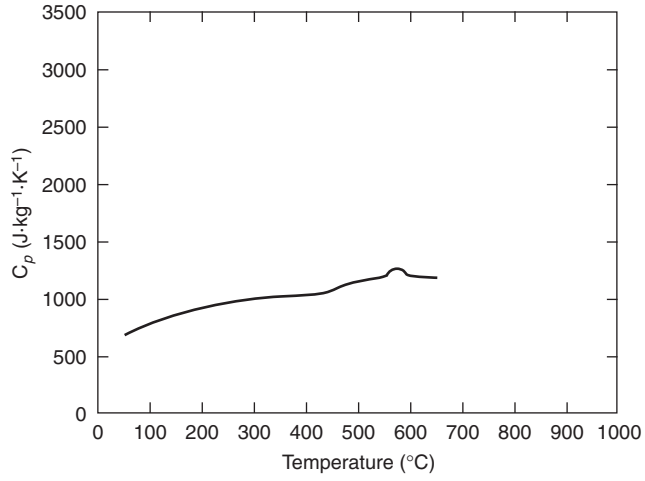

Figure 1-10.31. ***Apparent specific heat of a clay brick.[7]***

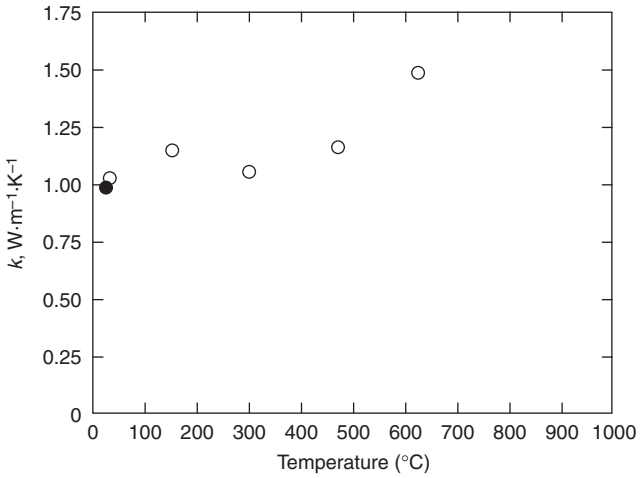

Figure 1-10.32. ***Thermal conductivity of a clay brick. Symbols: ○—heating cycle, ●—after cooling.[7]***

about 0.9 at 200°C and then declines sharply to about 0.2 at about 350°C.[39]

Wood is an orthotropic material, so the strength and stiffness in longitudinal and transverse directions are influenced by grain orientation. The mechanical properties of wood are affected by temperature and are influenced by moisture content, rate of charring, and grain orientation. The modulus of elasticity (E) of air-dry, clear wood along the grain varies from 5.5×10^3 to 15.0×10^3 MPa, and its crushing strength (σ_u) varies from 13 to 70 MPa. These properties are related and roughly proportional to the density, regardless of the species.[74]

Figure 1-10.33 shows the variation of the modulus of elasticity and compressive strength of oven-dry, clear wood with temperature.[75–77] [E_0 and $(\sigma_u)_0$ in the figure are modulus of elasticity and compressive strength at room temperature, respectively]. The modulus of elasticity decreases slowly with temperature up to about 200°C, when it reaches about 80 percent, and then the decline is more rapid. The compressive strength also drops linearly to about 80 percent at about 200°C, and then the drop is more rapid—to about 20 percent around 280°C.

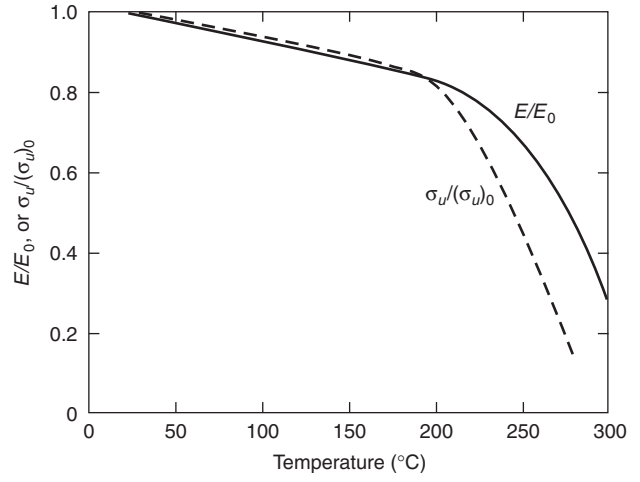

Figure 1-10.33. ***The effect of temperature on the modulus of elasticity and compressive strength of wood.[75–77]***

The tensile strength exhibits behavior similar to that of compressive strength, but the decline in tensile strength with temperature is less rapid. The moisture content plays a significant role in determining the strength and stiffness, with increased moisture content leading to higher reduction. There is very little information on stress-strain relationships for wood. The formulas for reduced stiffness and design strength can be found in Eurocode 5[78] (Part 1.2).

The coefficient of linear thermal expansion (β) ranges from 3.2×10^{-6} to 4.6×10^{-6} m·m^{-1}·K^{-1} along the grain, and from 21.6×10^{-6} to 39.4×10^{-6} m·m^{-1}·K^{-1} across the grain.[79] Wood shrinks at temperatures above 100°C, because of the reduction in moisture content. Lie[28] reported that the amount of shrinkage can be estimated as 8 percent in the radial direction, 12 percent in tangential direction, and an average of 0.1 to 0.2 percent in the longitudinal direction. The dilatometric and thermogravimetric curves of a pine with a 400 kg·m^{-3} oven-dry density are shown in Figure 1-10.34.[7]

The thermal conductivity (k) across the grain of this pine was measured as 0.86 to 0.107 W·m^{-1}·K^{-1} between room temperature and 140°C.[13] The thermal conductivity increases initially up to a temperature range of 150 to 200°C, then decreases linearly up to 350°C, and finally increases again beyond 350°C.

Figure 1-10.35 shows the apparent specific heat for the same pine, as a function of temperature.[7] The accuracy of the curve [developed by differential scanning calorimeter (DSC)] is somewhat questionable. However, it provides useful information on the nature of decomposition reactions that take place between 150 and 370°C.

Charring is one of the main high-temperature properties associated with wood and should be considered in predicting performance under fire conditions. The rate of charring is influenced by the radiant heat flux or, alternatively, the fire severity. Generally, a constant transverse-to-grain char rate of 0.6 mm/min can be used for woods subjected to standard fire exposure.[28] The charring rate parallel to the grain of wood is approximately twice the rate when it is transverse to the grain. These charring rates should be used only when attempting to model the performance of wood sections in the fire resistance furnace.

Charring is influenced by a number of parameters, the most important ones being density, moisture content, and contraction of wood. It is reasonable to modify the 0.6 mm/min to approximately 0.4 mm/min for moist dense wood, or to 0.8 mm/min for dry and light wood. The fire retardants, often used to reduce flame spread in wood on charring rate, may only slightly increase the time until ignition of wood.

Specific charring rates for different types of wood can be found in References 28 and 39. Eurocode[78] gives an expression for charring depth in a wood member exposed to standard fire.

Fiber-Reinforced Polymers

In recent years, there has been a growing interest in the use of fiber-reinforced polymers (FRPs) in civil engineering applications due to the advantages, such as high strength and durability (resistance to corrosion), that FRP offers over traditional materials. FRP composites consist of two key elements, namely the fibers (glass, carbon, or aramid) and a thermosetting polymer matrix such as epoxy, vinyl ester, phenolic, or polyester resin. The commonly used types of FRP composite materials are glass fiber–reinforced plastic (GFRP), carbon fiber–reinforced plastic (CFRP), and aramid fiber–reinforced plastic (AFRP) composites. FRPs are similar to wood in that they will burn when exposed to fire and can be classifed as an L/I/F type material.

FRP is used as an internal reinforcement (reinforcing bars as an alternative to traditional steel reinforcement) and as external reinforcement in forms, such as wrapping and sheeting for the rehabilitation and strengthening of concrete members. One of the main impediments to using FRPs in buildings is the lack of knowledge about the fire resistance of FRP.[80,81]

There are some major differences associated with FRP as a material. The properties depend on the type and composition of FRP, and the availability of various types of FRP makes it difficult to establish the properties at elevated temperatures. The material properties are controlled by the fibers in the longitudinal direction, and by the matrix in the transverse direction. In addition to thermal and mechanical properties, factors such as burning, charring, evolution of smoke, and toxicity in fire also play a significant role in determining the fire performance. A summary of typical mechanical properties for various types of FRPs, in comparison to other commonly used construction materials, at room temperatures, is presented in Table 1-10.3.

There is very little information on the material properties of FRPs at elevated temperatures.[80] The impact of high temperatures on the behavior of FRP composites is severe degradation of its properties: reduction of strength and stiffness, and increase in deformability, thermal expansion, and creep. Above 100°C temperature, the degradation can be quite rapid as the glass transition temperature of the matrix is reached.

The glass transition temperature, which is often considered the upper use temperature, varies with the type of resin used and was found to be as low as 100°C in some resins and as high as 220°C in others. From the limited studies, it appears that as much as 75 percent of the GFRP strength and stiffness is lost by the time the temperature reaches 250°C.[80,82]

The stress-strain relationships, from the studies conducted by Gates,[82] for a CFRP composite (IM7/5260) are shown in Figure 1-10.36 for various temperatures. It can be seen that the tensile strength of IM7/5260 composite reduces to approximately 50 percent at about 125°C, and to about 75 percent at a temperature of 200°C. The strain level, for a given stress, is also higher with the increase in temperature.

Table 1-10.3 ***Properties of Various FRP Composites and Other Materials***

Material	Modulus of Elasticity E_1 (MPa)	Modulus of Elasticity E_2 (MPa)	Tensile Strength σ_{t1} (MPa)	Comp. Strength σ_{c1} (MPa)	Shear Modulus G (MPa)	Shear Strength S (MPa)	Poisson's Ratio ν	Tensile Strength σ_2 (MPa)	Comp. Strength σ_{c2} (MPa)
GFRP (glass/epoxy)	55,000	18,000	1,050	1,050	9,000	42	0.25	28	140
GFRP (glass/epoxy) unidirectional	42,000	12,000	700	—	5,000	72	0.30	30	—
CFRP (carbon/epoxy) unidirectional	180,000	10,000	1,500	—	7,000	68	0.28	40	—

E_2 = modulus of elasticity in transverse direction

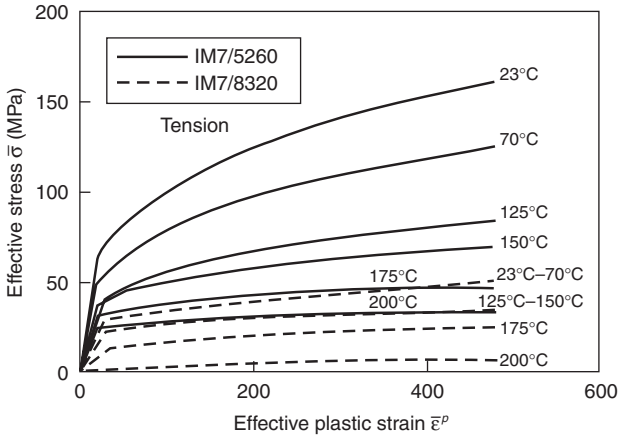

Figure 1-10.36. ***Tensile stress-strain curves for CFRP at various temperatures.[82]***

The variation of strength with temperature (ratio of strength at elevated temperature to that at room temperature) for FRP along with that of other traditional construction materials is shown in Figure 1-10.2. The curve showing the strength degradation of FRP is based on the limited information reported in the literature.[80,82] The rate of strength loss is much greater for FRP than for concrete and steel, resulting in a 50 percent strength loss by about 200°C.

The critical temperature of FRP is much lower than that for steel and depends on the composition of fibers and matrix. Kodur and Baingo have assumed a critical temperature of 250°C in modeling the behavior of FRP-reinforced concrete slabs.[80]

The variation of elastic moduli of FRP with temperature is different in each direction. Typical values for various types of FRP are given in Table 1-10.3.[80] The three values represent the longitudinal, transverse, and shear moduli, respectively, of different unidirectional FRPs. At high temperature, the elastic moduli of FRPs decreases at a faster rate than that for concrete or steel.

Similar to mechanical properties, the thermal properties of FRP are also dependent on direction, fiber type, fiber orientation, fiber volume fraction, and laminate configuration. Table 1-10.4 shows thermal properties for various types of FRP at room temperature. In the longitudinal direction, the thermal expansion of FRPs is lower than that of steel. However, in the transverse direction, it is much higher than that of steel. Some of the information available in the literature can be found in a review report by Kodur and Baingo.[80] At room temperatures, FRPs in general have low thermal conductivity, which makes them useful as insulation materials. With the exception of carbon fibers, FRPs have a low thermal conductivity.

Information on the thermal properties of FRP at elevated temperatures is very scarce, which is likely due to the fact that such information is proprietary to the composite materials' manufacturers. Also, there is not much information on evolution of smoke and toxins in FRP composites exposed to fire.

Gypsum

Gypsum (calcium sulfate dihydrate: $CaSO_4 \cdot 2H_2O$) is a Group I material. Gypsum board is produced by mixing water with plaster of paris (calcium sulfate hemihydrate: $CaSO_4 \cdot \frac{1}{2}H_2O$) or with Keene's cement (calcium sulfate an-

Concrete	6.16		1.36–1.90	
Steel	10.8–18		15.6–46.7	
Epoxy	—	54–90	—	0.346

hydrite: $CaSO_4$). The interlocking crystals of $CaSO_4 \cdot 2H_2O$ are responsible for the hardening of the material.

Gypsum products are used extensively in the building industry in the form of boards, including wallboard, formboard, and sheathing. The core of the boards is fabricated with plaster of paris, into which weight- and set-controlling additives are mixed. Furthermore, plaster of paris, with the addition of aggregates (such as sand, pearlite, vermiculite, or wood fiber) is used in wall plaster as base coat, and Keene's cement (neat or mixed with lime putty) is used as finishing coat.

Gypsum board, based on composition and performance, is classified into various types, such as regular gypsum board, type X gypsum board, and improved type X gypsum board. A gypsum board with naturally occurring fire resistance from the gypsum in the core is defined as regular gypsum. When the core of the gypsum board is modified with special core additives or with enhanced additional properties, to improve the natural fire resistance from regular gypsum board, it is classified as type X or improved type X gypsum board. There might be significant variation in fire performance of the gypsum board based on the type and the formulation of the core, which varies from one manufacturer to another.

Gypsum is an ideal fire protection material. The water inside the gypsum plays a major role in defining its thermal properties and response to fire. On heating, it will lose the two H_2O molecules at temperatures between 125 and 200°C. The heat of complete dehydration is 0.61×10^6 J per kg gypsum. Due to the substantial absorption of energy in the dehydration process, a gypsum layer applied to the surface of a building element is capable of markedly delaying the penetration of heat into the underlying load-bearing construction.

The thermal properties of the gypsum board vary depending on the composition of the core. The variation with temperature of the volume specific heat (ρc_p) of pure gypsum has been illustrated in Reference 83, based on information reported in the literature.[84,85] The thermal conductivity of gypsum products is difficult to assess, owing to large variations in their porosities and the nature of the aggregates. A typical value for plaster boards of about 700 kg·m^{-3} density is 0.25 W·m^{-1}·K^{-1}. Figures 1-10.37 and 1-10.38 illustrate the typical variation of the thermal conductivity and the specific heat, respectively, of the gypsum

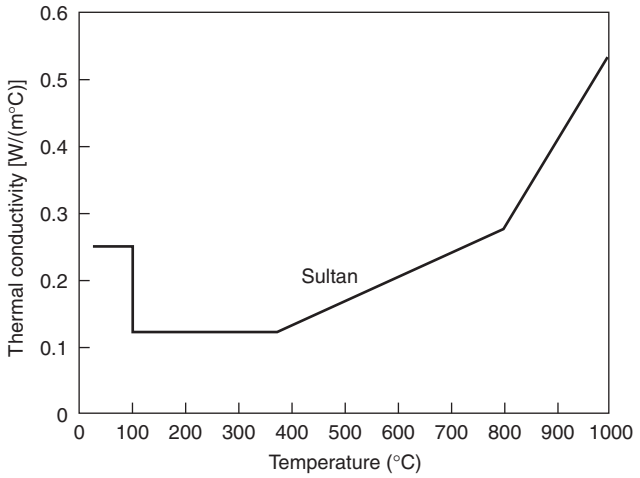

Figure 1-10.37. ***Thermal conductivity of type X Gypsum board core as a function of temperature.[86]***

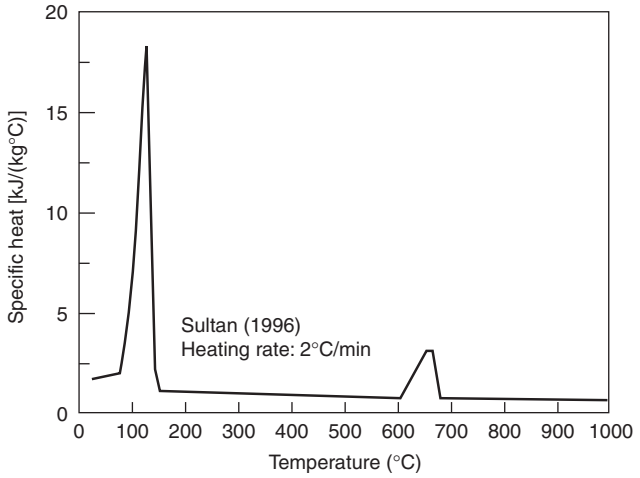

Figure 1-10.38. ***Specific heat of type X Gypsum board core as a function of temperature.[86]***

board core with temperature. The plots reflect the expressions proposed recently by Sultan,[86] based on tests conducted on type X gypsum board specimens. The specific heat measurements were carried out at a heating rate of 2°C/min. The dehydration of gypsum resulted in the two peaks that appear in the specific heat curve at temperatures around 100°C and 650°C. The peak values are slightly variant to those reported earlier by Harmathy;[14] this may be due to the differences in gypsum composition.

The coefficient of thermal expansion (β) of gypsum products may vary between 11.0×10^{-6} and 17×10^{-6} $m \cdot m^{-1} \cdot K^{-1}$ at room temperature, depending on the nature and amount of aggregates used. The dilatometric and thermogravimetric curves of a so-called fire-resistant gypsum board of 678 $kg \cdot m^{-3}$ density are shown in Figure 1-10.39.

There is not much information about the mechanical properties of the gypsum board at elevated temperatures because these properties are difficult to obtain experimentally. The strength of gypsum board at an elevated temperature is very small and can be neglected. The Gypsum Association[87] lists typical mechanical properties, at room temperature, for some North American gypsum board products. The attachment details (screw spacing, orientation of gypsum board joints, stud spacing, etc.) may have a noticeable effect on the fire performance of the gypsum board.

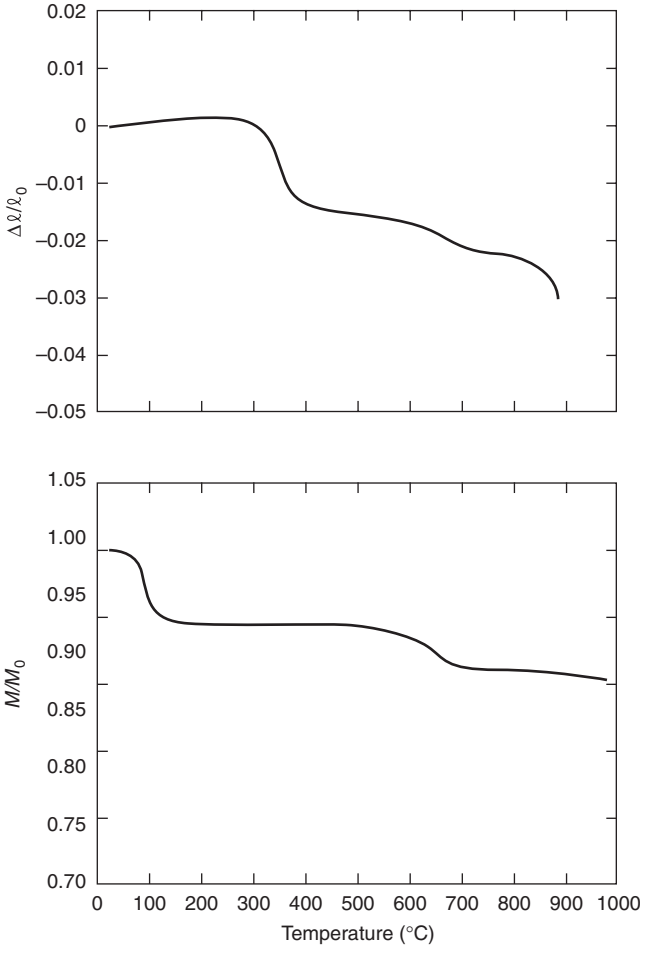

Figure 1-10.39. ***Dilatometric and thermogravimetric curves for a Gypsum board of 678 kg·m⁻³ density.[7]***

Insulation

Insulation is a Group I material and is often used as a fire protection material for both heavy structural members such as columns and beams, and for lightweight framing assemblies such as floors and walls. The insulation helps delay the temperature rise of structural members, thereby enhancing fire resistance. There are a number of insulation materials available in the market. Mineral wool and glass fiber are the two most widely used insulation materials in walls and floors.

The thermal properties of insulation play an important role in determining the fire resistance. However, there is not much information available on the thermal properties of various types of insulation. Figure 1-10.40 shows the variation of thermal conductivity with temperature for glass and rock fiber insulation types. The differences in thermal conductivity values at higher temperatures are mainly due to variation in the chemical composition of fiber.

Full-scale fire resistance tests on walls and floors have shown that the mineral fiber insulation performs better than glass fiber insulation. This is mainly because glass fiber melts in the temperature range of 700 to 800°C and cannot withstand direct fire exposure. The melting point for mineral fiber insulation is higher. The density of glass fiber is about 10 kg/m^3 and is much lower than that of rock fiber, which is about 33 kg/m^3.

The mineral wool insulation, when installed tightly between the studs, can be beneficial for the fire resistance of non-load-bearing steel stud walls because it acts as an additional fire barrier after the fire-exposed gypsum

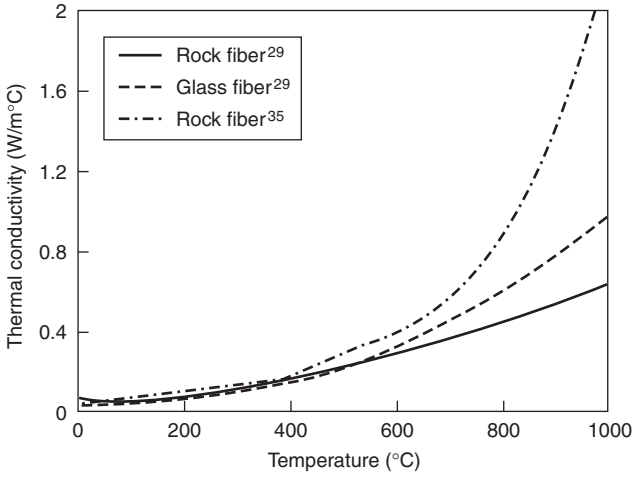

Figure 1-10.40. ***Thermal conductivity of insulation as a function of temperature.[39]***

board falls off.[88] On the other hand, cavity insulation slows down the flow of heat through the wall assembly and can cause an accelerated temperature rise in the fire-exposed gypsum board.

Other Miscellaneous Materials

Further information is available from the literature on the dilatometric and thermogravimetric behavior, apparent specific heat, and thermal conductivity of a number of materials in Group I, including asbestos cement board, expanded plastic insulating boards, mineral fiber fireproofing, arborite, and glass-reinforced cement board.[7] The properties of plastics and their behavior in fire are discussed in other chapters of this handbook and in Reference 2.

Summary

The use of numerical methods for the calculation of the fire resistance of various structural members is gaining acceptance. One of the main inputs needed in these models is the material properties at elevated temperatures. The thermal and mechanical properties of most materials change substantially within the temperature range associated with building fires.

Even to date, there is lack of adequate knowledge of the behavior of many building materials at elevated temperatures. While there is sufficient information available for some materials, such as normal-strength concrete and steel, there is a complete lack of information on certain properties for widely used materials, such as wood, insulation, and so on. Often, traditional materials are being modified (e.g., high strength concrete) to enhance their properties at room temperatures without giving due consideration to elevated temperatures. In many cases, these modifications will deteriorate the properties at elevated temperatures and introduce additional complexities, such as spalling in HSC.

In the field of fire science, applied materials research faces numerous difficulties. At elevated temperatures, many building materials undergo physicochemical changes. Most of the properties are temperature dependent and sensitive to testing method parameters such as heating rate, strain rate, temperature gradient, and so on. One positive note is that in the last two decades, there has been significant progress in developing measurement techniques and commercial instruments for measuring the properties. This will likely lead to further research in establishing material properties.

The review on material properties provided in this chapter is a broad outline of the available information. Additional details related to specific conditions on which these properties are developed can be found in cited references. Also, when using the material properties presented in this chapter, due consideration should be given to the material composition and other characteristics, such as fire and loading, since the properties at elevated temperatures depend on a number of factors.

Disclaimer: Certain commercial products are identified in this paper in order to adequately specify the experimental procedure. In no case does such identification imply recommendations or endorsement by the National Research Council, nor does it imply that the product or material identified is the best available for the purpose.

Nomenclature

a	material constant, dimensionless
b	constant, characteristic of pore geometry, dimensionless
c	specific heat ($J \cdot kg^{-1} \cdot K^{-1}$)
$\bar{c}$	specific heat for a mixture of reactants and solid products ($J \cdot kg^{-1} \cdot K^{-1}$)
E	modulus of elasticity (Pa)
h	enthalpy ($J \cdot kg^{-1}$)
Δh	latent heat associated with a "reaction" ($J \cdot kg^{-1}$)
ΔH_c	activation energy for creep ($J \cdot kmol^{-1}$)
k	thermal conductivity ($W \cdot m^{-1} \cdot K^{-1}$)
L_v	heat of gasification of wood
ℓ	dimension (m)
$\Delta \ell = \ell - \ell_0$	
m	exponent, dimensionless
M	mass (kg)
n	material constant, dimensionless
P	porosity ($m^3 \cdot m^{-3}$)
q_n	net heat flux to char front
R	gas constant (8315 $J \cdot kmol^{-1} \cdot K^{-1}$)
S	specific surface area ($m^2 \cdot m^{-3}$)
t	time (h)
T	temperature (K or °C)
ν	volume fraction ($m^{-3} \cdot m^3$)
w	mass fraction ($kg \cdot kg^{-1}$)
Z	Zener-Hollomon parameter (h^{-1})

Greek Letters

α	thermal diffusivity
β	coefficient of linear thermal expansion ($m \cdot m^{-1}$)
γ	expression defined by Equation 3, dimensionless
β_0	charring rate (mm/min)
δ	characteristic pore size (m)
ε	emissivity of pores, dimensionless
ε	strain (deformation) ($m \cdot m^{-1}$)
ε_{t0}	creep parameter ($m \cdot m^{-1}$)
$\dot{\varepsilon}_{ts}$	rate of secondary creep ($m \cdot m^{-1} \cdot h^{-1}$)
θ	temperature-compensated time (h)
ξ	reaction progress variable, dimensionless
π	material property (any)
ρ	density ($kg \cdot m^{-3}$)
σ	stress; strength (Pa)
σ	Stefan-Boltzmann constant (5.67×10^{-8} $W \cdot m^{-2} \cdot K^{-4}$)

Subscripts

a	of air
i	of the *i*th constituent
p	at constant pressure
s	of the solid matrix
t	true
t	time-dependent (creep)
T	at temperature *T*
u	ultimate
y	yield
0	original value, at reference temperature

CHAPTER 11

Probability Concepts

John R. Hall, Jr.

Introduction

This chapter introduces the basic definitions and methods of probability theory, which is the foundation for all work on statistics, fire risk evaluation, reliability analysis, and the other topics of this section. With increased availability of sizeable quantities of reliable data on a whole range of topics related to fire protection engineering, it is essential that the analysis of this data be based on sound mathematical principles from probability theory.

Basic Concepts of Probability Theory

Probability Theory

Probability theory is a branch of mathematics dealing with the modeling of uncertainty through measures of the relative likelihood of alternative occurrences, whether specifically or generally defined.

Set

A set is a collection of elements; to be well-defined it must be possible, for any object that can be defined or described, to say with certainty whether that object is or is not an element or part of the set.

Set Theory

The theory of sets is the most fundamental branch of mathematics and is relevant to probability theory, because all probabilities are built up from sets.

Dr. John R. Hall, Jr., is assistant vice president for fire analysis and research at the National Fire Protection Association. He has been involved in studies of fire experience patterns and trends, models of fire risk, and studies of fire department management experiences since 1974 at NFPA, the National Bureau of Standards, the U.S. Fire Administration, and the Urban Institute.

Subsets

A set, A, that consists entirely of elements that all are also contained in set B is called a subset of B. Each element in a set may also be considered a subset of that set.

Set Operators

There are three basic operators essential to the algebraic manipulation of sets:

Complement ($\sim$): The complement operator applies to a single set A and produces the set of all elements that are *not* in A. Such an operator is always applied relative to some specification of the set of all elements, which is called the *universal set*, ($\cup$). The complement of the universal set is the *null set* (ϕ) or *empty set*, the set with no elements.

Union ($\cup$): The union operator is applied to two sets, as in $A \cup B$. It produces the set consisting of all elements that are members of *either* A or B or both.

Intersection ($\cap$): The intersection operator is applied to two sets, as in $A \cap B$. It produces the set consisting of all elements that are members of *both* A and B.

Relationships among the Operators

$$\sim (A \cup B) = \sim A \cap \sim B$$

$$\sim (A \cap B) = \sim A \cup \sim B$$

$$(A \cup B \cap C = (A \cap C) \cup (B \cap C)$$

$$(A \cap B) \cup C = (A \cup C) \cap (B \cup C)$$

$$(A \cup B) \cup C = A \cup (B \cup C)$$

$$(A \cap B) \cap C = A \cap (B \cap C)$$

Venn diagrams: Venn diagrams are a graphical technique for displaying relationships among sets (represented by circles) and operators, within a rectangle that represents the universal set, ∪. (See Figures 1-11.1 through 1-11.3.)

Sample Space

Sample space is a set of mutually exclusive elements, each representing a possible outcome or occurrence and collectively representing all possible outcomes or occurrences for the experiment or problem under consideration. A sample space must also have the property that the set operators defined previously, if applied to the subsets of the sample space in any combination, will always produce subsets of the sample space. Subsets of a sample space are called *events.*

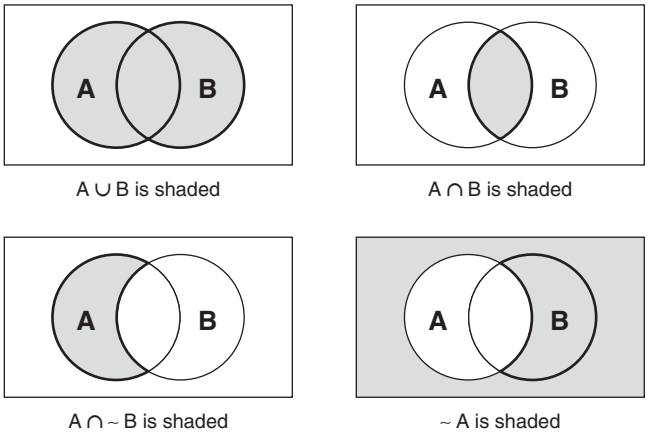

Figure 1-11.1.

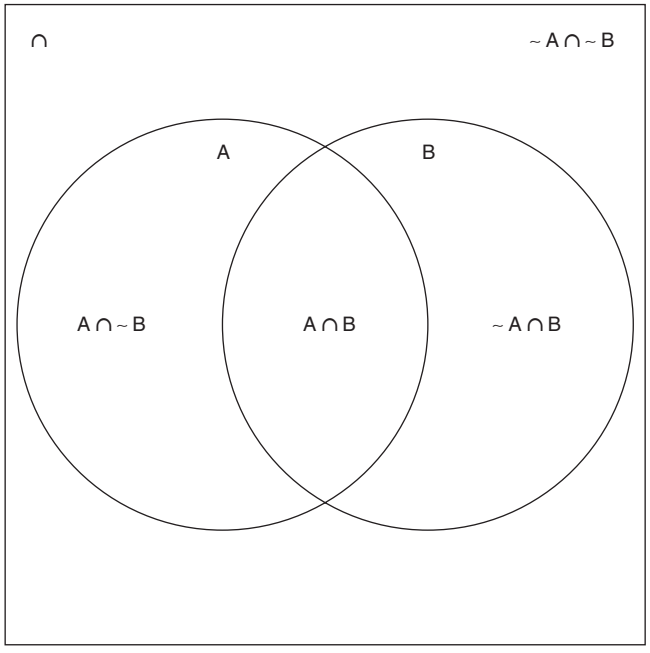

Figure 1-11.2.

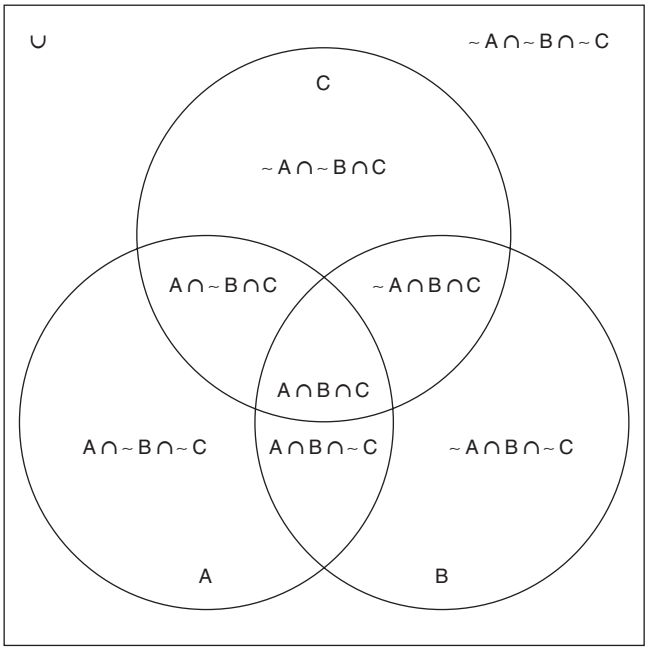

Figure 1-11.3.

Probability Measure

A probability measure is a mathematical function, *P,* defined on the subsets (events) of a sample space, *U,* and satisfying the following rules:

1. $P(A) \geq 0$ for any A, where A is an event subset of U.
2. $P(\phi) = 0$.
3. $P(U) = 1$.
4. If $A \cap B = \phi$, then $P(A \cup B) = P(A) + P(B)$.

In the classical theory of probability, it was assumed that all probability measures must be based on experiments (actual or at least imaginable) which could be run repeatedly, so that for each outcome e (an element of the sample space of possible outcomes), $P(e)$ would be given asymptotically as the ratio between the number of times outcome e occurs and the number of times the experiment is performed. This interpretation is called the *frequency interpretation of probability.* More recently, theorists associated with the Bayesian school of statistical inference have argued for the interpretation of probability only as a measure of the individual's strength of belief in the likelihood of an outcome. This interpretation is called *subjective probability.* Each of these two schools represents both an underlying conceptual model and an approach that makes practical sense in some but not all situations. In assigning probabilities to the outcomes of heads and tails for a single coin, for example, a relatively brief frequency experiment is easy to conduct. In assigning probabilities to the possible values of the annual inflation rate for next year,

the requisite experiment cannot be performed repeatedly. The mathematics of probability theory applies regardless of the source of the probability measure.

Probability Formulas Related to Set Operators

1. $P(A \cup B) = P(A) + P(B) - P(A \cap B)$
2. $P(\sim A) = 1 - P(A)$

These two formulas state, respectively, that (1) the probability that either (inclusive version) of two events will occur is equal to the sum of the probabilities that each event will occur minus the probability that both will occur; and (2) the probability that an event will not occur is equal to one minus the probability that it will occur.

Independence and Conditionality

The two events, A and B, are called *independent* if $P(A \cap B) = P(A) \times P(B)$. Two events that are not independent are called *dependent.*

The *conditional probability of A given B,* $P(A \mid B)$, is defined as $P(A \cap B)/P(B)$. It is normally interpreted to mean the probability that A will occur, given that B has occurred or will occur. If A and B are independent, then $P(A \mid B) = P(A)$ and $P(B \mid A) = P(B)$; in other words, the occurrence of A does not affect the likelihood of B, and vice versa.

It is important to note that two events may be dependent without either being the cause of the other and without any apparent logical connection. A common phenomenon involves two apparently unrelated variables (e.g., annual fire department expenditures on gasoline, annual sales revenue from plastics and petrochemicals) that are dependent because each is related in an understandable way to a third variable (e.g., price per barrel of oil).

Bayes's law (also called *Bayes's theorem* and *Bayes's formula)* states that

1. If B_i, $i = 1, \ldots, N$, are sets (events), and
2. If $B_1 \cup B_2 \cup \ldots \cup B_N = U$, and
3. If $B_i \cap B_j = \phi$ for all $i \neq j$ between 1 and N, and
4. If $P(B_i) \neq 0$, $i = 1, 2, \ldots, N$,

then

$$P(B_i|A) = \frac{P(B_i) \times P(A|B_i)}{[P(B_1) \times P(A|B_1) + P(B_2) \times P(A|B_2) + \cdots + P(B_N) \times P(A|B_n)]}$$

Bayes's law is a particularly powerful consequence of the laws of conditional probability and is the foundation for modern statistical decision theory. What makes it so powerful is this application. Suppose $P(B_1), \ldots, P(B_N)$ represent the current best estimates of the probabilities of various events of interest prior to the performance of an experiment (or the collection of some data on experience). These are called *prior probabilities.* Suppose A is a possible outcome of that experiment whose probability of occurrence, given each of the events $B_1, \ldots, B_N$, can be derived. Then Bayes's law can be used to develop a new set of probabilities, $P(B_1 \mid A), \ldots, P(B_N \mid A)$, that incorporate the information provided by the experiment. These are called *posterior probabilities* because they are probabilities calculated *after* the gathering of information (e.g., through an experiment).

EXAMPLE:

Suppose you have ten coins, nine of which are fair (0.5 probability of heads) and one of which is fixed (1.0 probability of heads). Choose one coin. With no other information, the probability that you have a fair coin (B_1) is 0.9 and the probability that you have the fixed coin (B_2) is 0.1. Suppose you flip the coin once.

If it comes up tails, you know it is a fair coin and Bayes's law confirms this. Let A be the event of getting tails on the one coin flip. Then

$$P(A \mid B_1) = 0.5 \quad \text{and} \quad P(A \mid B_2) = 0$$

Therefore,

$$P(B_1 \mid A) = \frac{(0.5)(0.9)}{(0.5)(0.9) + (0)(0.1)} = 1$$

If the coin comes up heads, you still do not know whether it is the fixed or a fair coin. Since heads is more likely with the fixed coin, the evidence points slightly in that direction. Let A' be the event of getting heads on the single coin flip. Then

$$P(A' \mid B_1) = 0.5 \quad \text{and} \quad P(A' \mid B_2) = 1$$

Therefore,

$$P(B_1 \mid A') = \frac{(0.5)(0.9)}{(0.5)(0.9) + (1.0)(0.1)} = 0.82$$

Thus the result of flipping the coin once and obtaining heads has lowered the estimate of the probability that you hold a fair coin from 0.9 to 0.82; correspondingly, your estimate that you hold the fixed coin has risen from 0.1 to 0.18.

Random Variables and Probability Distributions

A *random variable* is a real-number-valued function defined on the elements of a sample space. In some cases, the elements of a sample space may lend themselves to association with a particular random variable (e.g., the sample space consists of outcomes of tossing a die; the random variable is the number of spots on the exposed face). In other cases, the random variable may be only one of many that could easily have been associated with the sample space (e.g., the sample space consists of all citizens of the United States; the random variable is the weight to the nearest pound).

Each value of a random variable corresponds to an event subset of the sample space consisting of all elements for which the random variable takes on that value. The *probability of a value of the random variable,* then, is the probability of that event subset.

A *discrete probability distribution* is one for which the random variable has a finite or countably infinite number

of possible values (e.g., values can be any integer from 0 to 10; values can be any integer).

A *continuous probability distribution* is one for which the random variable can take on an uncountably infinite number of possible values (e.g., values can be any real number from 0 to 10; values can be any real number).

A *probability distribution function* (also called *probability density, probability density function,* and *probability distribution*) is a mathematical function, *f,* that gives the probability associated with each value of a random variable, $f(y) = P(x = y)$. The term *density* is usually reserved for random variables that can take on an uncountably infinite range of values, so that the probability of a range of values of the variable must be computed through integral calculus.

Because each value, *y,* of a random variable, *x,* is associated with a subset of the sample space, $f(y) \geq 0$ for all *y.*

Because no element of a sample space can take on two or more values of a random variable and each element must take on some value, the values of the random variable collectively correspond to a set of mutually exclusive subsets that exhaust all elements of the sample space, and so

$$\sum_{\text{all } x} f(x) = 1$$

for discrete probability distributions, and

$$\int_{\text{all } x} f(x)\,dx = 1$$

for continuous probability distributions.

A *cumulative distribution* is a mathematical function that, for each value of a random variable, gives the probability that the random variable will take on that value or any lesser value

$$F(y) = P(x \leq y) = \sum_{x \leq y} f(x)$$

for discrete probability distributions, and

$$F(y) = \int_{x \leq y} f(x)\,dx$$

for continuous probability distributions.

Note that some references use the term "probability distribution" to refer to the cumulative distribution function, *F,* of a continuous probability distribution, while referring to the probability density function, *f,* only as a probability density function.

A *survival function* is a mathematical function that, for each value of a random variable, gives the probability that the random variable will exceed that value

$$S(y) = P(x > y) = \sum_{x > y} f(x)$$

for discrete probability distributions, and

$$S(y) = \int_{x > y} f(x)\,dx$$

for continuous probability distributions.

Therefore, for any probability distribution function $P(x)$ and any value *y,* the cumulative distribution and the survival function based on $P(x)$ sum to one for all values of *y.*

$$F(y) + S(y) = 1$$

A *multivariate probability distribution* gives the probability for all combinations of values of two or more random values, for example, $f(u, v) = P(x = u \text{ and } y = v)$.

Key Parameters of Probability Distributions

Certain key parameters of probability distributions are of use because (1) they help to provide essential summary information about the random variable and its probability distributions and (2) they are included in the functional forms of certain probability distributions that are of use in many practical situations.

The mean, μ, of a random variable (also called its *expected value* or *average*) is defined as

$$\mu = \sum_{\text{all } x} xf(x)$$

for discrete probability distributions, and

$$\mu = \int_{\text{all } x} xf(x)\,dx$$

for continuous probability distributions.

It is also written as $E(x)$, which stands for *expected value of x.* This is the most commonly used of several parameters that relate to some concept of the most typical or average value of a random variable.

The expected value can also be calculated for a function of the random variable, as follows:

$$E[g(x)] = \sum_{\text{all } x} g(x)f(x)$$

for discrete probability distributions, and

$$E[g(x)] = \int_{\text{all } x} g(x)f(x)\,dx$$

for continuous probability distributions.

The *variance,* σ^2, of a random variable is a measure of the likelihood that a random variable will take on values far from its mean value. It is a parameter used in the functional form of some commonly occurring probability distributions.

$$\sigma^2 = \sum_{\text{all } x} (x - \mu)^2 f(x)$$

for discrete probability distributions, and

$$\sigma^2 = \int_{\text{all } x} (x - \mu)^2 f(x)\,dx$$

for continuous probability distributions.

The variance can also be expressed as the expected value of a function of the random variable, as follows:

$$\sigma^2 = E[(x-\mu)^2] = E(x^2) - \mu^2 = E(x^2) - [E(x)]^2$$

The variance is expressed as σ^2 because most calculations use the square root of the variance, which is called the *standard deviation*, σ.

The *moments* of a probability distribution are defined as the expected values of powers of the random variable. The nth moment is $E(x^n)$. Thus, the mean is the first moment, and the variance is the second moment minus the square of the first moment. The value given by $E[(x-\mu)^n]$ is defined as the nth moment about the mean.

The function defined by $E[e^{\theta x}]$ is called the moment generating function because it is equivalent to an infinite series whose terms consist of, for all k, the kth moment of x times $(\theta^k/k!)$.

For continuous probability distributions, the *median* is that value, y, for which the cumulative distribution, $F(y)$, is equal to 0.5. For discrete probability distributions, the median is that value, y, for which $f(x<y) = f(x>y)$. If the random variable can take on only a finite number of values, the median may not be uniquely defined. The median is less sensitive than the mean to extreme values of the random variable and is the "average" of choice for certain kinds of analyses.

Skewness refers to the symmetry of a probability distribution function around its mean. The median is not equal to the mean in a skewed distribution. An age distribution of fire department uniformed personnel will be skewed, for example, because the small number of personnel in their 50s and 60s will raise the average (mean) age well above the typical age (middle to late 20s). The term is used more frequently than is any specific measure of it. A symmetric distribution has a skewness of zero, no matter how skewness is measured.

Kurtosis is a rarely used term for the relative flatness of a distribution.

The *failure rate* or *hazard rate*, $r(x)$, is defined as: $r(x) = f(x)/S(x)$

When $f(x)$ is a probability density function for the time to failure, then $r(x)$ will give the conditional probability of time to failure, given survival to time x.

Degrees of freedom is the term given to certain parameters in many commonly used distributions (e.g., Student's t, chi-square, F). The distributions that use these parameters are used in tests of the variance of samples. In those tests the parameters always correspond to positive integer values based on the size of the sample (e.g., $n, n-1, n-2$). Since increasing sample size gives the sample more freedom to vary, it is natural to call those parameters measures of the "degrees of freedom" to vary in the sample.

Commonly Used Probability Distributions

Uniform and Rectangular Distributions

These distributions give equal probability to all values. The term *rectangular distribution* is reserved for the continuous probability distribution case.

1. $f(x) = 1/N$, for $x_1, \ldots, x_N$, if $f(x)$ is a discrete probability distribution over N values of a random variable.
2. $f(x) = 1/(b-a)$, for $a \le x \le b$, if $f(x)$ is a continuous probability distribution over a finite range.

Multivariate versions of the uniform distribution can be readily constructed for both the discrete and the continuous cases.

The uniform and rectangular distributions are used when every outcome is equally likely. As such, they tend to be useful, for example, as a first estimate of the probability distribution if nothing is known; that is, if nothing is known, treat every possibility the same.

EXAMPLE 1:

One of the 30 fire protection engineers in a firm is to be selected at random to accompany the local fire department on a fire code inspection. Each engineer is assigned a playing card, the reduced deck of 30 cards is shuffled and cut several times, and the top card is selected. Here, N is 30, so $f(x) = 1/30$, for each engineer.

EXAMPLE 2:

When the winning engineer arrives at the fire department, a random procedure is used to select one point on the city map. Whatever point is selected, they will inspect the buildings on the property of which that point is part.

Suppose A is the total area of the city. Then $f(x) = 1/A$, for every point in the city. For a given occupancy B, whose lot has area a, the probability of the event of choosing B (which corresponds to choosing any point on B's property) is equal to

$$\int_{\text{all points in } B} \left(\frac{1}{A}\right) dx = \frac{a}{A}$$

Note that while this is a uniform (rectangular) distribution over all *area* in the city, it is not a uniform distribution over all occupancies of the city, because an occupancy's probability of being chosen will be proportional to the size of its lot. In any analysis, there may be several different, incompatible ways of treating all possibilities "equally."

Normal Distribution (also called Gaussian Distribution)

The normal distribution, the familiar bell-shaped curve, is the most commonly used continuous probability density function in statistics; its density is a function of its mean, μ, and standard deviation, σ, as follows:

$$f(x) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left[-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2\right], \quad \text{for } -\infty < x < +\infty$$

The *Central Limit Theorem* establishes that for *any* probability density function, the distribution of the sample mean, $\bar{x}$, of a sample from that density asymptotically approaches a normal distribution as the size of the sample increases. This means that the normal distribution can be used validly to test hypotheses about the means of any population, even if nothing is known or can be assumed

about the population's underlying distribution. Also, the *Law of Large Numbers* establishes that the standard deviation of the distribution of the sample mean is inversely proportional to the square root of the sample size, which means that larger samples always produce more precise estimates of the sample mean. These two results are the cornerstones of sample-based statistical inference.

In addition to proving a valid distribution for sample *means* in all situations, the normal distribution also directly characterizes many *populations* of interest, including experimental measurement errors and quality control variations in materials properties.

A sample size of at least 30 should be used to obtain an acceptable fit of the sample mean distribution to the normal distribution.

The standard tables of the normal distribution are for a random variable with mean 0 and variance 1. They can be used for values from any normal distribution by subtracting the mean, then dividing the result by the standard deviation.

The multivariate form of the normal distribution is also commonly used. Its parameters are given by a vector of the means of all the variables and a matrix with both the variances of all the variables and the covariances of pairs of variables (which are functions of the variances and the correlation coefficients).

EXAMPLE 1:

The promotional examination for lieutenant is taken by 100 fire fighters, whose test scores, shown in Table 1-11.1 below, fit a normal distribution with mean score of 50 and standard deviation of 15. The fit is not exact because strictly speaking, the 100 scores comprise a discrete distribution, not a continuous distribution, and the possible scores are bounded by 0 and 100. Also, with only 100 scores, the fit to a normal distribution can be seen in this grouped data but might not be apparent if every score had its own frequency entered separately. (See Figure 1-11.4.)

EXAMPLE 2:

Suppose the widths of U.S. adults, fully clothed (including overcoats), at their widest points are normally distributed with mean 0.5 m and standard deviation of 0.053 m. Then, a door width equal to the mean (0.5 m) would accommodate 50.0 percent of the population [$F(x \leq \mu) = 0.50$]. A door width equal to the mean plus one standard deviation (0.553 m) would accommodate

Table 1-11.1 ***Normal Distribution Sample Test Scores***

Score	Number of Fire Fighters Receiving That Score
0–9	1
10–19	2
20–29	7
30–39	15
40–49	25
50–59	25
60–69	15
70–79	7
80–89	2
90–100	1

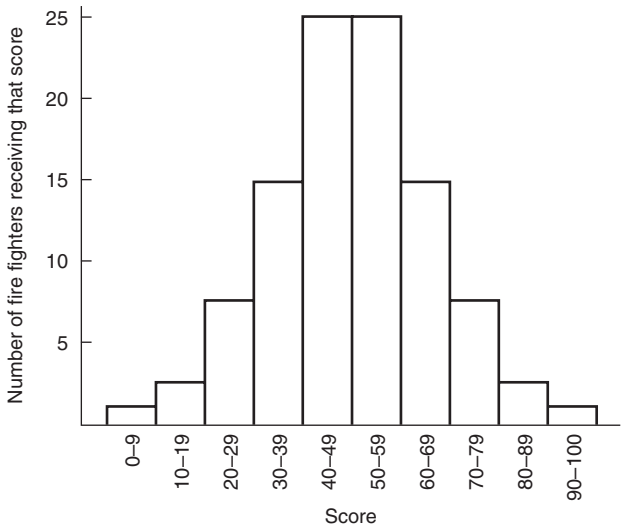

Figure 1-11.4.

84.1 percent of the population [$F(x \leq \mu + \sigma) = 0.841$]. A door width equal to the mean plus two standard deviations (0.606 m) would accommodate 97.7 percent of the population [$F(x \leq \mu + 2\sigma) = 0.977$].

But some buildings hold 10,000 persons, so suppose it is desired to construct a door width that will be too narrow for only one of every 20,000 persons. Then the value of a is desired, such that $F(x \leq \mu + a\sigma) = 0.99995$. That value of a is 3.87, which translates to a door width of 0.705 m, or more than 40 percent wider than the door width that sufficed for one-half the population.

All basic statistics texts contain tables of the cumulative distribution function for the normal distribution.

Log-Normal Distribution

It is not unusual to deal with random variables whose logarithms (to any base) are normally distributed. In such cases, the original variables are said to be log-normally distributed. For example, fire load density (i.e., mass of combustibles per unit floor area) typically has a log-normal distribution.

Student's t Distribution

For small samples, the distribution of the sample mean is not well approximated by the normal distribution. Even for somewhat larger samples, the population variance is typically not known, and the sample variance must be used instead. The Student's t distribution may be used instead of the normal distribution, but it does assume that the population is normally distributed. Its distribution is a function of its degrees of freedom, m.

$$f(t) = \frac{[\Gamma(m + 1/2)][(1 + t^2/m)^{-(m+1)/2}]}{\sqrt{\pi m}[\Gamma(m/2)]} \quad \text{for } -\infty < t < +\infty$$

where

$$\Gamma(u) = \int_0^\infty y^{u-1} e^{-y}\, dy$$

Expressed in this standard form, the t distribution has a mean of zero and a variance of $m/(m-2)$. Since the Student's t distribution is used primarily in statistical testing, an example of its use is included in Section 4, Chapter 3.

Chi-Square Distribution

Whereas the normal and t distributions may be used to test hypotheses about means, the chi-square distribution may be used to test hypotheses about variances or entire distributions. Its density is a function of its degrees of freedom, m.

$$f(x) = \frac{x^{(m-2)/2}e^{-x/2}}{2^{m/2}\Gamma(m/2)}, \quad \text{for } x \geq 0$$

where

$$\Gamma(u) = \int_0^\infty y^{u-1}e^{-y}\,dy$$

Expressed in this standard form, the chi-square distribution has its mean equal to m, the number of degrees of freedom, and its variance equal to $2m$.

F Distribution

Whereas the normal distribution may be used to test hypotheses about the means of samples of a single random variable, the F distribution permits simultaneous testing of hypotheses about the means of samples reflecting several random variables, each with its own variance, and each pair of variables correlated to some unknown degree. Its density is a function of two noninterchangeable degrees-of-freedom parameters, m_1 and m_2.

$$f(x) = \frac{(m_1/m_2)^{m_1/2}x^{(m_1-2)/2}\{\Gamma[(m_1+m_2)/2]\}}{[\Gamma(m_1/2)][\Gamma(m_2/2)][(1+m_1x/m_2)^{(m_1+m_2)/2}]}$$

where

$$\Gamma(u) = \int_0^\infty y^{u-1}e^{-y}\,dy$$

The mean of the F distribution is $m_2/(m_2-2)$, and the variance is given by

$$\sigma^2 = \frac{2m_2^2(m_1+m_2-2)}{m_1(m_2-2)^2(m_2-4)} \quad \text{if } m_2 > 4$$

Exponential Distribution

The exponential distribution is the simplest distribution for use in reliability analysis, where it can be used to model the time to failure. Its density is a function of a parameter, θ, that is equal to its mean and its standard deviation.

$$f(x) = \left(\frac{1}{\theta}\right)e^{-x/\theta} \quad \text{for } x \geq 0$$

Its hazard rate is a constant, $1/\theta$, so the exponential distribution is the one to use if the expected time to failure is the same, regardless of how much time has already elapsed. This distribution also is commonly used to represent the time required to serve customers waiting in a queue.

EXAMPLE:

A smoke detector is installed in a private home and is powered by a battery from a lot with average life of six months. Suppose the time until the battery dies can be represented by an exponential distribution. (In practice, retailed batteries have a more complex failure rate function.) Then the time until failure might look like that shown in Table 1-11.2.

Note that there is a high probability of failure in the first month and a high probability of survival past one year.

Poisson Distribution

If a system has exponentially distributed time to failure with mean time θ, then the distribution of the total number of failures, n, in time, t, has a Poisson distribution. Its distribution is given by a parameter, λ, that is equal to both its mean and its variance.

$$f(n) = \frac{\lambda^n e^{-\lambda}}{n!}$$

for

$$n = 0, 1, 2, \ldots, +\infty$$

where

$$\lambda = \frac{t}{\theta} \quad \text{and} \quad n! = n(n-1)(n-2)\cdots(3)(2)(1)$$

This distribution also is commonly used to represent the number of customers entering a queue for service in a unit of time. It assumes that the expected number of arriving customers in any short interval of time is proportional to the length of time.

EXAMPLE:

Using the smoke detector scenario in the previous example, suppose each time the battery fails, it is detected immediately and immediately replaced with a new battery of similar expected life. Then the number of times the batteries will fail in the first year is given by a Poisson dis-

Table 1-11.2 ***Example of Exponential Distribution (detector batteries)***

Months Old	Probability of Failure by This Age (i.e., this soon or sooner)
0–1	0.154
1–2	0.283
2–3	0.393
3–4	0.487
4–5	0.565
5–6	0.632
6–7	0.689
7–8	0.736
8–9	0.777
9–10	0.811
10–11	0.840
11–12	0.865
Over 12	1.000

Table 1-11.3 *Poisson Distribution*

Number of Times Detector Will Have Dead Batteries in One Year	Probability
0	0.135
1	0.271
2	0.271
3	0.181
4	0.090
5	0.036
6 or more	0.016

tribution. (See Table 1-11.3.) Here t is 12 months and θ is 6 months, so λ is 2.

Gamma Distribution (also called Erlang Distribution)

The gamma distribution is also commonly used to represent time to failure for a system, particularly in a situation where m independent faults, all with identical exponential distributions of time to occur, are required before the system fails. Its density is a function of two parameters, m and θ, which must both be greater than zero; m need not be an integer.

$$f(x) = \frac{x^{m-1}e^{-x/\theta}}{[\theta^m \Gamma(m)]} \quad \text{for } x \geq 0$$

where

$$\Gamma(m) = \int_0^\infty y^{m-1}e^{-y}\,dy$$

The mean is $m\theta$ and the variance is $m\theta^2$.

Weibull Distribution

Another distribution commonly used in reliability studies to represent time to failure, the Weibull distribution is flexible enough to permit failure rates that increase or decrease with system age. Its density is a function of two parameters, a and b, which must both be greater than zero.

$$f(x) = abx^{b-1}e^{-ax^b}, \quad \text{for } x \geq 0$$

$$\mu = a^{-(1/b)}\Gamma\left(\frac{b+1}{b}\right)$$

$$\sigma^2 = a^{-(2/b)}\left\{\left[\Gamma\left(\frac{b+2}{b}\right)\right] - \left[\Gamma\left(\frac{b+1}{b}\right)\right]^2\right\}$$

where

$$\Gamma(u) = \int_0^\infty y^{u-1}e^{-y}\,dy$$

The cumulative distribution can be expressed in closed form, as follows:

$$F(x) = 1 - e^{-ax^b}$$

Therefore, the failure rate has a simple form

$$h(x) = abx^{b-1}$$

The failure rate increases with x (e.g., system age) if $b > 1$ and decreases if $b < 1$. If $b = 1$, the Weibull distribution becomes an exponential distribution, with $\theta = 1/a$.

EXAMPLE:

Suppose the example in Table 1-11.2 is modified to show the time to failure for the detector batteries as having a Weibull distribution. Suppose $\alpha = 1/6$. Then if $b = 1$, the Weibull distribution will be the same exponential distribution shown in Table 1-11.2. If $b < 1$, early failures are less likely, and if $b > 1$, early failures are more likely. Some examples are shown in Table 1-11.4. Note that it is not necessary to reduce b in order to make early failures unlikely. An exponential distribution with a higher θ (or Weibull distribution with a lower α) will also make early failures unlikely.

Pareto Distribution

The Pareto distribution is not as commonly used but does provide a simple form for a distribution whose failure rate decreases with system age. Its density is a function of two parameters, a and b, which must both be greater than zero.

$$f(x) = ab^a x^{-(a+1)} \quad \text{for } x > b$$

$$\mu = ab/(a-1)$$

$$\sigma^2 = ab^2/[(a-1)^2(a-2)]$$

$$F(x) = 1 - b^a x^{-a}$$

$$h(x) = a/x$$

The parameter a must be greater than 2 for the mean and variance to converge to the values shown above. In general, a must be greater than k for the kth moment to converge.

Table 1-11.4 *Weibull Distribution (detector batteries)*

	Probability of Failure by This Age (i.e., this soon or sooner)			
Months Old	$b = 1$	$b = 2$	$b = 0.5$	$b = 0.1$

9–10	0.811	1.000	0.410	0.189
10–11	0.840	1.000	0.425	0.191
11–12	0.865	1.000	0.439	0.192
Over 12	1.000	1.000	1.000	1.000

Bernoulli Distribution

The Bernoulli distribution is the most basic of the discrete probability distributions and it represents a single trial or experiment in which there are only two possible outcomes—success (with probability p) and failure. The random variable is the number of successes.

$$f(x) = p^x(1-p)^{(1-x)} \quad \text{for } x = 0, 1$$

Therefore $f(x) = p$ if $x = 1$ and $f(x) = (1-p)$ if $x = 0$. The mean is p and the variance is $p(1-p)$.

EXAMPLE:

Suppose there are 100 fire fighters in a department, 15 of whom are minorities. If all fire fighters are equally qualified, the probability that a minority fire fighter will be chosen as the next lieutenant is give by a Bernoulli distribution, with $p = 15/100 = 0.15$.

Binomial Distribution

The binomial distribution is the probability distribution for the number of successes in n independent Bernoulli trials, all having the same probability of success.

$$f(x) = \binom{n}{x} p^x(1-p)^{(n-x)} \quad \text{for } x = 0, 1, \ldots, n$$

where

$$\binom{n}{x} = \frac{n!}{x!(n-x)!}$$

and

$$x! = x(x-1)(x-2)\ldots(3)(2)(1)$$

The mean is np and the variance is $np(1-p)$.

The use of *factorials* (e.g., $x!$) can lead to time consuming calculations. It is possible for large values of n to approximate the binomial distribution by a normal distribution [with $\mu = np$ and $\sigma^2 = np(1-p)$]. This approximation will work acceptably if $np \geq 5$ and $n(1-p) \geq 5$. For small values of p, μ, and σ^2 become very close, and one can approximate the binomial distribution by a Poisson distribution (with $\lambda = np$). This works acceptably if $n > 100$ and $p < 0.05$.

EXAMPLE:

Suppose in the fire fighter promotion example just used, five lieutenants have been selected sequentially. Also suppose that each time a fire fighter is promoted to lieutenant, that slot is filled with another fire fighter of the same race before the next lieutenant is selected. Under these conditions, the five promotions represent five Bernoulli trials, all having the same probability that a minority fire fighter will be promoted. The number of minority fire fighters promoted will then be governed by a binomial distribution, as shown in Table 1-11.5.

Table 1-11.5 ***Example of Binomial Distribution***

Number of Minority Fire Fighters Promoted	Probability
0	0.444
1	0.392
2	0.138
3	0.024
4	0.002
5	0.000

Geometric Distribution

In the case of a potentially unlimited number of independent Bernoulli trials with identical probabilities of success, the geometric distribution gives the distribution of the trial on which the first success will occur.

$$f(x) = p(1-p)^{(x-1)}, \quad \text{for } x = 1, 2, 3, \ldots, +\infty$$

The mean is $(1/p)$ and the variance is $(1-p)/p^2$.

EXAMPLE:

Continuing the example of serial promotions in which each open slot is filled by a new fire fighter of the same race, the geometric distribution would give the probability of which of the promotions will be the first to involve a minority fire fighter. (See Table 1-11.6.)

Note the high probability that chance alone will delay the first minority promotion past the tenth promotion.

Negative Binomial Distribution (also called Pascal Distribution)

This generalization of the geometric distribution gives the probability distribution for the trial on which the kth success will occur.

$$f(x) = \binom{x-1}{k-1} p^k(1-p)^{-(x-1)}$$
$$\text{for } x = k, k+1, k+2, \ldots, +\infty$$

where

$$\binom{x-1}{k-1} = \frac{(x-1)!}{(k-1)!(x-k)!}$$

and

$$x! = x(x-1)(x-2)\ldots(3)(2)(1)$$

Table 1-11.6 ***Geometric Distribution with Serial Promotion Example***

First Promotion to Involve a Minority Fire Fighter	Probability
First	0.150
Second	0.128
Third	0.108
Fourth	0.092
Fifth	0.078
Sixth	0.067
Seventh	0.057
Eighth	0.048
Ninth	0.041
Tenth	0.035
Later than tenth	0.196

Hypergeometric Distribution

The hypergeometric distribution is a variation on the binominal distribution that applies to cases where the initial probability of success, p, reflects a fixed number of total successes and failures, N, available for selection so that each trial reduces either the number of successes remaining or the number of failures remaining. (For example, imagine an urn filled with balls of two different colors. If each trial consists of removing a ball, then replacing it in the urn, the binomial distribution applies. If each trial consists of removing a ball and keeping it out, the hypergeometric distribution applies.)

$$f(x) = \frac{\binom{Np}{x}\binom{N(1-p)}{n-x}}{\binom{N}{n}} \quad \text{for } x = 0, 1, 2, \ldots, n$$

where

N is the total number of successes and failures possible, $n \leq N$ Np and $N(1-p)$ are integers

$$\binom{m}{y} = \frac{m!}{y!(m-y)!}$$

and

$$y! = y(y-1)(y-2)\ldots(3)(2)(1)$$

The mean is np and the variance is $np(1-p)[(N-n)/(N-1)]$. For very large values of N (relative to n), the hypergeometric distribution asymptotically approaches the binomial distribution.

EXAMPLE:

Continuing the fire fighter promotion example, suppose five promotions are carried out all at once. (See Table 1-11.7.) The hypergeometric distribution then gives the probability distribution for the number of minorities promoted; note how its probabilities differ from those generated by the binomial distribution.

For example,

$$0.436 = \frac{\binom{15}{0}\binom{85}{5}}{\binom{100}{5}} = \frac{[15!/(15!0!)][85!/(80!5!)]}{[100!/(95!5!)]}$$
$$= \frac{(85)(84)(83)(82)(81)}{(100)(99)(98)(97)(96)}$$

Table 1-11.7 ***Example of Hypergeometric Distribution***

Number of Minority Fire Fighters Promoted	Probability
0	0.436
1	0.403
2	0.138
3	0.022
4	0.001
5	0.000

Multinomial Distribution

The multinomial distribution is a generalization of the binomial distribution that addresses the case where there are more than two possible outcomes. Given k possible outcomes, such that the probability of the ith outcome is always p_i and the p_i collectively sum to unity, then for a series of n independent trials

$$f(x_1, \ldots, x_k) = \frac{n!}{x_1!x_2!\ldots x_k!} p_1^{x_1} p_2^{x_2} \ldots p_k^{x_k}$$

for all cases of $x_1 = 0, 1, 2, \ldots, n$, for $i = 1, 2, \ldots, k$, subject to

$$\sum_{i=1}^{k} x_i = n$$
$$\mu_i = np_i$$
$$\sigma_i^2 = np_i(1-p_i)$$

EXAMPLE:

Continuing the fire department example, suppose that the department's 100 fire fighters include 15 black fire fighters and 5 female fire fighters, none of whom is black. Suppose two promotions are made, and the slot vacated for the first promotion is filled by a fire fighter of the same race and sex before the second promotion is made. Then the multinomial distribution (Table 1-11.8) describes the possible outcomes of interest.

For example, this is the probability that the promotions will go to one white male and one white female:

$$0.080 = \frac{2!}{0!1!1!}(0.15)^0(0.05)^1(0.80)^1 = 2 \times 0.05 \times 0.80$$

Beta Distribution

In Bayesian statistical inference, if the phenomenon of interest is governed by a Bernoulli distribution, then one needs a probability distribution for the parameter, p, of that Bernoulli distribution, and a Beta distribution is typically used.

$$f(p) = \frac{\Gamma(a+b)}{[\Gamma(a)][\Gamma(b)]} p^{a-1} 1 - p^{(b-1)}$$

where

$$\Gamma(u) = \int_0^\infty y^{u-1} e^{-y}\, dy$$

Table 1-11.8 ***Example of Multinomial Distribution***

Number of Fire Fighters Promoted			Probability
Minority Males	Female	White Males	
0	0	2	0.640
0	1	1	0.080
0	2	0	0.002
1	0	1	0.240
1	1	0	0.015
2	0	0	0.023

The mean is $a/(a + b)$ and the variance is given by

$$\Gamma^2 = \frac{ab}{(a+b)^2(a+b+1)}$$

If a = b = 1, this becomes a *uniform distribution.* Larger values of b correspond to smaller variances, hence tighter confidence bands around the mean estimate of the parameter.

CHAPTER 12

Statistics

John R. Hall, Jr.

Introduction

Statistical analysis is basic to all aspects of fire protection engineering that involve abstracting results from experiments or real experience. Statistical analysis is the applied side of the mathematics of probability theory.

Basic Concepts of Statistical Analysis

Statistic

A statistic is (a) any item of numerical data, or (b) a quantity (e.g., mean) computed as a function on a body of numerical data, or the function itself.

Statistical Analysis

Statistical analysis is the use of mathematical methods to condense sizeable bodies of numerical data into a small number of summary statistics from which useful conclusions may be drawn.

Statistical Inference

Statistical inference is statistical analysis that consists of using methods based on the mathematics of probability theory to reason from properties of a body of numerical data, regarded as a sample from a larger population, to properties of that larger population.

In *classical statistical inference*, a single best estimate of each statistic of interest is developed from available data, the uncertainty of that statistic is estimated, and hypotheses are tested and conclusions drawn from those bases.

Dr. John R. Hall, Jr. is assistant vice president for fire analysis and research at the National Fire Protection Association. He has been involved in studies of fire experience patterns and trends, models of fire risk, and studies of fire department management experiences since 1974 at NFPA, the National Bureau of Standards, the U.S. Fire Administration, and the Urban Institute.

In *Bayesian statistical inference*, a probability distribution for each statistic of interest is developed, using a form that permits new information, when it is acquired, to be used to adjust that distribution. Bayes's law, which was described in Section 1, Chapter 11, "Probability Concepts," is used to adjust the distribution in light of the new information.

EXAMPLE:

Suppose there are 100 fire fighters in a department, 15 of them black, and in a group of 5 recent promotions, all the promotions were given to whites. How likely is it that the department never selects blacks for promotions?

A Bayesian analysis uses (a) a prior estimate of the probability that the department discriminated, made before considering the evidence of the recent promotions; (b) a computed probability that the promotions would have had this pattern if the department never selects blacks; and (c) a computed probability that the promotions would have had the result if promotions are random with respect to race. For (b), the probability is 1.0, because an all white promotion list is the only possible outcome under the hypothesis that blacks are never selected. For (c), the probability is given by the hypergeometric distribution

$$\frac{\binom{15}{0}\binom{85}{5}}{\binom{100}{5}} = 0.44.$$

By Bayes's law, then, given a prior probability, q, that blacks are never selected, the posterior probability is $q/(0.56q + 0.44)$. The new evidence produces some shift in the estimated likelihood of prejudice. If prejudice was considered an even proposition before ($q = 0.5$), then the new estimate is 0.69. If prejudice was considered certain ($q = 1.0$) or impossible ($q = 0.0$) before, no new evidence will alter those estimates. If prejudice was considered very unlikely before (say, $q = 0.01$), then it will still be considered very unlikely (new value of 0.022).

Suppose in the same example there had been 25 promotions with no blacks selected. This more extensive evidence would have produced a more dramatic shift in the estimated probability. Instead of 0.44, the probability of this outcome (given no prejudice) would be 0.009. If the prior probability was 0.5, the posterior probability would be 0.991. Even if the prior probability is 0.01, the posterior probability would be 0.529. In other words, the new evidence changes the estimate of the likelihood that the department never selects blacks from one chance in a hundred to a better than even chance.

In more sophisticated Bayesian statistical analysis, the prior probability is given not as a single probability but as a probability distribution, which permits the analyst to reflect the strength of the evidence that went into choosing the prior probability distribution.

Exploratory Data Analysis

Exploratory data analysis is the development of *descriptive statistics,* that is, statistical analysis that does not make inferences to a population.

Key Parameters of Descriptive Statistics

The *mean, median, variance,* and *standard deviation,* as described in the previous chapter, can all be applied here, using the relative frequency of occurrence of each value in the body of data to define a discrete probability distribution.

The *mode* is the value that occurs most frequently, that is, the value of x for which $f(x) > f(y)$ for all $y \neq x$.

A body of data is called *unimodal* if $f(z) < f(y)$ in all cases where $|z - x| > |y - x|$, that is, if the probability distribution function steadily decreases as one moves away from the mode.

A body of data is called *multimodal* if it is not unimodal. In such cases there will be two or more values of x for which $f(x) > f(y)$ for all $y \neq x$ and $|y - x| < \varepsilon$, where ε is some small value. Although there may be only one mode in the sense of a most frequently occurring value, the existence of local maximums in the probability distribution function is sufficient to make the distribution multimodal. Multimodal data usually occur when data are combined from two or more populations, each having an underlying unimodal distribution. For example, if data were collected on the lengths of fire department vehicles, it probably would be multimodal, having one peak each for automobiles, ambulances/vans, engines, and ladders.

A *geometric mean* is another type of average:

$$\text{G.M.} = (x_1 x_2 x_3 \ \ldots \ x_n)^{1/n}$$

The geometric mean is useful in averaging index numbers reflecting rates of change. For example, suppose a, b, and c are annual rates of increase in the fire department budget for three successive years. Then $A = 1 + a$, $B = 1 + b$, and $C = 1 + c$ would be index numbers reflecting those three rates. The index number, D, reflecting the cumulative increase over all three years, would be given by $D = ABC$, and so an index number yielding an "average" rate of inflation for the three-year period would be given by $(ABC)^{1/3}$, or the geometric mean of the index numbers. This geometric mean is the index number that could be compounded over the three years to obtain the actual cumulative increase. Note that the geometric mean is equivalent to computing the arithmetic mean of the logarithms of the data values, then exponentiating the result, that is, using the result as an exponential power to be applied to the base used in computing the logarithms.

The *harmonic mean* is a less commonly used average that consists of the reciprocal of the arithmetic mean of the reciprocals of the data values. For example, suppose $V_1, \ldots, V_n$ are a set of n values of the speed achieved by an engine company on a set of test runs from the firehouse to a single location. Then these speeds can also be represented as $d/t_1, d/t_2, \ldots, d/t_n$, where d is the constant distance and $t_1, \ldots, t_n$ are the times of the n runs. The average speed would be given by $nd/(t_1 + t_2 + \cdots + t_n)$, or total distance divided by total time. That value will also be given by the harmonic mean of the speed values. This example also helps illustrate why the harmonic mean is rarely used. It is likely that anyone who had access to the speed values would also have access to time values, $t_1, \ldots, t_n$, and could compute the average more quickly by using them directly.

The *range* is the difference between the highest and lowest values, or the term may be used to refer to those two values and the interval between them.

Quartiles, deciles, and *percentiles* are useful measures of the dispersion of the data. If the data are arranged in ascending or descending order, the three quartiles, Q_1, Q_2, and Q_3, are the values that mark off 25 percent, 50 percent, and 75 percent, respectively, of the data set. In other words,

Q_1 is chosen so that $F(Q_1) = 0.25$

Q_2 is chosen so that $F(Q_2) = 0.50$; Q_2 is also the median

Q_3 is chosen so that $F(Q_2) = 0.75$

Deciles and percentiles are defined analogously so as to divide the data set into tenths or hundredths, respectively, rather than fourths. Like the second quartile, the fifth decile equals the median. The *interquartile range,* or $Q_3 - Q_1$, is an alternative to the full range that is less sensitive to extreme values.

A *histogram* is a technique of exploratory data analysis for displaying the frequency of occurrence of a finite set of data. The data values are arrayed along the x-axis of a graph, and the y-axis is used to plot the frequency, usually as number of occurrences or percentage of total occurrences.

A *scatter plot* or *scatter diagram* is a technique of exploratory data analysis for displaying the patterns of a finite set of bivariate data. Each pair of data values is plotted on an (x, y) graph. This technique works best if both dimensions of the data are continuous so that the same pair of values does not occur more than once.

The *coefficient of variation* is given by the standard deviation divided by the mean. When the result is multiplied by 100, it gives the scatter about the mean in percentage terms relative to the mean.

Correlation, Regression, and Analysis of Variance

Correlation

In qualitative terms, correlation refers to the degree of association between two or more random variables. (Random variables with discrete and continuous probability distributions were defined in the previous chapter.)

The most common quantitative measure of correlation specifically addresses the extent to which two random variables are linearly related.

Correlation Coefficient (also called the Pearson product-moment correlation coefficient)

Let two discrete random variables, X and Y, have a joint probability distribution given by $f(x_i, y_j)$ = probability $(X = x_i \text{ and } Y = y_j)$.

Then the correlation coefficient of X and Y is given by

$$\rho_{XY} = \frac{[\sum_{i=1}^{\infty}\sum_{j=1}^{\infty}(x_i - \mu_X)(y_j - \mu_Y)f(x_i, y_j)]}{\sqrt{\sum_{i=1}^{\infty}\sum_{j=1}^{\infty}[(x_i - \mu_X)^2 f(x_i, y_j)]}\sqrt{\sum_{i=1}^{\infty}\sum_{j=1}^{\infty}[(y_i - \mu_Y)^2 f(x_i, y_j)]}}$$

where

$$\mu_X = \sum_{i=1}^{\infty}\sum_{j=1}^{\infty} x_i f(x_i, y_j)$$

and

$$\mu_Y = \sum_{i=1}^{\infty}\sum_{j=1}^{\infty} y_i f(x_i, y_j)$$

Let two continuous random variables, X and Y, have a joint probability density function given by $f(x, y)$ such that

$$\int_{-\infty}^{y}\int_{-\infty}^{x} f(u, v)\, du\, dv = \text{probability } (X \le x \text{ and } Y \le y)$$

Then the correlation coefficient of X and Y is given by

$$\rho_{XY} = \frac{\left[\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}(x - \mu_X)(y - \mu_Y)f(x, y)\, dx\, dy\right]}{\sqrt{\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}(x - \mu_X)^2 f(x, y)\, dx\, dy}\sqrt{\int_{-\infty}^{\infty}\int_{-\infty}^{\infty}(y - \mu_Y)^2 f(x, y)\, dx\, dy}}$$

where

$$\mu_X = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} x f(x, y)\, dx\, dy$$

and

$$\mu_X = \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} y f(x, y)\, dx\, dy$$

If $y = ax + b$, then $\rho = 1$ if $a > 0$ and $\rho = -1$ if $a < 0$.

It is possible for one variable to be a function of another, yet have zero correlation with it (e.g., $y = x$ for $x \ge 0$ and $y = -x$ for $x < 0$).

If two random variables are independent, they will have zero correlation. However, zero correlation can occur without independence.

Even if two variables are highly correlated, it is not necessary for either to be the cause of the other. Many so-called spurious correlations occur. An example is a case of two variables (e.g., sales of fire extinguishers, sales of chewing gum) that are both strongly influenced by a third variable (e.g., disposable income) and so will be highly correlated with each other because each is correlated with the third variable.

In the case of a multimodal joint probability distribution, the correlation may be quite different at a macro- and a microlevel. Consider the variables of fire rate per household and average income per household with regard to census tracts in a city. A small number of tracts typically will have high fire rates and low incomes; the rest will have low fire rates and high incomes. The two variables will be highly correlated if all census tracts are considered together, but if the two relatively homogeneous areas are analyzed separately, there may be little correlation.

If a sample of size n consists of pairs of values (x_i, y_i), then the sample correlation coefficient is

$$r_{XY} = \frac{\sum_{i=1}^{\infty}(x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^{n}(x_i - \bar{x})^2}\sqrt{\sum_{i=1}^{n}(y_i - \bar{y})^2}}$$

EXAMPLE:

Suppose the scores of ten fire fighters on a promotional exam are compared to their numbers of years with the fire service, with results shown in Table 1-12.1 and in Figure 1-12.1.

Then the mean age is 23.7 and the mean score is 72. The correlation coefficient is 0.67, indicating moderate correlation. If the second individual's score, which is the farthest from the group pattern, were changed from 85 to 60, the correlation coefficient would rise to 0.89, indicating high correlation.

The *coefficient of determination* (also called the *percentage of variation explained*) is given by the square of the correlation coefficient.

Table 1-12.1 *Distribution of Test Scores*

Age	Score
18	54
20	85
20	62
20	60
22	66
25	70
25	75
28	88
29	70
30	90

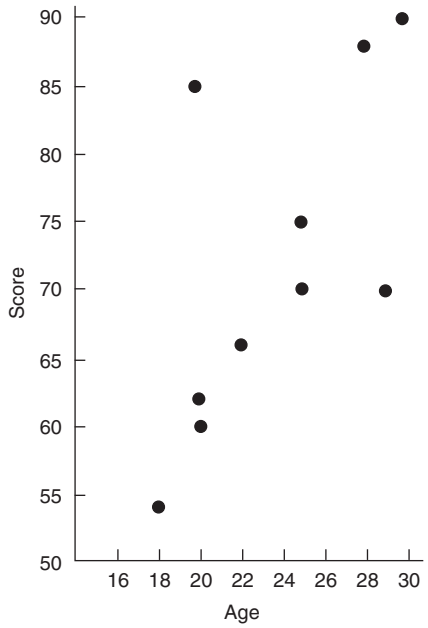

Figure 1-12.1. ***Distribution of test scores.***

Regression

Regression analysis consists of fitting a relationship, usually a linear relationship ($Y = aX + b$), to two random variables, X and Y. The term "regression" is left over from one of the findings in one of the earliest applications of the theory, where it was discovered that heights of parents are good predictors of heights of children but that heights of children tend to "regress" toward the mean. (In other words, for this problem, the best fit was $Y = a(X - \mu_x) + \mu_y$, where $a < 1$.)

Method of Least Squares

The method of least squares assumes that the best fit is obtained by minimizing the weighted sum of the squared differences between predicted and observed values of Y. In other words:

For two discrete random variables, X and Y, with joint probability distribution $f(x_i, y_j)$, choose a and b to minimize

$$\sum_{i=1}^{\infty} \sum_{j=1}^{\infty} (y_i - ax_i - b)^2 f(x_i, y_j)$$

For two continuous random variables, X and Y, with joint density function $f(x, y)$, choose a and b to minimize

$$\int_{-\infty}^{\infty} \int_{-\infty}^{\infty} (y - ax - b)^2 f(x, y)\, dx\, dy$$

For a sample of size n of pairs of values (x_i, y_i), choose a and b to minimize

$$\sum_{i=1}^{n} (y_i - ax_i - b)^2$$

The method of least squares is the best method if the deviations between observed and expected values of Y are themselves normally distributed, independent random variables. This condition would be satisfied, for example, in most experiments if the only source of deviation was error in reading a measuring device. The deviations are also called *residuals.*

Analysis of patterns in residuals can be done to confirm the normality assumptions cited above. Also, data points may be selected with extremely large residuals and studied for common characteristics as a means of trying to identify other factors that may be correlated to the outcomes, y. These results, in turn, may lead to a more sophisticated, multivariate regression analysis.

Regression Coefficients

The least-squares fit of a relationship of the form $Y = aX + B$ will be given by

$$a = \frac{\rho_{xy}\sigma_y}{\sigma_x}$$

$$b = \mu_y - a\mu_x$$

For a sample of size n of pairs (x_i, y_i), the formulas are

$$a = \frac{(n\sum_{i=1}^{n} x_i y_i) - [(\sum_{i=1}^{n} x_i)(\sum_{i=1}^{n} y_i)]}{(n\sum_{i-1}^{n} x_i^2) - [(\sum_{i=1}^{n} x_i)^2]}$$

$$b = \frac{[(\sum_{i=1}^{n} x_i^2)(\sum_{i=1}^{n} y_i)] - [(\sum_{i=1}^{n} x_i)(\sum_{i=1}^{n} x_i y_i)]}{(n\sum_{i=1}^{n} x_i^2) - [(\sum_{i=1}^{n} x_i)^2]}$$

EXAMPLE:

Reexamine the case of age versus test score examined earlier under the discussion of correlation. In that case, as noted, the correlation coefficient was 0.67, the mean age was 23.7, and the mean score was 72. The ratio of standard deviations can be calculated as 2.87. Therefore, a = 1.92 and b = 26.5. This means that the predicted score for age 20 would be 64.9, compared to the 60, 62, and 85 scored by persons of that age, while the predicted score for age 30 would be 84.1, compared to the 90 scored by the person of that age.

This regression line tends to overpredict scores for younger persons because the line is tipped as it tries to accommodate the 85 score achieved by one 20 year old. If that score had been a 60, then as noted the correlation coefficient would be 0.89; also, the mean score would be 69.5 and the ratio of standard deviations would be 2.78. Therefore, a would be 2.47 and b would be 11.0. The predicted score for age 20 would change from 64.9 to 60.4, and the predicted score for age 18 would change from 61.1 to 55.5, much closer to the score actually achieved by the 18 year old.

While it is theoretically possible to fit any relationship, not just a linear one, between X and Y, it is rarely possible to develop least-square formulas for a and b if the relationship is not linear. Accordingly, the analyst will usually want to try to transform problems into linear regression problems. For example, if the true relationship is believed to be of the form $y = c^{(x+d)}$, one would set up a linear regression of log y versus x. Then $d \log c = b$ and $\log c = a$.

Hypothesis Testing in Classical Statistical Inference

Hypothesis and Test

A statistical *hypothesis* is a well-defined statement about a probability distribution or, more frequently, one of its parameters. A classical *test* of a statistical hypothesis is based on the use of several concepts to organize the uncertainty inherent in any probabilistic situation.

The hypothesis being considered is called the *null hypothesis* and implies a probability distribution. Classical statistical inference asks whether the probability of having obtained the statistics actually collected, given the null hypothesis, is so low that the null hypothesis must be rejected.

The test works on the basis of a statistic computed from a sample. That statistic is compared to a reference value. If the statistic falls to one side of the reference value, then the null hypothesis is rejected; if the statistic falls to the other side, then the null hypothesis is not rejected.

For the reasons given above, a statistical test resolves doubts in favor of the null hypothesis. Therefore, an analyst may choose to say that the null hypothesis was "not rejected" rather than say it was "accepted." The analogy is to a criminal trial, which may find a defendant "not guilty" but does not make findings of "innocent."

A *Type I error* occurs when the null hypothesis is really true, but the test says that it should be rejected. A *Type II error* occurs when the null hypothesis is really false, but the test says it should not be rejected. (Informally, many analysts use the term *Type III error* to refer to analyses that set up the initial problem incorrectly, thereby producing results that, however precise, are irrelevant to the real issue.)

A *confidence coefficient*, or measure of the *degree of confidence*, is used to indicate the maximum acceptable probability of Type I error. In most cases, the null hypothesis corresponds to a single, well-defined probability distribution. Therefore, the probability of the sample statistic falling on the reject side of the reference value can be calculated precisely, and the reference value can be selected so as to set that probability equal to the confidence coefficient.

One way of using the confidence coefficient is to set *confidence limits* or define a confidence interval. These limits or internal boundaries are set so that if the null hypothesis is true, then the probability of obtaining a sample whose test statistic is outside the limits (or interval) is equal to the confidence coefficient. These confidence limits indicate to the user how precisely the probability distribution or its parameter can be defined, given the size of the sample and its variability.

The value of the confidence coefficient can be set at any of certain standard levels (90 percent, 95 percent, and 99 percent are often used), or it can be derived from an analysis that seeks to balance Type I and Type II errors. The latter approach is more comprehensive, but it is much more difficult because the alternative(s) to the null hypothesis rarely correspond(s) to a single probability distribution. In a typical case, the null hypothesis states a single value for a population parameter ($\mu = a$) and the alternative corresponds to all other values ($\mu \neq a$). Each specific alternative defines a specific probability distribution with a specific probability of Type II error. The *power function of the test* is that function which gives the probability of *not* committing a Type II error for each parameter value covered by the alternative(s) to the null hypothesis.

As the parameter value approaches the value in the null hypothesis (e.g., $\mu \rightarrow a$), the power of the test drops toward the confidence coefficient.

Test of Mean—z Test

If a sample has been collected from a population with known standard deviation σ, the central limit theorem indicates that the sample mean has an approximately normal distribution about the true population mean μ_0.

Let

$$z = (\sqrt{n})(\bar{x} - \mu_0)\sigma$$

where

n = sample size

μ_0 = hypothesized true value of μ

$\bar{x}$ = sample mean

Let z_α be the value for which $F(z_\alpha) = 1 - \alpha$, where F is the cumulative distribution function of a normal distribution with mean zero and variance one. (Note that $z_{1-\alpha} = -z_\alpha$.)

A *two-sided test* presumes that, if the true population mean is not μ_0, then it is equally likely to be greater than or less than μ_0. In that case, positive and negative values of z are treated the same and the confidence coefficient must be divided between the two sides of the confidence interval. Then if α is the confidence coefficient, the two-sided test says accept the null hypothesis if

$$-z_{\alpha/2} \leq z \leq z_{\alpha/2}$$

A *one-sided test* presumes that if the true population mean is not μ_0, then it must be greater than (or less than) μ_0. If α is the confidence coefficient, then the one-sided test says accept the null hypothesis if

$$z \geq -z_\alpha \quad \text{if the alternative to } \mu = \mu_0 \text{ is } \mu < \mu_0$$

or

$$z \leq z_\alpha \quad \text{if the alternative to } \mu = \mu_0 \text{ is } \mu > \mu_0$$

The value

$$\frac{\sigma}{\sqrt{n}}$$

is called the *standard error of the mean.*

Test of Difference between Two Means—z Test

If two samples from populations with known standard deviations, σ_1 and σ_2, have been collected, a null hypothesis might be that they are from the same population, which

means their means would be the same ($\mu_1 = \mu_2$). Then a two-sided test is applied, using the following statistic:

$$z = \frac{(\bar{x}_1 - \bar{x}_2)}{\sqrt{\sigma_1^2/n_1 + \sigma_2^2/n_2}}$$

where $\bar{x}_i$, σ_i^2, and n_i are the sample mean, population variance, and sample size, respectively, of the ith sample.

Test of Proportion—z Test

If a sample has been drawn from a population governed by a binominal distribution, then the normal approximation gives the following statistic, to be used in one- or two-sided tests

$$z = \frac{n(\bar{p} - p_0)}{\sqrt{p_0(1 - p_0)}}$$

where p_0 is the hypothesized true proportion and p is the sample proportion.

Test of Difference between Two Proportions—z Test

Again the normal approximation to the binomial distribution gives the test statistic

$$z = \frac{(\bar{p}_1 - \bar{p}_2)}{\sqrt{[\bar{p}_1(1 - \bar{p}_1)/n_1] + [\bar{p}_2(1 - \bar{p}_2)/n_2]}}$$

Test of Mean—t Test

The z tests assume known variance(s), so if variances are not known, a test based on Student's t distribution must be used. Let $t_{\alpha,m}$ be defined such that $F(t_{\alpha,m}) = 1 - \alpha$, where F is the cumulative distribution function for a Student's t distribution with m degrees of freedom. Note that $t_{(1-\alpha),m} = -t_{\alpha,m}$. Then

$$t = \frac{\sqrt{n}(\bar{x} - \mu_0)}{s}$$

where

n = sample size
μ_0 = hypothesized population mean
s = sample standard deviation

A two-sided test says accept the null hypothesis if

$$-t_{(\alpha/2),(n-1)} \leq t \leq t_{(\alpha/2),(n-1)}$$

Note that the number of degrees of freedom is one less than the sample size. An informal method of remembering this is that one degree of freedom is used to estimate the standard deviation.

A one-sided test says accept the null hypothesis if

$$t \geq -t_{\alpha,(n-1)} \quad \text{if the alternative to } \mu = \mu_0 \text{ is } \mu < \mu_0$$

or

$$t \leq -t_{\alpha,(n-1)} \quad \text{if the alternative to } \mu = \mu_0 \text{ is } \mu > \mu_0$$

A test of differences between two means is constructed analogously.

EXAMPLE:

This example will illustrate all the tests described thus far. Suppose there are two fire departments, each of which has given promotional tests to 100 fire fighters. Scores can range from 0 to 100, and the passing score is 70. The actual distributions of scores are shown in Table 1-12.2 and Figure 1-12.2.

Suppose that nationwide the standard deviation for this test is 17.45, the mean score is 50, and the proportion who pass is 0.17. Is Department A an average department? This suggests a two-sided test of the mean score, using the z test because the standard deviation is known. Let α be 0.05, so $z_{\alpha/2} = 1.96$. The z statistic for the test is

$$\frac{(\sqrt{100})(53.2 - 50)}{17.60} = 1.83$$

which is between -1.96 and $+1.96$, so the null hypothesis is accepted. Department A is average.

Table 1-12.2 ***Distribution of Test Scores***

Score	Number of Fire Fighters with That Score in Department A	Department B
10	0	5
20	6	5
30	5	10
40	20	20
50	29	25
60	20	20
70	9	10
80	5	3
90	3	2
100	3	0
Total	100	100
Sample mean	53.2	48.2
Sample standard deviation	17.54	17.34
Proportiion of sample passing	0.20	0.15

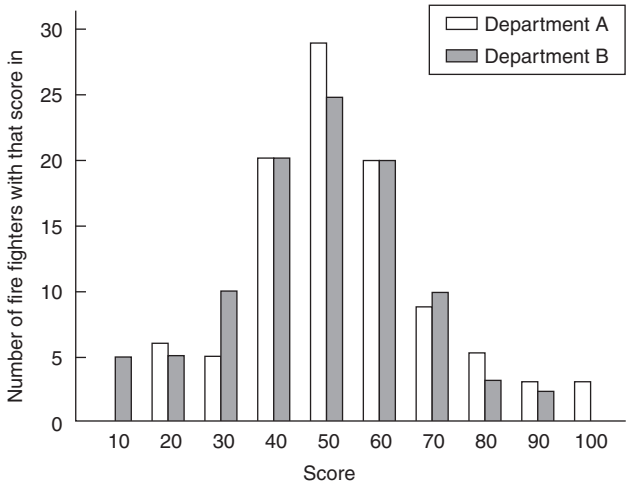

Figure 1-12.2. ***Distribution of test scores in two fire departments.***

Suppose it is asked instead whether Department A is a better-than-average department. This formulation suggests a one-sided test of the mean score, again using the z test because the standard deviation is known. Again, let $\alpha = 0.05$, so $Z_{\alpha/2} = 1.64$. The z statistic for the test is again 1.83, which is greater than 1.64, so we reject the null hypothesis and conclude that Department A is above average.

The results for these two tests seem contradictory because one concludes that Department A is average and the other concludes that Department A is above average. Such discrepancies are inherent to statistical tests. They can be sensitive to the choice of α. (If α were 0.10, both null hypotheses would be rejected, while if α were 0.01, both null hypotheses would be accepted. In either case, the two tests would give consistent results.) They can be sensitive to how the alternatives were posed, as was true here.

Suppose it is asked whether Departments A and B have significantly different mean scores. This formulation suggess a z test of the difference between two means. In this case the standard deviations are the same and the sample sizes are the same, so the z statistic reduces to

$$\frac{53.2 - 48.2}{\sqrt{2 \times 17.45/100}} = 8.46$$

The two-sided test reference value of 1.96, calculated earlier, is easily exceeded, and we conclude that the two departments do have statistically significant differences in their mean scores.

Suppose it is asked whether Department A's proportion of students passing (0.20) is statistically significantly greater than the overall average of 0.17. This formulation calls for a z test of a proportion, and the z statistic is

$$\frac{(\sqrt{100})(0.20) - 0.17}{\sqrt{(0.17)(0.83)}} = 0.80$$

This result is not statistically significant under either a one-sided or a two-sided test.

Are the proportions passing in Departments A and B different? This formulation suggests a z test of the difference between two proportions, and the z statistic is

$$\frac{0.20 - 0.15}{\sqrt{[(0.20)(0.80)/100] + [(0.15)(0.85)/100]}} = 0.93$$

Even though the average scores for Departments A and B were found to be different by a statistically significant margin, their percentage of test takers passing were not found to be significantly different.

Suppose the value of the overall standard deviation for the test was not known, or it was not known whether it applied to these departments, but it was known that the overall average score was 50. Is Department A's score significantly better? This formulation suggests a one-sided t test. The t statistic is

$$\frac{\sqrt{100}(53.2 - 50.0)}{17.54} = 1.82$$

For a one-sided t test with a 0.05 confidence level and 99 degrees of freedom, the reference value is the same as for a one-sided z test with a 0.05 confidence level, namely 1.64. Because the sample standard deviation is also nearly equal to the overall standard deviation used earlier, the test results are virtually the same, and the null hypothesis is rejected. This would not have been the case if the sample size had been considerably smaller, leading to a larger reference value. The smaller the difference you are examining, the larger the sample size required to be sure that difference is real and not just the result of random variation.

Test of Variance—Chi-Square Test

Assuming a normal population, one can test the hypothesis $\sigma = \sigma_0$ with the following:

$$\psi_2 = \frac{(n-1)s^2}{\sigma_0^2}$$

where n is the sample size and s^2 is the sample variance.

A two-sided test accepts the null hypothesis if

$$\psi^2_{(1-\alpha/2),(n-1)} \leq \psi^2 \leq \psi^2_{(\alpha/2),(n-1)}$$

where $\psi^2_{\alpha,m}$ is the value such that $F(\psi^2_{\alpha,m}) = 1 - \alpha$, where F is the cumulative distribution function of a chi square distribution with m degrees of freedom. Note that the degrees of freedom used in the test are one less than the sample size. One-sided tests can be constructed analogously.

Test of Goodness of Fit to a Distribution—Chi-Square Test

A special use of the test of variance is to test how well a set of experimental data fit a presumed theoretical probability distribution. Suppose the distribution in question is represented as a set of k values or ranges of values for the random variable. Let $p_i, \ldots, p_k$ be the hypothesized probabilities for those k values or ranges; let $p_i, \ldots, p_k$ be the sample estimates of those probabilities; and let n be the sample size. Then the statistic is

$$\psi^2 = \sum_{i=1}^{k} \left\{ \frac{[u(p_i, \overline{p}_i, n)]^2}{np_i} \right\}$$

where

$$u(p_i, \overline{p}_i, n) = \begin{Bmatrix} 0 & \text{if } -\frac{1}{2} \leq np_i - n\overline{p}_i \leq \frac{1}{2} \\ np_i - n\overline{p}_i - \frac{1}{2} & \text{if } np_i - n\overline{p}_i > \frac{1}{2} \\ n\overline{p}_i - np_i - \frac{1}{2} & \text{if } n\overline{p}_i - np_i > \frac{1}{2} \end{Bmatrix}$$

This process of reducing the gap between np_i and $n\overline{p}_i$ by ½ is called the *Yates continuity correction*, and it compensates for the fact that the chi-square distribution, a continuous function, is being used to approximate a discrete probability distribution. Also, to apply this test validly, one must make sure that the k classes are grouped sufficiently that $np_i \geq 5$ for all $i = 1, \ldots, k$.

The null hypothesis says this sample came from the distribution represented by $p_i, \ldots, p_k$. That hypothesis is accepted if

$$\psi^2 \leq \psi^2_{\alpha,j}$$

where j is at most $k - 1$ and may be less if the p_i are based in part on the sample.

For example, suppose an analyst wishes to test goodness of fit to a binomial distribution but has no prior estimate of which binomial distribution should be used. The analyst would select the particular binomial distribution that has p equal to the sample proportion. In that case one parameter has been estimated from the sample, and j would be reduced by one to $(k - 2)$. If the analyst were testing goodness of fit to a normal distribution and estimated both mean and variance from the sample, then j would drop by two to $(k - 3)$.

Contingency Test of Independence—Chi-Square Test

A special case of the goodness of fit test is a test of the hypothesis that two random variables are independent, in which case the goodness of fit test is displayed in a *contingency table,* as follows:

Let $X_1, \ldots, X_m$ be the m values or subranges of a random variable, X; and let $Y_1, \ldots, Y_k$ be the k values or subranges of a random variable, Y.

Let p_i be the estimated probability of X_i, for $i = 1, \ldots, m$, and let q_j be the estimated probability of Y_j, for $j = 1, \ldots, k$.

Let n be the size of a sample such that, for each sample entry, a value of X and a value of Y are provided. (Be sure $np_iq_j \geq 5$ for all i and j.)

Let r_{ij} be the number of sample entries for which $X = X_i$ and $Y = Y_j$.

Therefore

$$\sum_{i=1}^{m} \sum_{j=1}^{k} r_{ij} = n$$

Then the sample will provide estimated values of p_i and q_j as follows

$$p_i = \frac{\left(\sum_{j=i}^{k} r_{ij}\right)}{n}$$

and

$$q_j = \frac{\left(\sum_{i=i}^{m} r_{ij}\right)}{n}$$

If the two random variables are independent, then the expected values for r_{ij} are given by np_iq_j.

The test statistic, therefore, is given by

$$\psi^2 = \sum_{i=1}^{m} \sum_{j=1}^{k} \left\{ \frac{[u(r_{ij}, p_i, q_j, n)]^2}{np_iq_j} \right\}$$

where

$$u(r_{ij}, p_i, q_j, n) = \begin{Bmatrix} 0 & \text{if } -\frac{1}{2} \leq r_{ij} - np_iq_j \leq \frac{1}{2} \\ r_{ij} - np_iq_j - \frac{1}{2} & \text{if } r_{ij} - np_iq_j > \frac{1}{2} \\ np_iq_j - r_{ij} - \frac{1}{2} & \text{if } np_iq_j - r_{ij} > \frac{1}{2} \end{Bmatrix}$$

The null hypothesis of independence is accepted if

$$\psi^2 \leq \psi^2_{\alpha,[(m-1)(k-1)]}$$

The number of degrees of freedom comes from the formula given for goodness-of-fit tests. One begins with $mk - 1$ degrees of freedom. There are m values of p_i, but they sum to one, so only $m - 1$ need be estimated from the sample, and similarly $(k - 1)$ values of q_j must be estimated. Therefore the degrees of freedom for the test equal $(mk - 1) - (m - 1) - (k - 1) = (m - 1)(k - 1)$.

Nonparametric Tests

There are a large number of nonparametric tests, so called because they use no sample or population parameters and make no assumptions about the type of probability distribution that produced the sample.

Sampling Theory

A *random sample* is a sample chosen in accordance with a well-defined procedure that assures (a) each equal item (e.g., each person) has an equal chance of being selected; or (b) each value of a random variable (e.g., height) has a likelihood of being selected that is the same as its probability of occurrence in the full population. A sample that is selected with no conscious biases still may not be truly random; the burden of proof is on the procedure that claims to produce a random sample. A random sample may not be as representative as a sample that is chosen to be representative, but a sample chosen to be representative on a few characteristics may not be random and may not be representative with respect to other important characteristics.

In addition to requiring that each item have an equal chance of being selected, a random sample must assure that every combination of items also has an equal chance of being selected. For example, a random sample of currently married couples would not be a random sample of currently married persons, because spouses would be either selected or not selected together in the former but not necessarily in the latter.

A *sampling frame* is a basis for reaching any member of a population for sampling in a way that preserves the randomness of selection. An example would be a mailing list, although if it had missing names or duplicate names it would be deficient as a sampling frame, because each equally likely name would not have an equal chance at selection. A *sample design* is a procedure for drawing a sample from a sampling frame so that the desired randomness properties are achieved.

A *simple random sample* is a sample that is drawn by a procedure assuming complete randomness from a population all of whose elements are equally likely. If they are not all equally likely, a procedure that assures complete randomness is called a *probability sample.*

A *stratified random sample* is a sample that achieves greater precision than a simple random sample by taking advantage of existing knowledge about the variance structure of subpopulations. By concentrating a dispro-

portionate share of the sample in subpopulations that account for disproportionate shares of the total variance, a stratified random sample produces lower total variance for a given sample size. The annual National Fire Protection Association survey of fire departments that produces the annual estimates of total U.S. fire loss is a stratified random sample.

A *cluster sample* is a sample that randomly selects certain subpopulations, then samples only them. This approach often involves subpopulations that consist of geographical areas, in which case it is also called an *area sample.* The purpose of cluster sampling is to hold down the cost of sampling. It is not as statistically acceptable as a simple or stratified random sample.

A *systematic sample* begins with a listing of the population, then random selection of the first sample member, and finally selection of the remaining members at fixed intervals (e.g., every *k*th name on the list). This approach is simpler than true random sampling but not as acceptable.

A *representative sample* is one chosen to guarantee representation from each of several groups. If properly designed, it is a special case of stratified random sampling, but often the term is used for samples where the need for representation is the only part of the procedure specified. If the size of the representation is also specified, it is called a *quota sample.* The statistical properties of a sample constructed in this way cannot be determined, and nothing useful can be said about its accuracy or precision. That is also true of a *judgment sample,* in which the only rules governing sample selection are the statistician's judgments.

Characterization of Data from Experimentation or Modeling

Data Variability

Any data source is subject to variability for reasons other than those with substantive importance. Results of a test of burning behavior of a material may vary because of the ambient temperature or humidity. Such variation can be virtually eliminated through careful experimental controls. Results may vary because of naturally occurring variations in the composition of the material or human variability in the production process. Such variation can be reduced through careful controls, and it may be possible to measure the variation that cannot be eliminated. Test results may vary because of moment-to-moment variations in air flow or in the heat output of the heating apparatus or in many other physical conditions and characteristics. Such variation can be reduced through careful controls, but residual variation may be difficult or impossible to measure. And because test results may vary as a result of standardization and care, or the lack thereof, it is also true that test results may vary with the laboratories, organizations, and people conducting the tests.

Interpretation of test results—or of modeling results based on input test data—must take account of data variability from causes other than those of interest. Such variability is often called "error" in statistical terminology, where the term "error" is used to refer to all deviations between predicted and actual results, not just to deviations involving improper human behavior. Standards for test methods typically have sections for what is called *precision* and *bias* information. Precision refers to the magnitude of error. Bias refers to the symmetry of error. Precision asks, "Are large differences possible even if there is no difference in the characteristics we intended to test for?" Bias asks, "Are we more likely to err in one direction than in another?"

Precision and bias sections are often lacking in test method documentation—or at least lacking in detail. For laboratory testing the principal source of precision and bias information is interlaboratory studies. Through reported experiments at each of several laboratories under what are intended to be identical testing conditions, one can quantify the magnitude of variation from one run to the next in a single laboratory (called *repeatability*) and of variation between laboratories (called *reproduceability*).

There are standard statistical methods for assessing such variation, but the work is expensive, which accounts for the scarcity of such data. Also, the results, when published, are attached to a test method but may show more precision than a user will obtain in another application (e.g., different material) or in a laboratory without the heightened attention to precise controls that one expects in an interlaboratory evaluation. (No laboratory wishes to be found less precise, or less capable generally, than its competitors, but in most day-to-day work, there is no expectation of such calibration of performance, and people may relax.)

One might think that inherently statistical databases—such as fire incident databases—would be easier to assess, and it is true that precision can be readily calculated based on sample size. However, bias depends on the adequacy of the sampling—is the sample truly random and so representative of its universe?—and most statistical databases are not truly random. The National Fire Incident Reporting System (NFIRS) captures nearly a million fire incidents a year, typically close to half the total fires reported to fire departments. The precision of NFIRS is outstanding, on that basis. However, national estimates of specific fire problems project and calibrate NFIRS using a smaller database, the NFPA annual fire experience survey, and so reflect that smaller database's lesser (though still excellent) precision. More importantly, NFIRS is not a true random sample (although the NFPA survey is), and so its bias cannot be calculated from any standard statistical methods. Instead, NFIRS users note the large share of total fires it represents and the absence of any obvious sources of significant bias. (For example, NFIRS is believed to be less represented in rural or large urban areas but is well represented in both.)

In the end, engineering analysis must consider and address data variability issues but typically cannot hope to fully quantify or resolve them.

Testing Models for Goodness of Fit

Earlier in this chapter, the use of the chi-square test to assess goodness of fit was described for a statistical distribution. The same method can be used to assess goodness of fit between any set of model predictions and laboratory

data. In essence, this statistical test assumes that each laboratory data point is equally likely. If there are n data points, then the test is based on

$$\psi^2 = \sum_{i=1}^{n} \frac{(x_{i,\,\text{measured}} - x_{i,\,\text{predicted}})^2}{x_{i,\,\text{predicted}}}$$

This method is a one-sided test using $n - 1 - k$ degrees of freedom, where k is equal to the number of model parameters estimated from the data. (The more the data is used indirectly to predict itself, the less variation one would expect to see.)

The more common practice in assessing goodness of fit is to "eyeball" the two curves, that is, be guided by an impression of proximity. This can be highly misleading. The eye tends to measure distances between two curves as the shortest distance between the curves, whereas accuracy of prediction is based on differences in predicted versus actual y-axis values for given x-axis values. These differences can be very large between two curves with steep slopes that look close together, and steep slopes are commonplace in curves for variables that describe fire development and related environmental conditions.

On the other hand, sometimes the most relevant and appropriate measures of the correspondence between two curves lies in the correspondence between key summary measures and not in the exactness of the correspondence between the full curves. For example, the timing of the transition from smoldering to free burning is not well described by any model and is subject to enormous variability. However, this should not be allowed to obscure the agreement of model with empirical data during the free-burning stage.

One way to adjust the comparison so that it excludes the smoldering phase is through recalibration of the curve. Set the timing and fire conditions at the onset of free burning for the model equal to the timing and fire conditions from the lab data. Then, use formal statistical methods to assess how well the model predicts the data from that point on. Note, however, that the steepness of the curves makes it quite possible that calculated agreement will be poor even with this adjustment.

Another way to adjust the comparison is to compare the timing of transition points (also called *inflection points* in calculus), such as time from the onset of free burning to flashover; and appropriate maximums (e.g., peak heat release rate) and minimums (e.g., oxygen concentration). The problem with this approach is that there may not be simple statistical tests, such as the chi-square test for goodness of fit of whole curves, that will indicate how much difference in timing of transition points or in other summary measures can be expected statistically due to measurement error or other normal variability and how much difference is significant. There needs to be an extended dialogue between fire protection engineers and statisticians to determine which statistical bases for evaluating goodness of fit of models to empirical data are both executable as statistical tests and meaningful to the modelers.

Propagation of Uncertainty

The procedures just described form a basis for describing the readily quantifiable uncertainty associated with input data and modeling components for engineering analysis. Additional statistical procedures are needed to calculate how these component uncertainties translate into a combined measure of error or uncertainty in the output data. This is typically called *propagation of uncertainties* because the procedures measure how uncertainty at the early steps of the calculation is propagated—modified or passed through—the later steps of the calculation to affect the final result.

There is no general guidance possible for these procedures because they are highly dependent upon the functional forms and mathematical relationships linking the uncertain variables. The only practical guidance is cautionary. The step of propagating uncertainties and estimating cumulative uncertainty is a necessary step that is almost never performed in fire protection engineering analysis. A reasonable expectation is that uncertainties will accumulate, producing more uncertainty in the output data than in any of the components along the way, but uncertainties are rarely additive, even if the underlying variables are combined linearly, and it is possible for uncertainties to be reduced in the propagation analysis, due to interdependencies or mathematical transformations implied by the models, rather than to cumulate.

The issue of uncertainty propagation is another area where much more dialogue is needed between fire protection engineers and statisticians to identify or develop statistical assessment procedures that are soundly based and practical for routine use.

Fire Dynamics

Section 2 Fire Dynamics

CHAPTER 1

Fire Plumes, Flame Height, and Air Entrainment

Gunnar Heskestad

Introduction

Practically all fires go through an important, initial stage in which a coherent, buoyant gas stream rises above a localized volume undergoing combustion into surrounding space of essentially uncontaminated air. This stage begins at ignition, continues through a possible smoldering interval, into a flaming interval, and may be said to end prior to flashover. The buoyant gas stream is generally turbulent, except when the fire source is very small. The buoyant flow, including any flames, is referred to as a fire plume.

Combustion may be the result of pyrolysis of solid materials or evaporation of liquids because of heat feedback from the combustion volume, or of pressurized release of flammable gas. Other combustion situations may involve discharge of liquid sprays and aerosols, both liquid and solid, but these will not be discussed here. In the case of high-pressure releases, the momentum of the release may be important. Flames in these situations are usually referred to as *diffusion flames,* being the result of combustible vapor or gas mixing or diffusing into an ambient oxidant, usually air, as opposed to being premixed with an oxidant.

The properties of fire plumes are important in dealing with problems related to fire detection, fire heating of building structures, smoke filling rates, fire venting, and so forth. They can also be important in fire suppression system design.

This chapter deals with axisymmetric, turbulent fire plumes and reviews some relations for predicting the properties of such plumes. It is assumed throughout the chapter that the surrounding air is uncontaminated by fire products and that it is uniform in temperature, except where specifically treated as temperature stratified. Release of gas from a pressurized source is assumed to be vertical. The relations cease to be valid at elevations where the plume enters a smoke layer.

Main topics are flame heights, plume temperatures and velocities, virtual origin, air entrainment, and effects of ambient temperature stratifications. At the end of the chapter, a few additional aspects of diffusion flames are touched on briefly, including flame pulsations, wall/corner effects, and wind effects.

Dr. Gunnar Heskestad is principal research scientist at Factory Mutual Research, specializing in fluid mechanics and heat transfer of fire, with applications to fire protection.

Fire Plume Features

Figure 2-1.1 shows a schematic representation of a turbulent fire plume originating at a flaming source, which may be solid or liquid. Volatiles driven off from the combustible, by heat fed back from the fire mix with the surrounding air and form a diffusion flame. Laboratory simulations often employ controlled release of flammable gas through a horizontal, porous surface. The mean height of the flame is *L.* Surrounding the flame and extending upward is a boundary (broken lines) that confines the entire buoyant flow of combustion products and entrained air. The air is entrained across this boundary, which instantaneously is very sharp, highly convoluted, and easily discernible in smoky fires. The flow profile could be the time-averaged temperature rise above the ambient

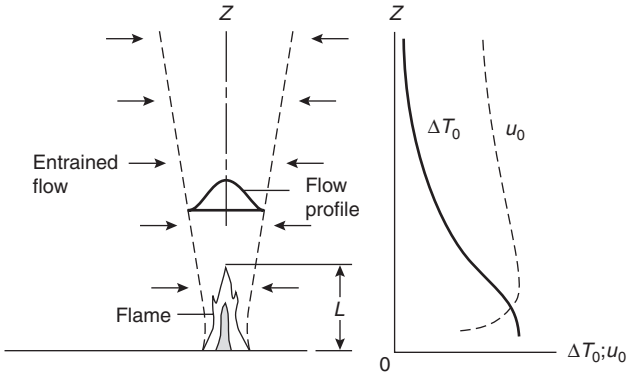

Figure 2-1.1. ***Features of a turbulent fire plume, including axial variations on the centerline of mean excess temperature, ΔT_0, and mean velocity, u_0.[34]***

temperature, or the concentration of a gas (such as CO_2) generated by the fire, or the axial velocity in the fire plume.

Figure 2-1.1 suggests qualitatively, based on experimental observations,[1–5] how the temperature rise on the centerline, ΔT_0, and the velocity on the centerline, u_0, might behave along the plume axis. In this example of a relatively tall flame, the temperatures are nearly constant in the lower portion of the flame. Temperatures begin to decay in the intermittent, upper portion of the flame as the combustion reactions trail off and air entrained from the surroundings cools the flow. The centerline velocities, u_0, tend to have their maxima slightly below the mean flame height and always decay toward higher elevations. If the combustible is porous and supports internal combustion, there may not be as pronounced a falloff in the gas velocity toward the top of the combustible, as suggested in Figure 2-1.1.[3]

The total heat release rate of a fire source, $\dot{Q}$, is either convected, $\dot{Q}_c$, or radiated, $\dot{Q}_r$, away from the combustion region. In a fire deep in a porous combustible pile (e.g., a stack of wood pallets), some of the total heat generated is trapped by and stored in the not yet burning material; the rest escapes from the combustible array as either convective or radiative energy flux. If most of the volatiles released undergo combustion above the fuel array, as in pool fires of liquids and other horizontal-surface fires, and even in well-developed porous pile fires, then the convective fraction of the total heat release rate is rarely measured at less than 60 to 70 percent of the total heat release rate.[6,7] The convective flux, $\dot{Q}_c$, is carried away by the plume above the flames, while the remainder of the total heat liberated, $\dot{Q}_r$, is radiated away in all directions.

The total heat release rate, $\dot{Q}$, is often assumed to be equal to the *theoretical* heat release rate, which is based on complete combustion of the burning material. The theoretical heat release rate in kW is evaluated as the mass burning rate in kg/s multiplied by the lower heat of complete combustion in kJ/kg. The ratio of the total heat release rate to the theoretical heat release rate, which is the combustion efficiency, is indeed close to unity for some fire sources (e.g., methanol and heptane pools),[6] but may deviate significantly from unity for others (e.g., a polystyrene fire, for which the combustion efficiency is about 45 percent,[7] and a fully involved stack of wood pallets, for which the combustion efficiency is 63 percent[6]).

Calculation Methods

Flame Heights

The visible flames above a fire source contain the combustion reactions. Tamanini[8] has investigated the manner in which combustion approaches completion with respect to height in diffusion flames.

Typically, the luminosity of the lower part of the flaming region appears fairly steady, while the upper part appears to be intermittent. Sometimes vortex structures, more or less pronounced, can be observed to form near the base of the flame and shed upward.[9,10]

Figure 2-1.2 helps to define the mean flame height, L.[10] It shows schematically the variation of flame intermittency, I, versus distance above the fire source, z, where $I(z)$ is defined as the fraction of time that at least part of the flame lies above the elevation, z. The intermittency decreases from unity deep in the flame to smaller values in the intermittent flame region, eventually reaching zero. The mean flame height, L, is the distance above the fire source where the intermittency has declined to 0.5. Objective determinations of mean flame height according to intermittency measurements are fairly consistent with (although tending to be slightly lower than) flame heights that are averaged by the human eye.[10]

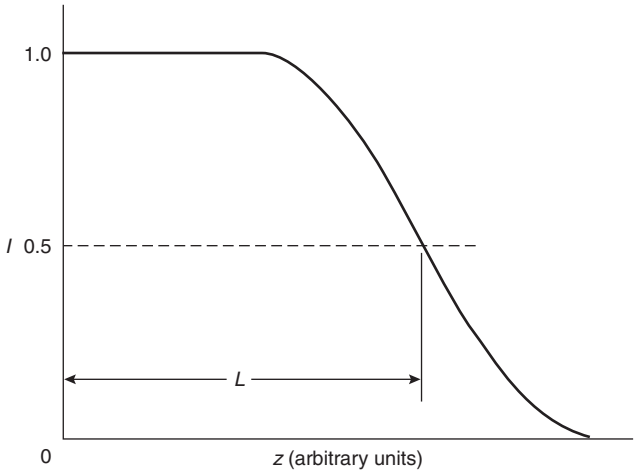

Figure 2-1.2. ***Definition by Zukoski et al.[10] of mean flame height, L, from measurements of intermittency, I.***

The mean flame height is an important quantity that marks the level where the combustion reactions are essentially complete and the inert plume can be considered to begin. Several expressions for mean flame height have been proposed. Figure 2-1.3, taken from McCaffrey,[11] shows normalized flame heights, L/D, as a function of a Froude number, $\dot{Q}^*$ (represented as $\dot{Q}^{*2/5}$ to compress the horizontal scale), from data correlations available in the literature. This Froude number is defined

$$\dot{Q}^* = \frac{\dot{Q}}{\rho_\infty c_p T_\infty \sqrt{gD} D^2} \tag{1}$$

where

$\dot{Q}$ = total heat release rate (given in terms of the mass burning rate, $\dot{m}_f$, as $\dot{m}_f H_c$)

ρ_∞ and T_∞ = ambient density and temperature, respectively

c_p = specific heat of air at constant pressure

g = acceleration of gravity

D = diameter of the fire source

Quoting McCaffrey with respect to this figure: "On the left are pool-configured fires with flame heights of the same order of magnitude as the base dimension D. In the middle is the intermediate regime where all flames are similar and the $\dot{Q}^{2/5}$ is seen as a 45-degree line in the figure. Finally, in the upper right is the high Froude number, high-momentum jet flame regime where flame height ceases to vary with fuel flow rate and is several hundred times the size of the source diameter."

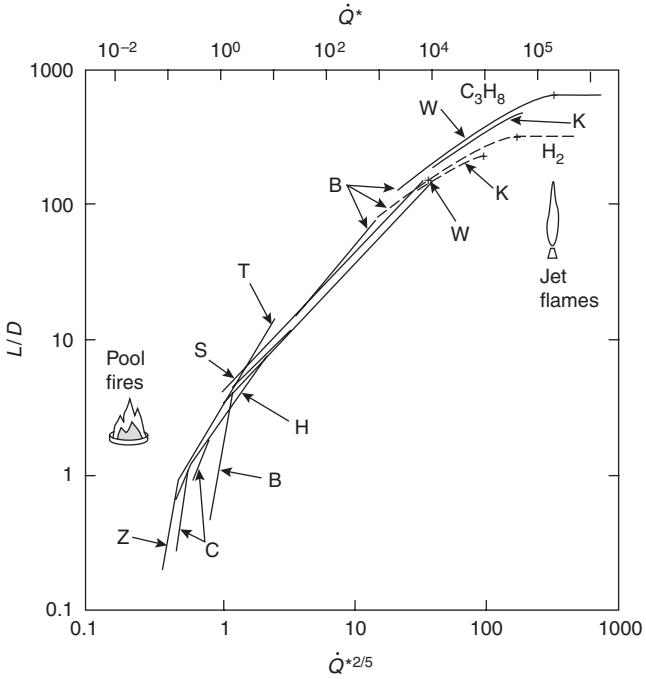

Figure 2-1.3. ***Flame height correlations compiled by McCaffrey.[11] Capital letters without subscripts correspond to various researchers as follows: B = Becker and Liang,[12] C = Cox and Chitty,[13] H = Heskestad,[14] K = Kalghatgi,[15] S = Steward,[16] T = Thomas,[17] W = Hawthorne et al.,[18] and Z = Zukoski.[19] Capital letters with subscripts represent chemical formulae.***

Buoyancy regime: The correlation by Heskestad (*H*) represented in Figure 2-1.3 covers the entire $\dot{Q}^*$ range except the momentum regime and has the following form given by McCaffrey:[11]

$$\frac{L}{D} = -1.02 + 3.7\dot{Q}^{*2/5} \tag{2}$$

Actually, this correlation was originally presented in the form:[14]

$$\frac{L}{D} = -1.02 + 15.6N^{1/5} \tag{3}$$

As before, D is the diameter of the fire source (or effective diameter for noncircular fire sources such that $\pi D^2/4$ = area of fire source) and N is the nondimensional parameter defined by

$$N = \left[\frac{c_pT_\infty}{g\rho_\infty^2(H_c/r)^3}\right]\frac{\dot{Q}^2}{D^5} \tag{4}$$

where H_c is the actual lower heat of combustion and r is the actual mass stoichiometric ratio of air to volatiles.

It is readily shown that N and $\dot{Q}^*$ are related as follows:

$$N = \left(\frac{c_pT_\infty}{H_c/r}\right)^3\dot{Q}^{*2} \tag{5}$$

This equation, combined with Equation 3, leads to Equation 2 when typical values are substituted for the environmental and fuel variables.

The parameter N was derived specifically by consideration of the flaming region,[14] whereas $\dot{Q}^*$ was originally derived by Zukoski[20] from analysis of the nonreacting turbulent plume. In a recent paper, Heskestad[21] presented results of flame height measurements at widely varying ambient temperatures. The parameter $\dot{Q}^*$ did not account correctly for the observed variations in flame height (increasing flame height with increasing ambient temperature), while the parameter N did. For that reason, N is considered the more appropriate scaling parameter.

Equation 3 is based on liquid pool fires, other horizontal-surface fires, and jet flames (but excluding high momentum jet discharge corresponding to values N well beyond 10^5). Subsequent to its derivation, the equation was found also to represent large, deep storages when the flames extended above the storage and flame heights were measured above the base of the fire (bottom of storage in the experiments).[22] The storages investigated included 4.5-m-high palletized storage of different commodities, 3 to 6 m high rack storage of two different commodities, and wood pallets stacked 0.3 to 3.3 m high. In these cases the fire diameter was calculated as the diameter of a fire area equal to the ratio of heat release rate to heat release rate per unit area.

A convenient form of Equation 3 can be developed. Let

$$A = 15.6\left[\frac{c_pT_\infty}{g\rho_\infty^2(H_c/r)^3}\right]^{1/5} \tag{6}$$

Then Equation 3 can be written in the dimensional form

$$L = -1.02D + A\dot{Q}^{2/5} \tag{7}$$

The coefficient, A, varies over a rather narrow range, associated with the fact that H_c/r, the heat liberated per unit mass of air entering the combustion reactions, does not vary appreciably among various combustibles. For a large number of gaseous and liquid fuels, H_c/r remains within the range of 2900 to 3200 kJ/kg, for which the associated range of A under normal atmospheric conditions (293 K, 760 mmHg) is 0.240 to 0.226 (m $kW^{-2/5}$), with a typical value of $A = 0.235$. Hence, under normal atmospheric conditions

$$L = -1.02D + 0.235\dot{Q}^{2/5} \tag{8}$$

(L and D in m; $\dot{Q}$ in kW).

Fairly common fuels that deviate significantly from the cited range 0.240 to 0.226 for A include acetylene, hydrogen (0.211), and gasoline (0.200). In general, the coefficient $A = 0.235$ in Equation 8 may be considered adequate unless actual values of H_c and r are known that indicate otherwise, and/or atmospheric conditions deviate significantly from normal.

Referring to any of the flame-height relations in Equations 3, 7, and 8, it can be seen that negative flame heights are calculated for sufficiently small values of the heat release rate. Of course, this situation is unphysical and the correlation is not valid here. For pool fires, there are indications that a single flaming area breaks down

into several zones when heat release rates decrease to the point where negative flame height (L) is calculated.[23]

EXAMPLE 1:

Consider a 1.5-m-diameter pan fire of methyl alcohol with a heat release intensity of 500 kW/m^2 of surface area. Normal atmospheric conditions prevail (760 mm Hg, 293 K). Calculate the mean flame height.

SOLUTION:

Available values of the lower heat of combustion (H_c = 21,100 kJ/kg) and stoichiometric ratio (r = 6.48) give H_c/r = 3260 kJ/kg. With this value for H_c/r substituted in Equation 6, together with c_p = 1.00 kJ/kg K, T_∞ = 293 K, g = 9.81 m/s^2 and ρ_∞ = 1.20 kg/m^3, the coefficient A is calculated as 0.223 (m kW$^{-2/5}$). The total heat release rate is $\dot{Q} = 500\pi 1.5^2/4 = 884$ kW. Equation 7 gives a mean flame height of $L = -1.02 \cdot 1.5 + 0.223 \cdot 884^{2/5} = 1.83$ m.

EXAMPLE 2:

This example is similar to Example 1, except for new atmospheric conditions representative of Denver, Colorado, on a hot day: 630 mm Hg pressure and 310 K temperature.

SOLUTION:

Using Equation 6, the new coefficient, A, increases from 0.223 to 0.249 [most readily calculated from $(310/293)^{3/5}$ $(760/630)^{2/5}$ 0.223 = 0.249, where the equation of state for a perfect gas has been used]. Using Equation 7, the new flame height is L = 2.23 m, increased from 1.83 m for normal atmospheric conditions.

Example 3:

One 1.2-m high stack of wood pallets (1.07 × 1.07 m) burns at a total heat release rate of 2600 kW under normal atmospheric conditions. Calculate the mean flame height above the base of the pallet stack.

SOLUTION:

The square flaming area can be converted to an equivalent diameter: $\pi D^2/4 = 1.07^2$, which gives the equivalent diameter, D, of 1.21 m. Since the combustion efficiency of wood is considerably less than 100 percent, it is difficult to select reliable and consistent values for H_c and r to form the ratio H_c/r. Instead, it can be assumed that A = 0.235, the typical value. Using Equation 7, the mean flame height above the base of the pallet stack is calculated as $L = -1.02 \cdot 1.21 + 0.235 \cdot 2600^{2/5} = 4.22$ m.

Momentum regime: In Figure 2-1.3 it is seen that at high values of $\dot{Q}^*$ the normalized flame heights begin to level off and eventually attain constant values, but not at the same value of $\dot{Q}^*$ and not at the same normalized flame height.

Flame heights of vertical turbulent jet flames have been studied by a number of investigators reviewed by Blake and McDonald,[24,25] who proposed a new correlation of normalized flame heights versus a "density-weighted Froude number." Although an improvement over previous work, the correlation still exhibits significant scatter. At about the same time, Delichatsios[26] proposed an alternative approach. Previously, other authors had proposed flame height relations, including Becker and coworkers,[12,27] and Peters and Göttgens.[28] More recently, Heskestad[29] also considered the high-momentum regime, especially with respect to defining an unambiguous transition to momentum control and flame heights in this regime.

Heskestad's work[29] was based on an extension of the author's correlation for buoyancy-controlled turbulent diffusion flames. A momentum parameter is defined, R_M, which is the ratio of gas release momentum to the momentum generated by a purely buoyant diffusion flame:

$$R_M = 1.36\left[\left(\frac{T_\infty}{T_L}\right)\left(\frac{c_p \Delta T_L}{(H_c/r)}\right)^{4/5}\right]\left(\frac{\rho_\infty/\rho_s}{r^2}\right)N^{2/5} \qquad (9)$$

Here, T_L and ΔT_L are the plume centerline temperature and excess temperature (above ambient), respectively, at the mean flame height of purely buoyant diffusion flames, and ρ_s is the density of the source gas in the discharge stream. A value of 500 K is assigned[29] to ΔT_L. Note that the first two sets of parentheses are nearly constant for normal ambient temperatures and fuels with comparable values of (H_c/r). Under these circumstances, the momentum parameter is closely linked to the parameter N, but is affected quite significantly by the source gas density at the discharge conditions as well as the mass stoichiometric ratio. If the gas discharge is sonic or choked, the density of the source gas can be considerably higher than is the case at atmospheric pressure.

Figure 2-1.4 presents flame heights of jet diffusion flames in the form L/L_B versus R_M, where L is the flame height reported by various investigators and L_B is the buoyancy-controlled flame height according to Equation 3. The data scatter about a value L/L_B = 1.2, approximately, for $R_M < 0.1$. At higher values of R_M, the flame height ratio approaches an asymptotic slope of –1/2, indicated by a dashed line. The associated values of N are so large that we can take $L_B/D \propto N^{1/5}$ (see Equation 3), which together with Equation 9 imply that L/D is constant when the slope

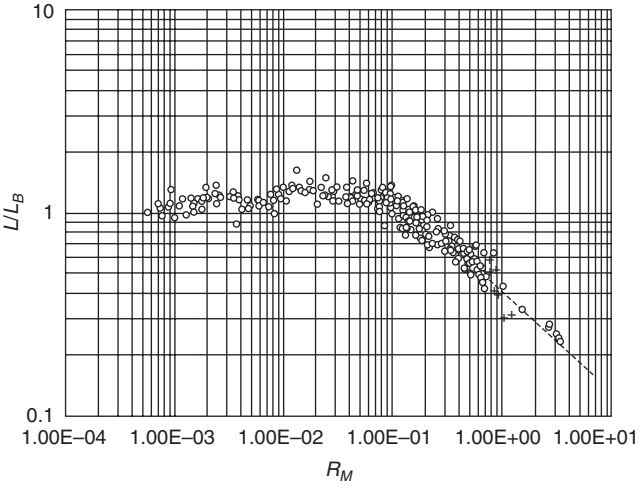

Figure 2-1.4. ***Data on flame heights of turbulent jet diffusion flames in ratio to the corresponding buoyancy-controlled flame heights, plotted versus the ratio of gas release momentum to buoyancy momentum (from Reference 29). Data plotted as + pertain to choked discharge of hydrogen.***

is equal to –1/2 (for constant source gas and discharge density). Constant slope and constant L/D (for a given gas and density) appear to be achieved reasonably quickly above $R_M = 0.1$.

The fact that the low-R_M flame height ratios in Figure 2-1.4 tend to scatter about a level higher than unity has been attributed to several possible factors.[29] One of the two most important may be the working definition of mean flame height employed by some investigators, producing greater values than the 50 percent flame-intermittency height. Another may be retinal retention of flame images in visual averaging of rapidly pulsating flames (typical of the scales of the experiments), tending to make an observer exaggerate the mean flame height.

Above $R_M = 0.1$, adopting the dashed line in Figure 2-1.4 as representative of the momentum regime, the normalized flame height is

$$\frac{L_M}{D} = \left[5.42\left(\frac{T_m}{T_\infty}\right)^{1/2}\left(\frac{H_c/r}{c_p\Delta T_m}\right)^{2/5}\right]\left(\frac{\rho_s}{\rho_\infty}\right)^{1/2} r \qquad (10)$$

where L_M is the flame height in the momentum regime. For $H_c/r = 3100$ kJ/kg (many common gases), $\Delta T_m = 500$ K, and $T_\infty = 293$ K, Equation 10 becomes

$$\frac{L_M}{D} = 18.5\left(\frac{\rho_s}{\rho_\infty}\right)^{1/2} r \qquad (11)$$

In this case the nondimensional flame height in the momentum regime depends in a simple manner on the mass stoichiometric ratio and the source gas density at discharge.

It should be pointed out that the transition to the momentum regime, $R_M = 0.1$, and the flame height in the momentum regime, Equations 10 and 11, differ significantly from previously proposed relations, as discussed in Reference 29.

EXAMPLE 4:

Calculate the normalized height of a hydrogen jet flame from a 5-mm diameter nozzle connected to a reservoir (tank, pipe, etc.) at ambient temperature of 293 K and a pressure above ambient of either (a) 150 kPa or (b) 300 kPa.

SOLUTION:

(a) The ratio of ambient pressure (101 kPa) to the reservoir pressure (150 kPa) is 0.673, corresponding to subsonic discharge (sonic discharge occurs at a pressure ratio of 0.528, as for air). The mass flow of hydrogen from the nozzle is calculated with the aid of a compressible flow formula (e.g., Shapiro[30]) as 1.74 g/s, using a ratio of specific heats $k = 1.4$ (as for air). Based on a heat of combustion of 120,000 kJ/kg, the heat release rate is $\dot{Q} = 209$ kW. The source gas density in the discharge stream, ρ_s, is calculated from the source gas density at ambient temperature and pressure, $\rho_{s\infty}$, as follows: $\rho_s = (\rho_s/\rho_{s\infty})\rho_{s\infty} = (\rho_s/\rho_{s0})(\rho_{s0}/\rho_{s\infty})\rho_{s\infty}$, where ρ_{s0} is the source gas density in the gas reservoir. The density ratios can be expressed in terms of pressure ratios, with the result: $\rho_s = (p_s/p_{s0})^{1/k}(p_{s0}/p_\infty)\rho_{s\infty}$, where p_s is the pressure in the discharge stream (ambient pressure for subsonic discharge) and p_{s0} is the pressure of the gas reservoir. Finally we obtain $\rho_s = (101/150)^{1/1.4}(150/101)\rho_{s\infty} = 1.12 \times 0.083 = 0.093$ kg/m^3, where 0.083 (kg/m^3) is the density of hydrogen at ambient temperature and pressure. Now the momentum parameter can be calculated from Equation 9, taking $\Delta T_L = 500$ K, $H_c = 120{,}000$ kJ/kg, $r = 34.3$, and $\rho_s = 0.093$ kg/m^3, yielding $R_M = 1.16 \times 10^{-3}N^{2/5}$. The parameter N is calculated from Equation 4, with the result $N = 6.76 \times 10^6$, which results in $R_M = 0.62$ and places the flame in the momentum regime. The normalized flame height is calculated from Equation 10 as $L_M/D = 185$. NOTE: The calculated height may include the visual-averaging bias toward somewhat higher than actual values built into the data base.

(b) The ratio of ambient pressure (101 kPa) to reservoir pressure (300 kPa) is 0.337, corresponding to sonic, or choked discharge. The mass flow of hydrogen from the nozzle is calculated with the aid of an appropriate compressible flow formula for choked discharge (e.g. Shapiro[30]) as 3.65 g/s, corresponding to a heat release rate of 436 kW. The source gas density for choked flow is calculated as in (a), except the ratio (p_s/p_{s0}) is set equal to the value for a Mach number of unity, 0.528, that is, $\rho_s = 0.528^{1/k}(p_{s0}/p_\infty) \times 0.083 = 0.634(300/101) \times 0.083 = 0.156$ kg/m^3. The parameter N is calculated from Equation 4 as 2.94×10^7 and the momentum parameter from Equation 9 as $R_M = 6.93 \times 10^{-4}N^{2/5} = 0.67$, indicating the flame is in the momentum regime as in (a). The normalized flame height is calculated from Equation 10 as $L_M/D = 239$, somewhat higher than for the lower discharge pressure in (a).

NOTE: If the nozzles of cases (a) and (b) are sharp-edged holes or openings instead, it is recommended that the source diameter be multiplied by (discharge coefficient)$^{1/2}$; see, for example, Shapiro[30] for values of the discharge coefficient of sharp-edged orifices in compressible flow (varying from 0.60 near incompressible flow conditions to 0.77 for choked flow).

Plume Temperatures and Velocities

The first plume theories assumed

1. A point source of buoyancy
2. That variations of density in the field of motion are small compared to the ambient density
3. That the air entrainment velocity at the edge of the plume is proportional to the local vertical plume velocity, and
4. That the profiles of vertical velocity and buoyancy force in horizontal sections are of similar form at all heights

Morton et al.[31] developed an integral formulation on the further assumption that the profiles are uniform "top hat" profiles. The mean motion is then governed by the following three conservation equations for continuity, momentum, and buoyancy:

Continuity $$\frac{d}{dz}(b^2u) = 2\alpha bu \qquad (12)$$

Momentum $$\frac{d}{dz}(b^2u^2) = b^2g\frac{\rho_\infty - \rho}{\rho_\infty} \qquad (13)$$

Buoyancy $$\frac{d}{dz}\left(b^2ug\frac{\rho_\infty - \rho}{\rho_\infty}\right) = 0 \qquad (14)$$

In these equations, z is the elevation above the point source of buoyancy; b is the radius to the edge of the plume; u is the vertical velocity in the plume; α is the entrainment coefficient (the proportionality constant relating the inflow velocity due to entrainment at the edge of the plume to u); ρ is the density in the plume; and ρ_∞ is the ambient density. Equation 14 can be integrated immediately to

$$b^2 u g \frac{\rho_\infty - \rho}{\rho_\infty} = B = \text{constant} \tag{15}$$

Here, B is the buoyancy flux in the plume which remains constant at all heights. The flux can be related to the convective heat in the plume, $\dot{Q}_c$, by noting

$$\dot{Q}_c = \rho u \pi b^2 c_p (T - T_\infty) = \pi u b^2 c_p (\rho_\infty - \rho) T_\infty \tag{16}$$

where the ideal gas law has been used. In this equation, T is the plume temperature and T_∞ is the ambient temperature. Combining Equations 15 and 16 gives

$$B = g(\pi c_p T_\infty \rho_\infty)^{-1} \dot{Q}_c \tag{17}$$

Solutions to Equations 12, 13, and 15 can be determined[31] in the form (expressing B in terms of $\dot{Q}_c$ using Equation 17)

$$b = \frac{6\alpha}{5} z \tag{18}$$

$$u = \frac{5}{6}\left(\frac{9}{10\pi\alpha^2}\right)^{1/3} g^{1/3} (c_p \rho_\infty T_\infty)^{-1/3} \dot{Q}_c^{1/3} z^{-1/3} \tag{19}$$

$$\frac{\Delta\rho}{\rho_\infty} = \frac{5}{6}\left(\frac{9\pi^2\alpha^4}{10}\right)^{-1/3} g^{-1/3} (c_p \rho_\infty T_\infty)^{-2/3} \dot{Q}_c^{2/3} z^{-5/3} \tag{20}$$

Equations 18 through 20 are the weak plume (small density deficiency) relations for point sources. To account for area sources, a virtual source location or virtual origin, z_0, is introduced[31,32] and z in Equations 18 through 20 is replaced by $z - z_0$. In addition, to accommodate large density deficiencies as are present in fire plumes, Morton's extension of the weak-plume theory[33] leads to the result that $\Delta\rho/\rho_\infty$ in Equation 20 should be replaced by $\Delta\rho/\rho$ [$= \Delta T/T_\infty$ using the ideal gas law]. Also, Equation 18 for growth in plume radius should incorporate the additional factor $(\rho_\infty/\rho)^{1/2}$ [$= (T/T_\infty)^{1/2}$ using the ideal gas law] on the right side of the equation. Relaxing the assumption that the flow profiles are uniform renders the numerical coefficients in the resulting equations in doubt.

Measurements in fire plumes above the flames have to a large extent supported the theory. The plume radius and centerline values of mean excess temperature and mean velocity have been found[34] to obey the following relations:

$$b_{\Delta T} = 0.12\left(\frac{T_0}{T_\infty}\right)^{1/2} (z - z_0) \tag{21}$$

$$\Delta T_0 = 9.1\left(\frac{T_\infty}{g c_p^2 \rho_\infty^2}\right)^{1/3} \dot{Q}_c^{2/3} (z - z_0)^{-5/3} \tag{22}$$

$$u_0 = 3.4\left(\frac{g}{c_p \rho_\infty T_\infty}\right)^{1/3} \dot{Q}_c^{1/3} (z - z_0)^{-1/3} \tag{23}$$

Here, $b_{\Delta T}$ is the plume radius to the point where the temperature rise has declined to $0.5\Delta T_0$; T_0 is the centerline temperature, $\dot{Q}_c$ is the convective heat release rate, z is the elevation above the fire source, and z_0 is the elevation of the virtual origin above the fire source.* (If z_0 is negative, the virtual origin lies below the top of the fire source.)

The virtual origin is the equivalent point source height of a finite area fire. This origin is usually located near the fuel surface for pool fires and may be assumed coincident with the fuel surface when the plume flow is predicted at high elevations. Near the fire source, however, it is important to know the location of the virtual origin for accurate predictions. Calculation of the virtual origin is discussed in the following section for both pool fires and three-dimensional storage arrays.

Equations 21 through 23 are known as the *strong plume relations.* The numerical coefficients for the relations have been determined from data sets for which the locations of the virtual origin, z_0, have been established and the convective heat release rates, $\dot{Q}_c$, are known.[4,35]

We may compare the experimentally derived numerical coefficients in Equations 21 through 23 to the theoretical coefficients indicated in Equations 18 through 20, which are based on the integral theory of Morton et al.[31] for weak plumes, point sources, and top hat profiles. Forcing equality between the coefficients for ΔT_0 in Equation 22 and $\Delta\rho/\rho_\infty$ in Equation 20, we obtain a value for the entrainment coefficient of $\alpha = 0.0964$. With this value for α, the theoretical coefficient for centerline velocity in Equation 19 becomes 2.61, compared to the experimental value 3.4 in Equation 23. The theoretical coefficient for plume radius in Equation 18 becomes 0.116, compared to the experimental value 0.12 in Equation 21. There is good consistency between the theoretical and experimental coefficients. However, the theoretical expression for mass flow rate in a weak plume, generated from the product $\rho_\infty u(\pi b^2)$ (using Equations 18 and 19) and the value for α above, produces a numerical coefficient that is only 56 percent of the coefficient based on experiments (see discussion of Equation 40 later in the chapter).

In addition to the temperature radius of a plume, $b_{\Delta T}$, a velocity radius, b_u, can also be defined. The velocity radius is the plume radius to the point where the gas velocity has declined to 0.5 u_0. The most reliable measurements[35] indicate that b_u is perhaps 10 percent larger than $b_{\Delta T}$. Other measurements indicate ratios $b_u/b_{\Delta T}$ of 0.86,[36] 1.00,[37] 1.08 and 1.24,[38] 1.31,[5] 1.05,[1] and 1.5.[2] The widely differing results can probably be attributed to the difficulty of positioning the measuring probes accurately with respect to the plume centerline, and to different, intrinsic errors associated with the diverse types of anemometers used (pitot tube, bidirectional flow probe, hot wire, vane anemometer, cross-correlation techniques, laser Doppler anemometer).

*For normal atmospheric conditions ($T_\infty = 293$ K, $g = 9.81$ m/s^2, $c_p = 1.00$ kJ/kg K, $\rho_\infty = 1.2$ kg/m^3), the factor $9.1[T_\infty/(g c_p^2 \rho_\infty^2)]^{1/3}$ has the numerical value 25.0 K m$^{5/3}$ kW$^{-2/3}$, and the factor $3.4[g/(c_p \rho_\infty T_\infty)]^{1/3}$ has the numerical value 1.03 m$^{4/3}$s^{-1}kW$^{-1/3}$.

Often, profiles of temperature rise and velocity are represented as Gaussian in shape, although there is no theoretical foundation for this distribution.

$$\Delta T = \Delta T_0 \exp\left[-\left(\frac{R}{\sigma_{\Delta T}}\right)^2\right] \tag{24}$$

$$u = u_0 \exp\left[-\left(\frac{R}{\sigma_u}\right)^2\right] \tag{25}$$

Here, ΔT and u are the local values, at the radius, R, in the plume of temperature rise and gas velocity. The quantities $\sigma_{\Delta T}$ and σ_u are measures of the plume width, corresponding to the radii where local values of temperature rise and velocity are $e^{-1} = 0.368$ multiplied by the centerline values. For Gaussian profiles, the plume radii $\sigma_{\Delta T}$ and σ_u are 1.201 multiplied by the plume radii, $b_{\Delta T}$ and b_u, discussed previously.

Equations 21 through 23 cease to be valid at and below the mean flame height. However, it is possible to represent ΔT_0 such that a general plot of experimental temperature variations is produced throughout the length of the plume, including the flames. The method is based on the observation that $\dot{Q}_c^{2/3}(z - z_0)^{-5/3}$ in Equation 22 can be written as $[(z - z_0)/\dot{Q}_c^{2/5}]^{-5/3}$. This result suggests plotting ΔT_0 versus $(z - z_0)/\dot{Q}_c^{2/5}$. Figure 2-1.5 shows the result in logarithmic coordinates for normal atmospheric conditions. For values of the abscissa greater than 0.15 to 0.20 (m/kW$^{2/5}$), the centerline temperature rise falls off with the $-\frac{5}{3}$ power of the abscissa, in accordance with the plume law for temperature (Equation 22). Abscissa values in the 0.15 to 0.20 range correspond to the mean flame height; an associated temperature rise of about 500 K is indicated in Figure 2-1.5. At smaller abscissa values, the experimentally observed temperature rise increases more slowly, approaching a value deep in the flame of approximately $\Delta T_0 = 900$ K. When closer to the fuel surface than represented in Figure 2-1.5, the temperatures on the plume axis tend to decrease again.[1,2,5]

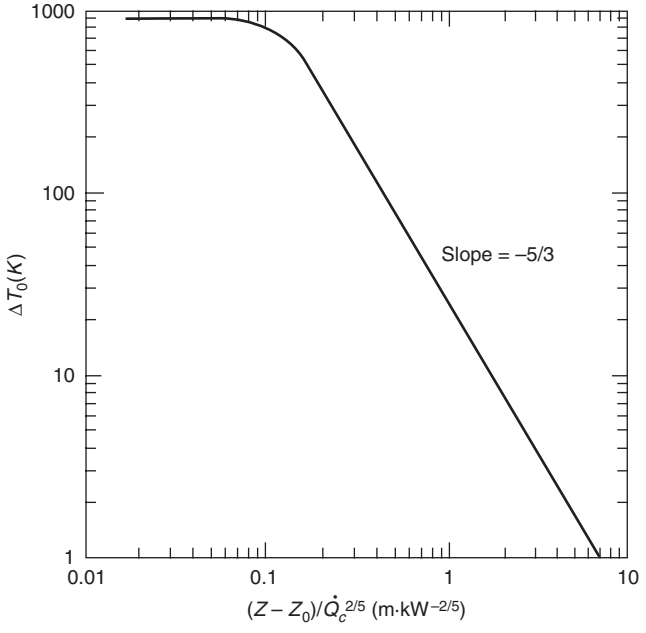

Figure 2-1.5. ***Temperature rise on the plume centerline of pool fires for normal atmospheric conditions[34] in a form attributable to McCaffrey,[1] and Kung and Stavrianidis.[4]***

The plume law for velocity, Equation 23, may be combined with the plume law for temperature, Equation 22, to produce the following useful nondimensional parameter[3]

$$\xi = \left[\frac{T_\infty^{2/5}(c_p\rho_\infty)^{1/5}}{g^{2/5}}\right]\frac{u_0}{(\Delta T_0 \dot{Q}_c)^{1/5}} \tag{26}$$

In the plume region where Equations 22 and 23 are valid, their numerical coefficients correspond to a constant value $\xi = 2.2$. This value has been confirmed for a number of test fires,[3] at heights as low as the mean flame height and even somewhat lower. Equation 26 with $\xi = 2.2$ is a useful relation for determining the maximum velocity in the plume, which occurs slightly below the mean flame height where the temperature rise may be taken at approximately $\Delta T_0 = 650$ K. For normal atmospheric conditions and the value $\xi = 2.2$, Equation 26 becomes

$$\frac{u_0}{(\Delta T_0 \dot{Q}_c)^{1/5}} = 0.54 \tag{27}$$

The maximum velocity just under the mean flame height, u_{0m}, is obtained by setting $\Delta T_0 = 650$ K

$$u_{0m} = 1.97 \dot{Q}_c^{1/5} \tag{28}$$

Fires with low flame height-to-diameter ratios have not been investigated extensively and may require special consideration. For one particular fire with very low flame height[4] in which a proprietary silicone transformer fluid was burned in a 2.44-m diameter pool, a flame height ratio of $L/D = 0.14$ was measured* at a convective heat release rate of $\dot{Q}_c = 327$ kW. Using the results in the next section, the virtual origin is calculated at $z_0 = -1.5$ m, assuming $\dot{Q}_c/\dot{Q} = 0.7$. With respect to the abscissa in Figure 2-1.5, the lowest possible value is $-z_0/\dot{Q}_c^{2/5}$ corresponding to the fuel surface, $z = 0$. For the present case, $-z_0/\dot{Q}_c^{2/5} = 1.5/327^{2/5} = 0.15$ (m kW$^{-2/5}$). At this abscissa value, a centerline temperature rise of 580 K is indicated in Figure 2-1.5. From the experiment,[4] a near surface ΔT_0 of 440 K can be determined by slight extrapolation, fairly close to the prediction from Figure 2-1.5. Fires with very low flame height-to-diameter ratios may generally be expected to produce lower maximum mean temperatures than other fires. However, it is not yet clear whether the type of prediction attempted here for a particular low L/D fire is generally valid.

*A ratio $L/D = 0.02$ can be calculated from Equation 7 assuming $H_c/r = 3470$ kJ/kg, an average for silicone oils from values reported by Tewarson[39] and assuming a convective heat fraction $\dot{Q}_c/\dot{Q} = 0.7$. If a value of H_c/r near the bottom of the reported range[39] is selected, 3230 kJ/kg, the observed value $L/D = 0.14$ is reproduced; slight changes in the assumed convective fraction will also reproduce the measured value.

There is also uncertainty associated with assuming that ξ in Equation 26 remains completely constant down to the flame level in low *L/D* fires. It may be found that ξ still remains approximately constant down to the height where the maximum gas velocity occurs, although this maximum will probably occur above the flames. The associated temperatures at this height cannot as yet be predicted. Consequently, the relation in Equation 28 becomes somewhat uncertain as *L/D* decreases (ΔT_0 is overestimated, resulting in u_{0m} being overestimated, although the effect is probably not very large because of the slow, $\frac{1}{5}$th power dependence on ΔT_0).

The turbulence intensities in a fire plume are quite high. On the axis, George et al.[35] report an intensity of temperature fluctuations of approximately $T'/\Delta T_0 = 0.38$, where T' is the root mean square (rms) temperature fluctuation. Centerline values of the intensity of axial velocity fluctuations were measured near $u'/u_0 = 0.27$ by George et al.[35] and near $u'/u_0 = 0.33$ by Gengembre et al.,[5] where u' is the rms velocity fluctuation in the axial direction.

EXAMPLE 5:

Example 1 concerned a 1.5-m-diameter methyl alcohol fire burning under normal atmospheric conditions, generating $\dot{Q} = 884$ kW with a calculated mean flame height of 1.83 m. For an elevation of 5 m and given a virtual origin $z_0 = -0.3$ m (from Example 7), calculate the temperature radius, $b_{\Delta T}$, as well as the centerline value of temperature rise, ΔT_0, and gas velocity, u_0. Also calculate the maximum gas velocity in the flame.

SOLUTION:

Assume* $\dot{Q}_c = 0.8\dot{Q}$ and first calculate the temperature rise, using Equation 22 and properties for normal atmospheric conditions ($T_\infty = 293$ K, $g = 9.81$ m/s^2, $c_p = 1.00$ kJ/kg K, $\rho_\infty = 1.20$ kg/m^3)

$$\Delta T_0 = 9.1\left(\frac{293}{9.81 \cdot 1.00^2 \cdot 1.20^2}\right)^{1/3}(0.8 \cdot 884)^{2/3}(5 + 0.3)^{-5/3}$$
$$= 123 \text{ K}$$

The temperature radius can now be calculated from Equation 21

$$b_{\Delta T} = 0.12\left(\frac{123 + 293}{293}\right)^{1/2}(5 + 0.3)$$
$$= 0.76 \text{ m}$$

The velocity is calculated from Equation 23

$$u_0 = 3.4\left(\frac{9.81}{1.00 \cdot 1.20 \cdot 293}\right)^{1/3}(0.8 \cdot 884)^{1/3}(5 + 0.3)^{-1/3}$$
$$= 5.3 \text{ m/s}$$

Instead of Equation 23, the velocity can also be calculated from Equation 26 in this case, since ΔT_0 is already known. Actually, because normal ambient conditions prevail, Equation 27 can be used

$$u_0 = 0.54(123 \cdot 0.8 \cdot 884)^{1/5} = 5.3 \text{ m/s}$$

Finally, the maximum velocity in the flame is given by Equation 28

$$u_{0m} = 1.97(0.8 \cdot 884)^{1/5} = 7.3 \text{ m/s}$$

EXAMPLE 6:

Recalculate the quantities called for in Example 5 using ambient conditions representative of Denver, Colorado, on a hot day: 630 mm Hg pressure and 310 K temperature.

SOLUTION:

Changed ambient variables entering the equations include $T_\infty = 310$ K and $\rho_\infty = 0.78$ kg/m^3. From Equation 22, the new temperature rise is

$$\Delta T_0 = 167 \text{ K (versus 123 K in Example 4)}$$

The new velocity from Equation 23 is

$$u_0 = 6.0 \text{ m/s (versus 5.3 m/s)}$$

For the new ambient conditions, the relation analogous to Equation 28 is calculated as

$$u_{0m} = 2.10\dot{Q}_c^{1/5}$$

from which the new maximum velocity in the flame is

$$u_{0m} = 7.8 \text{ m/s (versus 7.3 m/s)}$$

Plumes in Temperature-Stratified Ambients

When a buoyant, turbulent plume rises, it cools by entrainment of ambient air. If the ambient air increases in temperature with height, which is normal in buildings, and the fire source is weak, the temperature difference between the plume and the ambient, which gives the plume buoyancy, may vanish and actually reverse in sign. Eventually the plume ceases to rise.

The maximum height achieved by plumes in temperature-stratified space has been given by Heskestad,[40] based on pioneering theoretical and experimental work by Morton et al.[31]

$$z_m = 3.79\left[\frac{T_{a1}}{g(\rho_{a1}c_p)^2}\right]^{1/8}\dot{Q}_c^{1/4}\left(\frac{dT_a}{dz}\right)^{-3/8} \qquad (29)$$

Here, dT_a/dz is the ambient temperature gradient, T_{a1} and ρ_{a1} are the ambient temperature and density, respectively, at the level of the fire source, and the constant 3.79 traces to experiments using dyed light liquid injected into a density stratified salt solution.[31] Other results are presented in Figure 2-1.6, which shows the ratio on the plume centerline of stratified value versus unstratified value for

*Without specific knowledge, $\dot{Q}_c/\dot{Q}$ may usually be assumed at 0.7. However, methyl alcohol produces a fire of low luminosity and radiation, for which $\dot{Q}_c/\dot{Q} = 0.8$ is a good estimate.

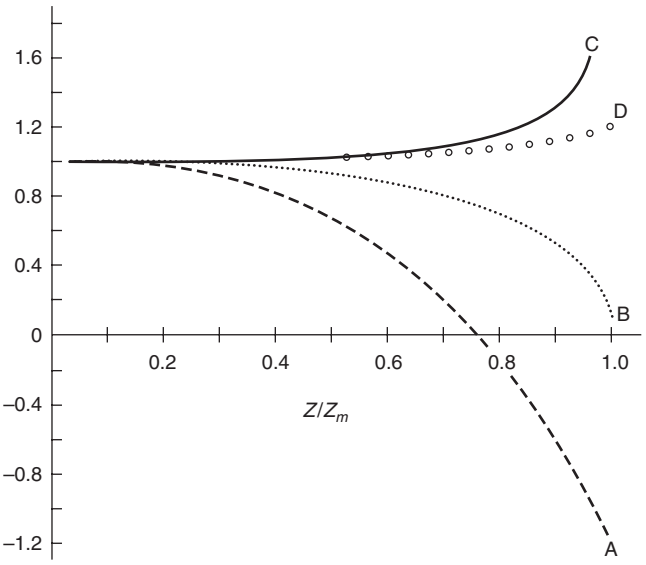

Figure 2-1.6. ***Theoretical behavior of centerline plume variables in linearly temperature-stratified ambients. From Heskestad,[40,64] traceable to Morton et al.[31] Curve A: ratio of temperature rises (stratified versus unstratified), Curve B: ratio of axial velocities. Curve C: ratio of plume radii. Curve D: ratio of volumetric species concentrations.***

various plume variables: temperature rise relative to the pre-existing value at each level (curve A), axial velocity (curve B), plume radius (curve C), and volume concentration of a combustion species (curve D). The ratios are plotted against the fraction of maximum elevation achieved by the plume, z/z_m. By definition, the stratified velocity (B) decreases to zero at $z/z_m = 1$. The stratified temperature rise (A) becomes negative below the maximum reach. The stratified plume radius (C) grows rapidly in approach to the maximum plume reach. However, there is little effect of the stratification on the centerline variation of concentration of a combustion species.

Fire experiments in temperature stratified space[41] have largely supported the validity of Figure 2-1.6 for temperature rise (A) and volume concentrations (D), except that the experimental values needed an incremental height, roughly equal to 25 percent of the theoretical plume reach, to return to zero.

The maximum plume reach can be interpreted in terms of a critical ambient temperature rise from the source level to an elevated observation plane, just strong enough to prevent plume fluid from penetrating the plane. Experiments[41] show that the critical ambient temperature rise for a linear profile is *7.4 times the centerline temperature rise at the level of the observation plane which results from a fire source in a uniform environment*. Furthermore, the critical temperature rise is surprisingly insensitive to the shape of the stratification profile. For a profile where one-half of the ambient temperature rise to the observation plane occurred higher than 75 percent of the elevation of the observation plane above the source, the critical ambient temperature rise was only 12 percent greater than that for the linear profile.

EXAMPLE 7:

Consider a 20-m high atrium where the temperature rise, floor to ceiling, is 5 K. What heat release rate is required of a floor-level fire to drive the plume to the ceiling? What would be the effect of doubling the ceiling height?

SOLUTION:

The temperature rise in unstratified space is required as a reference and is calculated from Equation 22, taking $z_0 = 0$ for simplicity since deviations of the virtual origin from the level of the fire can be assumed to be inconsequential in this case. We have

$$\Delta T_0 = 25.0 \dot{Q}_c^{2/3} z^{-5/3} \tag{30}$$

The temperature rise of the stratification, 5 K, is 7.4 times the value of ΔT_0 for this associated, unstratified-space fire, which will just drive the plume to the ceiling. Solving Equation 30 for $\dot{Q}_c$, setting $\Delta T_0 = 5/7.4$ K and $z = 20$ m, we get $\dot{Q}_c = 7.9$ kW. Assuming a ratio of 0.7 for convective in ratio to the total heat release rate, the latter is $\dot{Q} = 11.4$ kW. If the ceiling height is doubled to 40 m, the new result is $\dot{Q} = 64$ kW.

Virtual Origin

Pool fires: As pointed out earlier in this chapter, knowledge of the virtual origin of fire plumes is important for predicting the near source plume behavior. The virtual origin is a point source from which the plume above the flames appears to originate.

The virtual origin of a test fire is most conveniently determined from temperature data above the flames along the plume axis. According to Equation 22, a plot of $\Delta T_0^{-3/5}$ versus z should produce a straight line which intercepts the z-axis at z_0. Despite this apparent simplicity of obtaining z_0, the task is very difficult in practice. Slight inaccuracies in the determinations of centerline temperatures have large effects on the intercept, z_0; such inaccuracies may be associated with off-axis placement of sensors, radiation-induced errors in the temperature signal, or inadequate averaging of the signal.

Data obtained in this manner on the virtual origin for pool fires varying in diameter from 0.16 to 2.4 m,[1,3,4] were examined for consistency with a theoretical model by Heskestad.[42] The model relied heavily on the flame-height correlation represented by Equation 3 and led to the prediction

$$\frac{z_0}{D} = -1.02 + F \frac{\dot{Q}^{2/5}}{D} \tag{31}$$

where F is a rather complex dimensional function of environmental variables c_p, T_∞, ρ_∞, g; H_c/r for the combustible, the fraction of the total heat release carried away by convection,[42] and the mean centerline temperature at the mean flame height, T_L. It appeared that F could be considered a constant for wide variations in ambient temperature and pressure, but might be affected by wide swings in the fuel variables, H_c/r and convective fraction. The available data did not reflect any sensitivity to fuel identity within their scatter, and led to the determination $F = 0.083$ m kW$^{-2/5}$, with Equation 31 becoming

$$\frac{z_0}{D} = -1.02 + 0.083 \frac{\dot{Q}^{2/5}}{D} \quad (\dot{Q} \text{ in kW}, D \text{ in m}) \tag{32}$$

Later, Hasemi and Tokunaga[43] analyzed their temperature measurements in plumes from gas burners of diameters in the 0.2 to 0.5 m range and established alternative correlations for the virtual origin. In terms of the nondimensional parameter $\dot{Q}^*$ defined in Equation 1, their correlations are

$$\begin{aligned} \frac{z_0}{D} &= 2.4(\dot{Q}^{*2/5} - 1) && \dot{Q}^* \geq 1.0 \\ \frac{z_0}{D} &= 2.4(\dot{Q}^{*2/3} - \dot{Q}^{*2/5}) && \dot{Q}^* < 1.0 \end{aligned} \tag{33}$$

For normal ambient conditions, these correlations can be written in terms of the variable $\dot{Q}^{2/5}/D$ (cf. Equation 32)

$$\begin{aligned} \frac{z_0}{D} &= -2.4 + 0.145\frac{\dot{Q}^{2/5}}{D} && \frac{\dot{Q}^{2/5}}{D} \geq 16.5 \\ \frac{z_0}{D} &= 0.0224\left(\frac{\dot{Q}^{2/5}}{D}\right)^{5/3} - 0.145\frac{\dot{Q}^{2/5}}{D} && \frac{\dot{Q}^{2/5}}{D} < 16.5 \end{aligned} \tag{34}$$

Cetegen et al.[44] have proposed correlations for the virtual origin on the basis of their air entrainment measurements in fire plumes and attempts to apply entrainment theory for a point source to the laboratory fires. Their experiments involved gas burners (natural gas) with diameters of 0.10, 0.19, 0.30, and 0.50 m. The experiments were performed with and without a floor mounted flush with the upper surface of the burners located some distance above the floor of the laboratory. Their correlations for the virtual origin are

$$\begin{aligned} \frac{z_0}{D} &= c + 1.09\dot{Q}^{*2/5} && \dot{Q}^* > 1 \\ \frac{z_0}{D} &= c + 1.09\dot{Q}^{*2/3} && \dot{Q}^* \leq 1 \end{aligned} \tag{35}$$

where $\dot{Q}^*$ has been defined by Equation 1, and where $c = -0.50$ with a flush floor around the burners and $c = -0.80$ without a flush floor. Using Equation 1, Equation 35 can be written in terms of $\dot{Q}^{2/5}/D$ yielding

$$\begin{aligned} \frac{z_0}{D} &= c + 0.0659\frac{\dot{Q}^{2/5}}{D} && \frac{\dot{Q}^{2/5}}{D} > 16.5 \\ \frac{z_0}{D} &= c + 0.01015\left(\frac{\dot{Q}^{2/5}}{D}\right)^{5/3} && \frac{\dot{Q}^{2/5}}{D} \leq 16.5 \end{aligned} \tag{36}$$

where $c = -0.50$ and $c = -0.80$ with and without a flush floor, respectively.

Figure 2-1.7 is a composite plot of the various correlations for the virtual origin of pool fires, plotted as z_0/D versus $\dot{Q}^{2/5}/D$. Despite the diverse approaches, the overall correlations are surprisingly similar. Precise measurements are not yet available to clearly identify an optimal correlation. In the meantime, curve 1 in Figure 2-1.7 (i.e., Equation 32) is recommended for its simplicity, clear foundation in theory,[42] and central position among the other correlations.

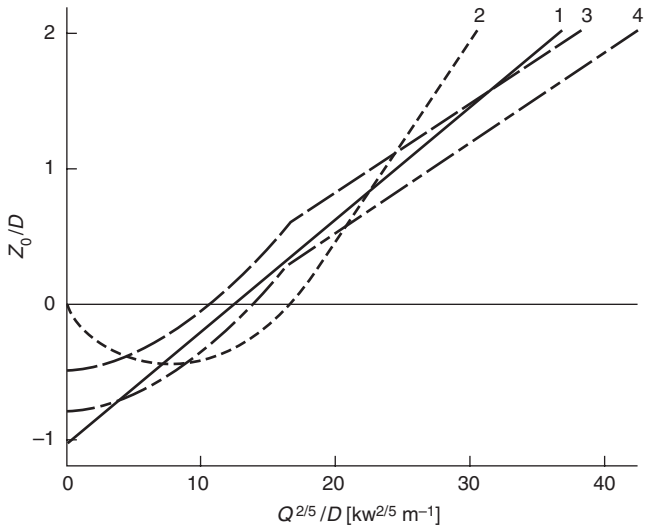

Figure 2-1.7. ***Correlations for the virtual origin of pool fires. Curve 1—Equation 32; Curve 2—Equation 34; Curve 3—Equation 36 with floor; Curve 4—Equation 36 without floor.***

Other fire types: The original derivation of Equation 31 for pool fires[42] includes the following expression:

$$z_0 = L - 0.175\dot{Q}_c^{2/5} \qquad (L \text{ and } z_0 \text{ in m; } \dot{Q}_c \text{ in kW}) \tag{37}$$

In addition to representing pool fires, Equation 37 has also been verified to represent deep storage fires,[22] allowing the location of the virtual origin to be calculated from knowledge of the mean flame height and the convective heat release rate. As discussed earlier, mean flame heights above the base of a fire in storages can be determined from Equation 3 when the flames extend above the storage, which implies that values of z_0 calculated refer to the distance above the base of the fire (usually the base of the storage). Equation 37 may also be assumed to be valid for turbulent jet fires.

EXAMPLE 8:

Example 1 concerned a 1.5-m diameter methyl alcohol fire generating $\dot{Q} = 884$ kW. Calculate the virtual origin.

SOLUTION:

In this example, $D = 1.5$ m. Direct substitution into Equation 32 gives

$$\begin{aligned} \frac{z_0}{D} &= -1.02 + \frac{0.083(884)^{2/5}}{1.5} \\ &= -1.02 + 0.83 = -0.19 \end{aligned}$$

from which

$$z_0 = -0.19 \cdot 1.5 = -0.29 \text{ m}$$

This is the value for z_0 (rounded off) used in Example 1.

EXAMPLE 9:

Negative values for z_0 are often calculated for low heat release fires and sufficiently large fire diameters, as in Example 7. Positive virtual origins are often found for high heat release fires. Substituting heptane for methyl alcohol in Example 7 (2500 kW/m^2 rather than 500 kW/m^2 measured for methyl alcohol),[6] calculate the new virtual origin.

SOLUTION:

The new heat release rate is

$$\dot{Q} = \frac{\pi 1.5^2}{4} 2500 = 4420 \text{ kW}$$

From Equation 32,

$$\frac{z_0}{D} = -1.02 + 0.083 \cdot \frac{4420^{2/5}}{1.5} = 0.57$$

from which

$$z_0 = 0.57 \cdot 1.5 = 0.85 \text{ m}$$

EXAMPLE 10:

A 3-m deep storage is known to produce a heat release rate per unit floor area of 4000 kW/m^2 when fully involved. At a stage of fire development in such a storage, a heat release rate of 1500 kW is reached. What is the location of the virtual origin?

SOLUTION:

First determine the flame height. Evaluate the effective fire diameter from $\pi D^2/4 = 1500/4000 = 0.375$ m^2, which gives $D = 0.69$ m. From Equation 7, calculate the flame height as 3.67 m (above base of storage), which is 0.67 m above the top of the storage. The height of the virtual origin above the base of the storage is calculated from Equation 37, assuming $\dot{Q}_c = 0.7\dot{Q} = 1050$ kW, yielding $z_0 = 3.67 - 0.175 \times 1050^{2/5} = 0.84$ m.

Entrainment

After ignition, the fire plume carries fire products diluted in entrained air to the ceiling. A layer of diluted fire products, or smoke, forms under the ceiling, which thickens and generally becomes hotter with time. The fire environment is intimately tied to the behavior of this layer which, in turn, depends to a major extent on the mass flow rate of plume fluid into the layer. Consequently, it is important to be able to predict the mass flow rate that may occur in a fire plume.

The mass flow at a particular elevation in a fire plume is almost completely attributable to air entrained by the plume at lower elevations. The mass flow contributed by the fire source itself is insignificant in comparison.

For a weak plume, the mass flow rate at a cross section can be written

$$\dot{m}_{\text{ent}} = E\rho_\infty u_0 b_u^2 \tag{38}$$

where E is a nondimensional constant of proportionality. With the aid of Equation 23 and the equivalent of Equation 21 written for b_u (setting $T_0/T_\infty = 1$ because of the weak plume assumption), Equation 38 becomes

$$\dot{m}_{\text{ent}} = E\left(\frac{g\rho_\infty^2}{c_p T_\infty}\right)^{1/3} \dot{Q}_c^{1/3}(z - z_0)^{5/3} \tag{39}$$

Early measurements by Yih[45] indicated a value $E = 0.153$.

Cetegen et al.[44,46] concluded from theoretical analysis that Equation 39 also applies to strongly buoyant plumes. From extensive entrained-flow measurements for natural gas burners of several diameters, these authors proposed a coefficient $E = 0.21$ based on the total heat release rate, corresponding to $E = 0.24$ based on the convective heat release rate as in Equation 39 (assuming a convective fraction of 0.7). However, the plume flow rates at large heights were somewhat overpredicted and those at low heights, approaching the flames, were somewhat underpredicted.

Heskestad[47] reconsidered the entrainment problem for strong plumes, assuming self-preserving density deficiency profiles instead of self-preserving excess temperature profiles as traditionally assumed. This approach led to the following extension of Equation 39

$$\dot{m}_{\text{ent}} = E\left(\frac{g\rho_\infty^2}{c_p T_\infty}\right)^{1/3} \dot{Q}_c^{1/3}(z - z_0)^{5/3} \cdot \left[1 + \frac{G\dot{Q}_c^{2/3}}{(g^{1/2}c_p\rho_\infty T_\infty)^{2/3}(z - z_0)^{5/3}}\right] \tag{40}$$

Equation 40, with $E = 0.196$ and $G = 2.9$, was found to represent the data of Cetegen et al.[44,46] very well over the entire nonreacting plume for all their fire diameters, ranging from 0.10 m to 0.50 m.[47] At large heights, the bracketed term involving G approaches unity, and at levels approaching the flame tip (Equation 3), this term approaches 1.5, approximately. Equation 40, with $E = 0.196$ and $G = 2.9$, is the recommended relation for calculating mass flow rates in plumes, at and above the mean flame height.

The entrained flow at the mean flame height, $\dot{m}_{\text{ent},L}$, follows from setting $z - z_0 = L - z_0$ in Equation 40 (with $E = 0.196$ and $G = 2.9$), taking L from Equation 3 and z_0 from Equation 31 (with substitution of full expression for F), with the result,

$$\dot{m}_{\text{ent},L} = 0.878\left[\left(\frac{T_L}{T_\infty}\right)^{5/6}\left(\frac{T_\infty}{\Delta T_L}\right) + 0.647\right]\frac{\dot{Q}_c}{c_p T_\infty} \tag{41}$$

The numerical values are linked to the experimental calibration coefficient for F (based on $F = 0.083$ m kW$^{-2/5}$ at normal atmospheric conditions as indicated under Equation 31) and taking $\Delta T_L = 500$ K. Interestingly, $\dot{m}_{\text{ent},L}$ is independent of the acceleration of gravity, g.

Mass flow rates in fire plumes at levels below the flame tip have been found to increase linearly with height for fire diameters of 0.3 m and greater,[47] where the flames are substantially turbulent, from zero (essentially) at the fire base to the flame-tip value in Equation 41, that is,

$$\dot{m}_{\text{ent}} = \dot{m}_{\text{ent},L} z/L \tag{42}$$

Measurements in the flaming region for fire diameters *smaller* than 0.30 m do not show a linear variation of mass flow rate with height, including data by Cetegen et al.[44,46] (fire diameters of 0.10 and 0.19 m) and Beyler[48] (0.19 m and 0.13 m). (It is important to note, however, that all these data are consistent with an approach to the mass flow rate at the mean flame height given by Equation 41.[47]) Neither do the mass flow measurements in turbulent jet flames by Delichatsios and Orloff[49] show a linear variation with height (estimated values of N in range 50–6300 and momentum parameter R_M in range 0.0015–0.010); in fact, these measurements indicate a 5/2 power dependence, within the flames, of mass flow rate on height above the nozzle exit. As a guide to entrainment estimates in the flaming region for sources smaller than 0.30 m in diameter, it appears that a second power variation of mass flow rate with height is quite representative of the fire sources referred to above of diameters 0.13 and 0.10 m, in which case Equation 42 is replaced by

$$\dot{m}_{\text{ent}} = \dot{m}_{\text{ent},L}\left(\frac{z}{L}\right)^2 \tag{43}$$

The 0.19-m diameter sources generated scattered results between the linear and second power variation.[47] Delichatsios[50] as well as Quintiere and Grove[51] have also analyzed mass flow rates in the flaming region.

We digress briefly on the appropriateness of relating entrainment behavior to the diameter of the fire source. The governing parameters for fire plumes from horizontal, circular sources have been considered so far to be the parameter N and the momentum parameter R_M. However, for small fire sources it is common to see a laminar flame sheet preceding transition to turbulence around the rim of the fire source, and the degree to which such laminar regions and effects exists will depend on the flame Reynolds number. A flame Reynolds number can be formulated as $u_{0m}b_{um}/\nu_m$, where u_{0m} is the characteristic gas velocity in the flame, proportional to $\dot{Q}^{1/5}$ according to Equation 28; b_{um} is the associated characteristic flame radius, proportional to[52] $\dot{Q}^{2/5}$; and ν_m is the kinematic viscosity evaluated at the mean maximum flame temperature, which can be considered constant. Hence, the flame Reynolds number can be considered proportional to $\dot{Q}^{3/5}$. Assuming the discharge momentum is not important (small R_M), the flame entrainment behavior should be a function of N and $\dot{Q}$. When the entrainment behavior is represented on N, $\dot{Q}$ coordinates for the various test fires indicated above, it is found that the fires with linear increase of mass flow rate with height in the flame plot above a line $\dot{Q} \propto N^{1/2}$, with some uncertainty about the precise level. With the aid of Equation 4 it becomes clear that this relation implies an equivalent limit line $D = constant$, which justifies relating the entrainment behavior to the source diameter.

For normal atmospheric conditions Equations 40 through 42 can be written as follows for the plume mass flow rate at various heights:

Above the mean flame height, L ($\dot{Q}_c$ in kW, z and z_0 in m):

$$\dot{m}_{\text{ent}}\,(\text{kg/s}) = 0.071\dot{Q}_c^{1/3}(z - z_0)^{5/3} \cdot [1 + 0.027\dot{Q}_c^{2/3}(z - z_0)^{-5/3}] \tag{44}$$

At the mean flame height, L ($\Delta T_L = 500$ K):

$$\dot{m}_{\text{ent},L}\,(\text{kg/s}) = 0.0056\dot{Q}_c\,(\text{kW}) \tag{45}$$

At and below the mean flame height, L, for fire source diameters of 0.3 m and greater:

$$\dot{m}_{\text{ent}}\,(\text{kg/s}) = 0.0059\dot{Q}_c\,(\text{kW}) \cdot \frac{z}{L} \tag{46}$$

Under the prevailing assumptions, and the further assumption $\dot{Q}_c/\dot{Q} = 0.7$ and $H_c/r \approx 3100$ kJ/kg, Equation 45 implies that the mass flow at the flame tip is 13 times the mass stoichiometric requirement of the fuel.[47]

Fires with very low flame height-to-diameter (L/D) ratios have not been investigated extensively. It is not clear to what L/D limit the entrained-flow relations presented here apply, but this limit is smaller than 0.9, the lowest L/D ratio associated with the data of Cetegen et al.[44,46] For plume mass flows above the flames, there is no L/D limit for predictions at the higher elevations, but predictions of mass flows at levels just above the flames may begin to deteriorate before $L/D = 0.14$ is reached, as seems to be implied in the observations following Equation 28.

Further, mention should be made of a plume mass flow formula often used because of its simplicity, originally developed for the flaming region of large fires by Thomas et al.[53]

$$\dot{m}_{\text{ent}} = 0.096(g\rho_\infty\rho_{f\ell})^{1/2}W_f z^{3/2} \tag{47}$$

Here $\rho_{f\ell}$ is the gas density in the flames and W_f is the fire perimeter. This formula has also been tested against mass flow data above the flames by Hinkley,[54] who claims it is very satisfactory for heights up to 10 times the linear dimension (or diameter) of a fire, although there is little theoretical justification for its use above the flames. The following version of Equation 47 is often used[54] (based on normal atmospheric conditions and an assumed flame temperature):

$$\dot{m}_{\text{ent}}(\text{kg/s}) = 0.188W_f\,(\text{m})\,z\,(\text{m})^{3/2} \tag{48}$$

It is instructive to compare the predictions of Equations 44 and 48 for plume regions above the flames. In a number of comparisons for heat release rates in the range 1000 to 8000 kW, heat release rates per unit area in the range 250 to 1000 kW/m^2, and heights varying from the flame level to 128 m, the predictions of Equation 48 range from 0.64 to 1.38 times the predictions of Equation 44.

Cetegen et al.,[44,46] whose data have contributed most to the mass flow recommendations in this text, have carefully pointed out that their fire plumes were produced in as quiet an atmosphere as could be maintained in their laboratory. They report that small ambient disturbances could provide 20 to 50 percent increases in the measured plume mass flows. Clearly, there is need for further research.

EXAMPLE 11:

Calculate plume mass flow rates for the methyl alcohol fire of Examples 1, 5, and 7.

SOLUTION:

From Example 1, $\dot{Q} = 884$ kW and $L = 1.83$ m; from Example 5, $\dot{Q}_c = 0.8\dot{Q} = 707$ kW; from Example 7, $z_0 = -0.29$ m. At the mean flame height, 1.83 m, the mass flow rate follows from Equation 45

$$\dot{m}_{\text{ent},L} = 0.0059 \cdot 707 = 4.2 \text{ kg/s}$$

Mass flow rates in the flaming region are calculated using Equation 46

$$\dot{m}_{\text{ent}} \text{ (kg/s)} = 4.2 \cdot \frac{z}{1.83} = 2.3z \text{ (m)}$$

Mass flow rates above the flames are obtained from Equation 44; for example, at a height of 3.66 m (twice the flame height)

$$\begin{aligned}\dot{m}_{\text{ent}} &= 0.071 \cdot 707^{1/3}(3.66 + 0.29)^{5/3} \\ &\quad \cdot [1 + 0.027 \cdot 707^{2/3}(3.66 + 0.29)^{-5/3}] \\ &= 6.24(1 + 0.22) \\ &= 7.6 \text{ kg/s}\end{aligned}$$

Illustration

In addition to the previous examples, it is instructive to work through a somewhat larger problem to illustrate handling of the equations and their limitations. Units used throughout this section are kW for heat release rate, m for length, s for time, K for temperature, and m/s for velocity.

The example can be used of a large building that will allow clear, uncontaminated air to exist around a particular growing fire for at least 10 minutes before smoke begins to recirculate into the region. Normal atmospheric conditions prevail. Wood pallets are stored in a large, continuous array on the floor to a height of 1.2 m. This array is ignited locally at an interior point, and the fire spreads in a circular pattern at constant radial speed (as predicted and observed for wood cribs),[55] such that the heat release rate grows with the second power of time

$$\dot{Q} \text{ (kW)} = 1000\left(\frac{t}{t_g}\right)^2 \tag{49}$$

Here, t is time and t_g is the so-called growth time. When t_g is 60 s, the fire grows through a magnitude of 1000 kW in 60 s. When t_g is 600 s, the fire grows through a magnitude of 1000 kW in 600 s, a much slower growth rate. In this illustration, it is assumed that the growth time is $t_g = 140$ s.[56] It is also assumed that the fully involved pallet storage generates a total heat release rate of 2270 kW/m^2 of floor area.[6] The objective is to determine flame height as a function of time, as well as the variation of plume centerline temperature, plume centerline velocity, and plume width at an elevation of 5 m above the base of the fuel array where a structural member may cross and be heated by the plume.*

*In addition to convective heating, which depends on gas temperature and velocity, radiative heating would also be important in such cases and might even dominate over convective heating if the structure is immersed in flames.

For the assumed growth time, $t_g = 140$ s, the variation of total heat release rate with time comes from Equation 49

$$\dot{Q} = 5.10 \times 10^{-2} t^2 \tag{50}$$

The convective heat release rate is assumed at 70 percent of the total heat release rate

$$\dot{Q}_c = 3.57 \times 10^{-2} t^2 \tag{51}$$

The instantaneous fire diameter, D, is determined as follows. Since the heat release rate per unit floor area is 2270 kW/m^2

$$\dot{Q} = 2270 \frac{\pi D^2}{4} \tag{52}$$

Upon eliminating $\dot{Q}$ between Equations 50 and 52, the following can be obtained:

$$D = 5.35 \times 10^{-3} t \tag{53}$$

First, the behavior of flame height may be calculated using Equation 8. Substitution of Equations 50 and 53 into Equation 8 gives the following relation of flame height as a function of time

$$L = -5.46 \times 10^{-3} t + 7.15 \times 10^{-2} t^{4/5} \tag{54}$$

This relation is plotted in Figure 2-1.8 for the 10-min (600-s) fire interval and is labeled L. The fire diameter, D, is also plotted in Figure 2-1.8, based on Equation 53.

The virtual origin, z_0, is determined from Equation 32, with substitutions for $\dot{Q}$ a from Equation 50 and for D from Equation 53

$$z_0 = -5.46 \times 10^{-3} t + 2.52 \times 10^{-2} t^{4/5} \tag{55}$$

The curve labeled z_0 in Figure 2-1.8 represents the virtual origin according to Equation 55. It is seen that z_0 nearly levels off in the time interval plotted in the figure; actually, z_0 begins to decrease again at somewhat larger times.

With this foundation, there is sufficient information to calculate gas temperatures, velocities, and plume widths at the 5-m height above the base of the fuel array.

The temperature rise on the plume centerline at the selected height is determined from Equation 22 by substituting $z = 5$ (m), z_0 from Equation 55; $\dot{Q}_c$ from Equation 51, and values of T_∞, g, c_p, and ρ_∞ for the normal atmosphere, yielding

$$\Delta T_0 = \frac{2.71 t^{4/3}}{(5 + 5.46 \times 10^{-3} t - 2.52 \times 10^{-2} t^{4/5})^{5/3}} \tag{56}$$

This relation is valid up to the time that a temperature rise associated with the flame tip, $\Delta T_0 = 500$ K, is felt at the selected height, which occurs at $t = 303$ s. The plot of ΔT_0 in Figure 2-1.9 is according to Equation 56 up to the time $t = 303$ s. At larger times, ΔT_0 is determined from Figure 2-1.5 in the following manner: at each selected time, $z - z_0$ is calculated using Equation 55; $\dot{Q}_c$ is calculated from Equation 51; the quantity $(z - z_0)/\dot{Q}_c^{2/5}$ is determined and ΔT_0 is read from Figure 2-1.5. The resulting extension of the ΔT_0 curve is seen in Figure 2-1.9.

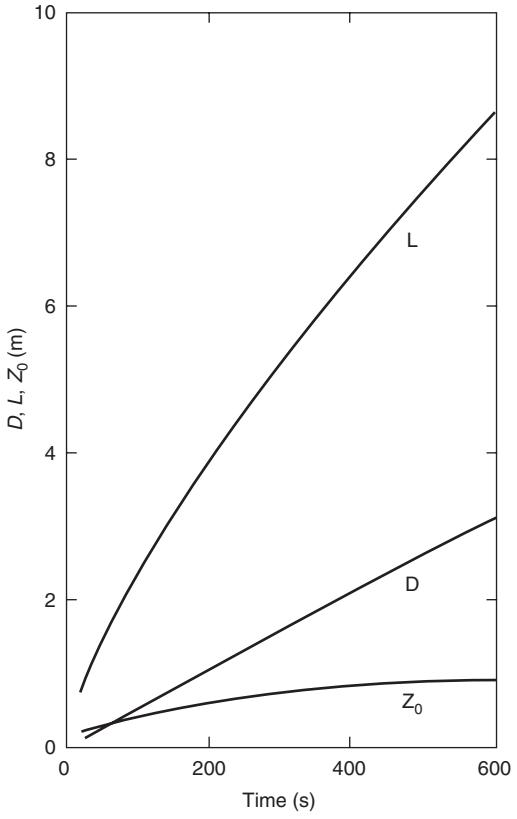

Figure 2-1.8. ***Growing fire illustration: fire diameter, D, flame height, L, and virtual origin, z_0.***

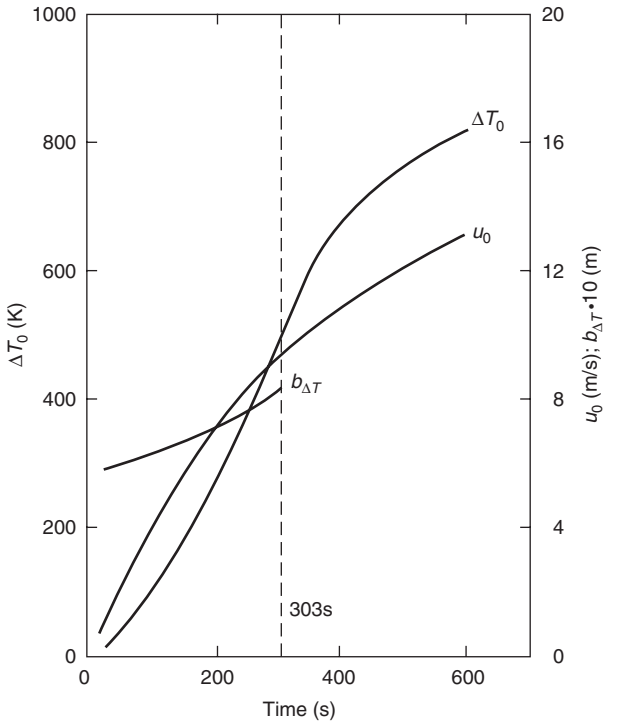

Figure 2-1.9. ***Growing fire illustration: plume width, $b_{\Delta T}$, and centerline values of temperature rise, ΔT_0, and velocity, u_0, at 5 m above the base of the fuel.***

The centerline gas velocity at the 5-m height above the base of the fuel array can then be considered. Equation 23 can be used up to the moment that the flame tip reaches the 5-m height; that is, at $t = 303$ s. After substitution of $z = 5$ (m), z_0 from Equation 55, $\dot{Q}_c$ from Equation 51, and normal ambient conditions, Equation 23 becomes

$$u_0 = \frac{0.339t^{2/3}}{(5 + 5.46 \times 10^{-3}t - 2.52 \times 10^{-2}t^{4/5})^{1/3}} \qquad (57)$$

The u_0 curve in Figure 2-1.9 follows Equation 57 to the limit, $t = 303$ s. As stated in conjunction with Equation 27, the maximum velocity (for a given size fire) occurs just below the mean flame height where $\Delta T_0 = 650$ K, which corresponds to $(z - z_0)/\dot{Q}_c^{2/5} = 0.135$ according to Figure 2-1.5. Using $z = 5$ (m), z_0 and $\dot{Q}_c$ from Equations 55 and 51, the 0.135 limit is found to correspond to a time of $t = 385$ s, where Equation 28 gives the centerline velocity in terms of $\dot{Q}_c$. In fact, it appears that Equation 28 can be used with good accuracy to even larger times, at least to times associated with a lower limit of $(z - z_0)/\dot{Q}_c^{2/5} = 0.08$, according to available measurements.[1,5] Since the largest time in Figure 2-1.9 corresponds to $(z - z_0)/\dot{Q}_c^{2/5} = 0.092$, Equation 28 has been used to calculate the entire extension of the u_0 curve in Figure 2-1.9.

The temperature radius of the plume at the 5-m height above the fuel array is calculated from Equation 21, which can be written

$$b_{\Delta T} = 0.12\left(1 + \frac{\Delta T_0}{T_\infty}\right)^{1/2}(z - z_0) \qquad (58)$$

With substitution of $z = 5$ (m), ΔT_0 from Equation 56 and z_0 from Equation 55, Equation 58 becomes

$$b_{\Delta T} = 0.12\left[\frac{1 + 9.25 \cdot 10^{-3}t^{4/3}}{(5 + 5.46 \cdot 10^{-3}t - 2.52 \cdot 10^{-2}t^{4/5})^{5/3}}\right]^{1/2} \cdot (5 + 5.46 \cdot 10^{-3}t - 2.52 \cdot 10^{-2}t^{4/5}) \qquad (59)$$

This equation is plotted in Figure 2-1.9 up to the time the flames reach the 5-m height at $t = 303$ s. The temperature radius at the 5-m height is seen to vary from 0.59 m early in the fire to 0.83 m at 303 s. Plume fluid will reach a minimum of twice the temperature radius, $b_{\Delta T}$; hence, the total width of the plume in this example will be at least four times $b_{\Delta T}$, growing from a minimum of 2.4 m early in the fire to a minimum of 3.3 m as the flames reach the 5-m height.

Additional Flame Topics

Flame Pulsations

Flame pulsations have been studied by a number of investigators, tracing at least as far back as Rashbash et al.[56] and reviewed in conjunction with a recent study reported by Cetegen and Ahmed.[57] The two latter authors

summarize the published data on pulsation frequency in a single plot for burner or pool diameters ranging from 0.03 to 20 m and propose the simple curve fit

$$f(Hz) = 1.5[D(m)]^{-1/2} \quad (60)$$

As a measure of the data scatter it is noted that measured frequencies near a given diameter differ by a factor of up to two.

Wall/Corner Effects

McCaffrey[11] has reviewed effects on flame height of placing fire sources next to a wall or in a corner, referring to experiments by Hasemi and Tokunaga,[58] Back et al.,[59] Mizuno and Kawagoe,[60] and Kokkala.[61] The effects are generally reported to be small.

Windblown Flames

The main effect of wind is to bend or deflect the flames away from the vertical. Another effect, observed in wind tunnel studies by Welker and Sliepcevich[62] is "flame trailing," in which the flames trail off the burner along the floor in the downwind direction for a significant distance. Flame trailing was thought to be associated primarily with fuel vapors of greater density (higher molecular weight) than air, as was the case with all the various liquid fuels used in the experiments.

Wind tunnel measurements of flame deflection angle,[63] involving fire diameters in the range 0.10–0.60 m, and large scale data for square LNG pools in the effective diameter range 2–28 m, obtained by Attalah and Raj,[63] have been found to correlate well against the ratio of wind velocity to the maximum velocity in the flame according to Equation 28.[64] The relationship indicates that a flame deflection angle of approximately 25 degrees can be expected for a velocity ratio of 0.10. Effects of wind on flame length were minor for velocity ratios up to 0.35 (flame deflection angle of approximately 60 degrees). Data by Huffman et al.[65] indicate that at the considerably higher velocity ratio of 1.0, flame lengths are approximately 30 percent greater than under quiescent conditions.

Data Sources

NFPA 204M, *Guide for Smoke and Heat Venting*,[66] was referenced in this chapter for tables of heat release rate per unit floor area, kW/m^2, and growth times, t_g, of a number of fuel arrays. The same information has been incorporated by Alpert and Ward,[67] together with additional data.

In Section 3, Chapter 4 by Tewarson, tables are included to estimate combustion efficiencies as well as total and convective heat release rates per unit exposed area of materials under full-scale burning conditions.

Nomenclature

A	defined in Equation 6 (m·kW$^{-2/5}$)
B	buoyancy flux defined in Equation 15 (m^4·s^{-3})
b	plume radius (m)
$b_{\Delta T}$	plume radius to point where $\Delta T/\Delta T_0 = 0.5$ (m)
b_u	plume radius to point where $u/u_0 = 0.5$ (m)
b_{um}	b_u at level of maximum gas velocity near flame tip (m)
c	adjustable constant, Equation 35
c_p	specific heat of air at constant pressure (kJ/kg·K)
D	diameter (m)
F	function (c_p, T_∞, ρ_∞, g); see Equation 31 (m·kW$^{-2/5}$)
f	frequency (s^{-1})
g	acceleration due to gravity (m/s^2)
H_c	actual lower heat of combustion (kJ/kg)
I	intermittency
k	ratio of specific heats, constant-pressure versus constant-volume
L	mean flame height (m)
L_B	buoyancy controlled flame height (m)
L_M	momentum controlled flame height (m)
$\dot{m}_{ent}$	entrained mass flow rate in plume (kg/s)
$\dot{m}_{ent,L}$	$\dot{m}_{ent}$ at the mean flame height, L (kg/s)
$\dot{m}_f$	mass burning rate (kg/s)
N	nondimensional parameter defined in Equation 4
p_s	pressure in source gas discharge stream (Pa)
p_{s0}	pressure in source gas reservoir (Pa)
$\dot{Q}$	$\dot{m}_f H_c$, total heat release rate (kW)
$\dot{Q}_c$	convective heat release rate (kW)
$\dot{Q}_r$	radiative heat release rate (kW)
$\dot{Q}^*$	nondimensional parameter defined in Equation 1
R	radius (m)
r	actual mass stoichiometric ratio, air to fuel volatiles
R_M	momentum parameter defined in Equation 8
T	mean temperature (K)
T_0	mean centerline temperature in plume (K)
T_∞	ambient temperature (K)
T'	rms temperature fluctuation (K)
$T_a(z)$	ambient temperature at level z (K)
T_{a1}	ambient temperature at source level (K)
T_L	T_0 at mean flame height (K)
ΔT	$T - T_\infty$, mean temperature rise above ambient (K)
ΔT_0	value of ΔT on plume centerline (K)
ΔT_L	$T_L - T_\infty$ (K)
t	time (s)
t_g	growth time; see Equation 38 (s)
u	mean axial velocity (m/s)
u_0	mean axial velocity on centerline (m/s)
u_{0m}	maximum value of u_0, near flame tip (m/s)
u'	rms velocity fluctuation in axial direction (m/s)
W_f	fire perimeter (m)
z	height above top of combustible (m)
z_0	height of virtual origin above top of combustible (m)
z_m	maximum vertical penetration of plume fluid in stratified ambient (m)

α entrainment coefficient
ξ nondimensional parameter defined in Equation 26
ν_m kinematic viscosity of flame gases at maximum flame temperature ($m^2 \cdot s^{-1}$)
ρ mean density (kg/m^3)
ρ_{a1} ambient density at source level (kg/m^3)
$\rho_{f\ell}$ mean density in flames (kg/m^3)
ρ_s density of source gas discharge stream (kg/m^3)
ρ_{s0} density of source gas in reservoir (kg/m^3)
$\rho_{s\infty}$ density of source gas at ambient temperature and pressure (kg/m^3)
ρ_∞ ambient density (kg/m^3)
$\Delta\rho$ $\rho_\infty - \rho$, mean density deficiency (kg/m^3)
$\sigma_{\Delta T}$ plume radius to point where $\Delta T/\Delta T_0 = e^{-1}$ (m)
σ_u plume radius to point where $u/u_0 = e^{-1}$ (m)

CHAPTER 2

Ceiling Jet Flows

Ronald L. Alpert

Introduction

Much of the hardware associated with detection and suppression of fire, in commercial, manufacturing, storage, and modern residential buildings is located near the ceiling surfaces. In case of a fire, hot gases in the fire plume rise directly above the burning fuel and impinge on the ceiling. The ceiling surface causes the flow to turn and move horizontally under the ceiling to other areas of the building remote from the fire position. The response of smoke detectors, heat detectors, and sprinklers installed below the ceiling so as to be submerged in this hot flow of combustion products from a fire provides the basis for building fire protection.

Studies quantifying the flow of hot gases under a ceiling resulting from the impingement of a fire plume have been conducted since the 1950s. Studies at the Fire Research Station in Great Britain,[1,2] Factory Mutual Research Corporation,[3–7] the National Institute of Standards and Technology (NIST),[8,9] and at other research laboratories[10,11] have sought to quantify the gas temperatures and velocities in the hottest portion of the flow produced by steady fires beneath smooth, unconfined horizontal ceilings.

Ceiling jet refers to the relatively rapid gas flow in a shallow layer beneath the ceiling surface that is driven by the buoyancy of the hot combustion products from the plume. Figure 2-2.1 shows an idealization of an axisymmetric ceiling jet flow at varying radial positions, r, beneath an unconfined ceiling. In actual fires within buildings, the simple conditions pictured—a hot, rapidly moving gas layer sandwiched between the ceiling surface and tranquil, ambient-temperature air—exist only at the beginning of a fire, when the quantity of combustion gases produced is not sufficient to accumulate into a stagnant, heated gas layer in the upper portion of the compartment. Venting the ceiling jet flow through openings in the ceiling surface or edges can retard the accumulation of this heated gas layer.

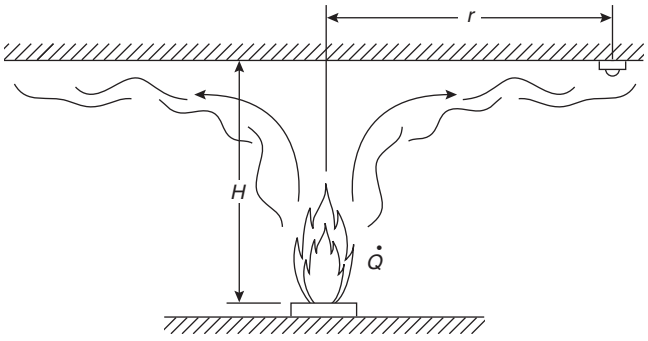

Figure 2-2.1. ***Ceiling jet flow beneath an unconfined ceiling.***

As shown in Figure 2-2.1, the ceiling jet flow emerges from the region of plume impingement on the ceiling, flowing radially away from the fire. As it does, the layer grows thicker by entraining room air at the lower boundary. This entrained air cools the gases in the jet and reduces its velocity. As the hot gases move out across the ceiling, heat transfer cools the portion adjacent to the ceiling surface.

Steady Fires

Weak Plume-Driven Flow Field

A generalized theory to predict gas velocities, gas temperatures, and the thickness (or depth) of a steady fire-

Dr. Ronald L. Alpert received his undergraduate and graduate education at the Massachusetts Institute of Technology, where he majored in mechanical engineering. He is manager of the Flammability Technology Research Program at Factory Mutual Research. Dr. Alpert currently chairs the ASTM subcommittee on Fire Safety Engineering and the U.S. Technical Advisory Group to ISO TC92/SC4 (Fire Safety Engineering). He has published numerous papers in refereed journals and technical reports.

driven ceiling jet flow has been developed by Alpert[4] for the case of a weak plume, when flame height is much less than the height, H, of the ceiling above the burning fuel. This work involves the use of several idealizations in the construction of the theoretical model, but results are likely to provide reasonable estimates over radial distances of one or two ceiling heights from the point of fire plume impingement on the ceiling.

Ceiling jet thickness: Alpert defined the thickness of the ceiling jet, ℓ_T, as the distance below the ceiling where the excess of gas temperature above the ambient value, ΔT, drops to $1/e$ (1/2.718 …) of the maximum excess temperature. Based on this definition, measurements obtained with a liquid pool fire 8 m beneath a ceiling show that ℓ_T/H is about 0.075 at an r/H of 0.6, increasing to a value of 0.11 for r/H from about 1 to 2. These results are in good agreement with detailed measurements and analysis for the region $r/H < 2$ performed by Motevalli and Marks[12] during their small-scale (0.5- and 1.0-m ceiling heights) experiments. The following correlation for ℓ_T/H developed by Motevalli and Marks from their temperature data confirms the predicted constancy of ceiling jet thickness (at about 10 to 12% of H) for $r/H > 1$ from Alpert's theory:

$$\frac{\ell_T}{H} = 0.112\left[1 - \exp\left(-2.24\,\frac{r}{H}\right)\right] \qquad \text{for } 0.26 \le \frac{r}{H} \le 2.0 \tag{1}$$

Additional measurements of ceiling jet thickness, for steady flows induced by strong plumes and for transient flows, are discussed later.

Within the ceiling jet flow, the location of maximum excess temperature and velocity are predicted[4] to be highly scale dependent, even after normalization by the ceiling height. Measurements of the distance below the ceiling at which these maxima occur have been made mainly for 1-m scale experiments.[12,15] Results show distances below the ceiling ranging from about 1 to 2 percent of the ceiling height for r/H from less than 1 to 2, with predicted reductions in the percent of ceiling height at larger scales.

Much of the discussion below deals with predictions and correlations of the maximum excess temperature and velocity in the ceiling jet flow, which occur, as already noted, relatively close to the ceiling surface. Often fire detectors or sprinklers are placed at ceiling standoff distances that are outside of this region and therefore will experience cooler temperatures and lower velocities than predicted. In facilities with very high ceilings, the detectors could be closer to the ceiling than 1 percent of the fire source-to-ceiling separation and will fall in the ceiling jet thermal and viscous boundary layers. In low-ceiling facilities, it is possible for sprinklers or detectors to be placed outside of the ceiling jet flow entirely if the standoff is greater than 12 percent of the fire source-to-ceiling height. In this case, response time could be drastically increased.

Ceiling jet temperature and velocity: Alpert[3] has developed easy-to-use correlations to quantify the maximum gas temperature and velocity at a given position in a ceiling jet flow produced by a steady fire. These correlations are widely used in hazard analysis calculations. Evans and Stroup[13] have employed the correlations in the development of a generalized program to predict heat detector response for the case of a detector totally submerged in the ceiling jet flow. The correlations are based on measurements collected during fire tests involving fuel arrays of wood and plastic pallets, empty cardboard boxes, plastic materials in cardboard boxes, and liquid fuels. Heat release rates for these fuels range from 668 kW to 98 MW while total ceiling heights range from 4.6 to 15.5 m. In SI units, Alpert's[3] correlations for maximum ceiling jet temperatures and velocities are as follows:

$$T - T_\infty = 16.9\,\frac{\dot{Q}^{2/3}}{H^{5/3}} \qquad \text{for } r/H \le 0.18 \tag{2}$$

$$T - T_\infty = 5.38\,\frac{\dot{Q}^{2/3}/H^{5/3}}{(r/H)^{2/3}} \qquad \text{for } r/H > 0.18 \tag{3}$$

$$U = 0.96\left(\frac{\dot{Q}}{H}\right)^{1/3} \qquad \text{for } r/H \le 0.15 \tag{4}$$

$$U = 0.195\,\frac{(\dot{Q}/H)^{1/3}}{(r/H)^{5/6}} \qquad \text{for } r/H > 0.15 \tag{5}$$

where temperature, T, is in °C; velocity, U, is in m/s; total heat release rate, $\dot{Q}$, is in kW; and radial position and ceiling height (r and H) are in m.

Data from these fire tests are correlated using the total rate at which heat is actually released in the fire. Even though it is the convective component of this total heat release rate that is directly related to the buoyancy of the fire, most available data are correlated using the total heat release rate. For the liquid alcohol pool fires that constitute the primary basis of the correlation developed by Alpert, the total heat release rate is roughly the same as the convective heat release rate, $\dot{Q}_c$. However, for the remaining solid commodities and pallets, the convective heat release rate is about 60 percent of the total rate at which heat is actually released. Hence, for general commodities, it may be inaccurate to assume that convective heat release rate is always equal to the total heat release rate, $\dot{Q}$.

The correlations for both temperatures and velocities (Equations 2, 3, 4, and 5) are broken into two parts. One part applies for the ceiling jet in the area of the impingement point where the upward flow of gas in the plume turns to flow out beneath the ceiling horizontally. These correlations (Equations 2 and 4) are independent of radius and are actually axial plume-flow temperatures and velocities calculated at the ceiling height above the fire source. The other correlations apply outside of this turning region as the flow moves away from the impingement area.

Certain constraints should be understood when applying these correlations in the analysis of fire flows. The correlations apply only during times after fire ignition when the ceiling flow may be considered unconfined; that is, no accumulated warm upper layer is present. Walls close to the fire affect the temperatures and velocity in the ceiling jet independent of any effect on the fire-burning rate due to radiant heat received from the walls. The correlations were developed from test data to apply in cases

where the fire source is at least a distance 1.8 times the ceiling height from the enclosure walls. For special cases where burning fuel is located against a flat wall surface or two wall surfaces forming a 90-degree corner, the correlations are adjusted based on the method of reflection. This method makes use of symmetry to account for the effects of the walls in blocking entrainment of air into the fire plume. For the case of a fire adjacent to a flat wall, $2\dot{Q}$ is substituted for $\dot{Q}$ in the correlations. For a fire in a 90-degree corner, $4\dot{Q}$ is substituted for $\dot{Q}$ in the correlations.[3]

Experiments have shown that unless great care is taken to ensure that the fuel perimeter is in contact with the wall surfaces, the method of reflection used to estimate the effects of the walls on ceiling jet temperature will be inaccurate. For example, Zukoski et al.[14] found that a circular burner placed against a wall so that only one point on the perimeter contacted the wall, behaved almost identically to a fire far from the wall with plume entrainment only decreasing by 3 percent. When using Equations 2, 3, 4, and 5, this fire would be represented by replacing $\dot{Q}$ with $1.05\dot{Q}$ and not $2\dot{Q}$ as would be predicted by the method of reflections. The value of $2\dot{Q}$ would be appropriate for a semicircular burner with the entire flat side pushed against the wall surface.

Consider the following calculations, which demonstrate typical uses of the correlations Equations 2, 3, 4, and 5.

(a) The maximum excess temperature under a ceiling 10 m directly above a 1.0-MW heat-release-rate fire is calculated using Equation 2 as

$$T - T_\infty = \frac{16.9(1000)^{2/3}}{10^{5/3}}$$

$$= \frac{16.9(100)}{46.42}$$

$$\Delta T = 36.4\ ^\circ C$$

(b) For a fire that is against noncombustible walls in a corner of a building and 12 m below the ceiling, the minimum heat release rate needed to raise the temperature of the gas below the ceiling 50°C at a distance 5 m from the corner is calculated using Equation 3 and the symmetry substitution of $4\dot{Q}$ for $\dot{Q}$ to account for the effects of the corner as

$$T - T_\infty = 5.38\,\frac{(4\dot{Q})^{2/3}/H^{5/3}}{(r/H)^{2/3}}$$

$$50 = 5.38\,\frac{(4\dot{Q})^{2/3}}{12^{5/3}(5/12)^{2/3}}$$

$$\dot{Q} = \frac{5}{4}\left[\frac{50(12)}{5.38}\right]^{3/2}$$

$$\dot{Q} = 1472\ \text{kW} = 1.472\ \text{MW}$$

(c) The maximum velocity at this position is calculated from Equation 5, modified to account for the effects of the corner as

$$U = 0.195\,\frac{(4\dot{Q}/H)^{1/3}}{(r/H)^{5/6}}$$

$$= \frac{0.195(5888)^{1/3}}{(5/12)^{5/6}12^{1/3}}$$

$$U = 3.2\ \text{m/s}$$

Nondimensional ceiling jet relations: Heskestad[7] developed correlations* for maximum ceiling jet excess temperature and velocity based on alcohol pool-fire tests performed at the U.K. Fire Research Station in the 1950s. These correlations are cast in the following heat-release-rate, excess temperature, and velocity variables that are nondimensional (indicated by the superscript asterisk) and applicable to steady-state fires under unconfined ceilings (indicated by the subscript 0):

$$\dot{Q}_0^* = \frac{\dot{Q}}{\rho_\infty c_p T_\infty g^{1/2} H^{5/2}} \tag{6}$$

$$\Delta T_0^* = \frac{\Delta T/T_\infty}{(\dot{Q}_0^*)^{2/3}} \tag{7}$$

$$U_0^* = \frac{U/\sqrt{gH}}{(\dot{Q}_0^*)^{1/3}} \tag{8}$$

Figure 2-2.2 shows a plot of the Heskestad correlation for excess temperature and velocity data as solid line curves. The correlations developed by Alpert[3] are plotted as broken curves, using the same dimensionless parameters with assumed ambient temperature of 293 K (20°C), normal atmospheric pressure, and convective heat release rate equal to the total heat release rate, $\dot{Q}_c = \dot{Q}$. Generally, the results of Heskestad[7] predict slightly higher excess temperatures and substantially greater gas velocities than Alpert's[3] results. Another curve shown in Figure 2-2.2 is a fit to the mean ceiling jet velocity predicted by the generalized theory of Reference 4, which also predicts that the turning-region boundary should be at $r/H = 0.17$. This predicted velocity is reasonably close to Heskestad's[7] experimental correlation for velocity. Based on the results shown in Figure 2-2.2, the nondimensional excess temperature from the Heskestad[7] correlation and the nondimensional velocity from Alpert's theory,[4,15] are recommended for the prediction of steady ceiling jet flows beneath unobstructed ceilings. The Heskestad correlation and the Alpert theory are adequately fit, respectively, by the following expressions:

$$\Delta T_0^* = \left(0.225 + 0.27\,\frac{r}{H}\right)^{-4/3} \qquad \text{for } 0.2 \le r/H < 4.0 \tag{9}$$

$$\Delta T_0^* = 6.3 \qquad \text{for } r/H \le 0.2 \tag{10}$$

$$U_0^* = 1.06\left(\frac{r}{H}\right)^{-0.69} \qquad \text{for } 0.17 \le r/H < 4.0 \tag{11}$$

$$U_0^* = 3.61 \qquad \text{for } r/H \le 0.17 \tag{12}$$

*Originally developed by G. Heskestad and C. Yao in "A New Approach to Development of Installation Standards for Fired Detectors," *Technical Proposal No. 19574,* prepared for The Fire Detection Institute, by Factory Mutual Research Corporation, Norwood, MA (1971).

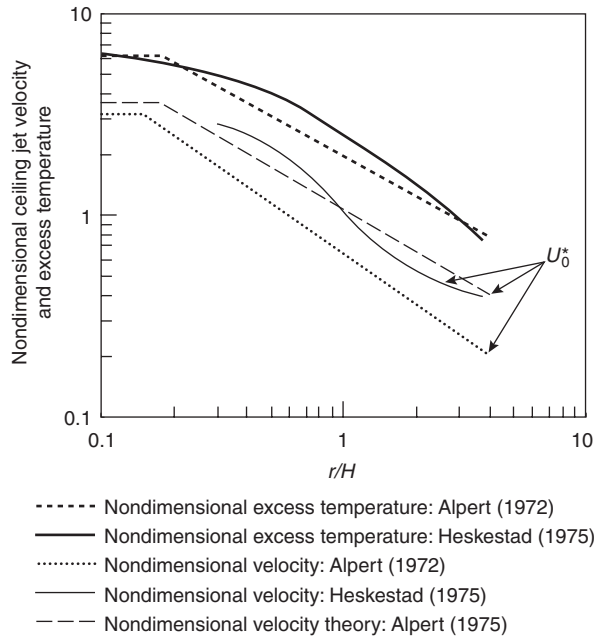

Figure 2-2.2. ***Dimensionless correlations for maximum ceiling jet temperatures and velocities produced by steady fires. Solid line: Heskestad;[7] dotted line: Alpert.[3]***

Heskestad and Delichatsios[24] examined the original data from Reference 7 and concluded that nondimensional velocity and temperature could be related by the following equation:

$$\frac{U_0^*}{\sqrt{\Delta T_0^*}} = 0.68\left(\frac{r}{H}\right)^{-0.63} \qquad \text{for } r/H \geq 0.3 \qquad (13)$$

The preceding relation has been found applicable to a much wider range of conditions than just steady-state alcohol pool fires having weakly buoyant plumes. For example, this relationship between ceiling jet velocity and excess temperature is consistent with measurements[24] for time-dependent fires having strong plumes.

Other methods used to calculate ceiling jet velocity and maximum possible (when the ceiling is adiabatic) ceiling jet temperatures are reported by Cooper and Woodhouse.[9] A critical review of correlation formulas for excess temperature and velocity in the ceiling jet under a variety of conditions has been assembled by Beyler.[16] To apply these and the preceding expressions to realistic burning situations, it is recommended that the convective heat release rate should be used.

Strong Plume-Driven Flow Field

Ceiling jet temperature: When the flame height of a fire plume is comparable to the height of the ceiling above the burning fuel, the resultant ceiling jet is driven by a strong plume. Heskestad and Hamada[6] measured ceiling jet temperatures for ratios of free flame height (in the absence of a ceiling, obtained from existing knowledge of flame heights) to ceiling height ranging from 0.3 up to 3. A correlation of excess temperatures could be achieved by using the plume radius, b, at the ceiling as a normalizing length scale, rather than the ceiling height used for the case of a weak plume. This correlation takes the form:

$$\frac{\Delta T}{\Delta T_p} = 1.92\left(\frac{r}{b}\right)^{-1} - \exp\left[1.61\left(1 - \frac{r}{b}\right)\right] \qquad \text{for } 1 \leq \frac{r}{b} \leq 40 \qquad (14)$$

where ΔT_p is the excess temperature on the plume centerline at the level of the ceiling (obtained from Equations 2 or 10 or other fire-plume relations) and b is the radius where the velocity of the impinging plume is one-half the centerline value. The expression for this characteristic plume radius is given by

$$b = 0.42[(c_p\rho_\infty)^{4/5} T_\infty^{3/5} g^{2/5}]^{-1/2} \frac{T_p^{1/2} \dot{Q}_c^{2/5}}{\Delta T_p^{3/5}} \qquad (15)$$

The Heskestad and Hamada[6] correlation is derived from measurements made with propane burner fires having heat release rates from 12 to 764 kW and beneath ceilings up to 2.5 m in height. This correlation is found to be accurate for ratios of free flame height to ceiling height less than or equal to about 2.0. At greater flame-height ratios, significant heat released in the ceiling jet itself appears to be the cause for a lack of agreement with the correlation.

Flame lengths in the ceiling jet: It is very interesting to note an often-overlooked finding of Heskestad and Hamada.[6] When there is flame impingement on the ceiling (flame-height ratio > 1), the mean flame radius along the ceiling from the plume centerline is observed to be about equal to the difference between the free flame height and the ceiling height. Hence, Heskestad and Hamada find that the total average length of flame from the burning fuel to the flame tip under the ceiling is virtually the same as the free flame height.

In an earlier study involving small (0.36 to 8 kW) pool fires beneath ceilings up to 0.336 m in height, Yu (You)* and Faeth[10] measure the mean flame radius along the ceiling. Their results yield a flame radius about one-half the difference between the free flame height and the ceiling height, or one-half that of Heskestad and Hamada, perhaps due to the smaller scale of their experiment.

Ceiling jet thickness: For strong plumes, Atkinson and Drysdale[17] demonstrate that much of the plume kinetic energy is lost (possibly 75 percent of that in the incident plume) during the process of ceiling impingement. As a result of this kinetic energy loss, the initial ceiling jet thickness after the turning region may be twice that expected for the case of weak plumes, about 11 percent of the ceiling height at $r/H = 0.2$. Measurements made by Atkinson and Drysdale and by Yu[5] show that the ceiling jet thickness may reach a minimum of 8 percent of ceiling height at $r/H = 0.5$ and then increase up to 12 percent of ceiling height at large radial distances, as for weak plumes.

*H. Z. Yu formerly published under the spelling *You.*

Convective Heat Transfer to the Ceiling

Convection is the dominant mode of heat transfer for the case of weak plumes impinging on ceilings. This heat-transfer regime is important for the prediction of activation times for detection devices and the prediction of damage for objects, such as cables or pipes, suspended below the ceiling. However, damage to the ceiling structure itself will much more likely be the result of strong plume (flame) impingement, for which heat transfer due to thermal radiation will be just as important or more important than convection. The maximum convective heat flux to a ceiling occurs when the ceiling surface is at or near ambient temperature, T_∞, before there has been any significant heating of the ceiling material. This maximum convective flux is the subject of the following discussion. For additional discussion of ceiling heat loss, see Section 2, Chapter 14.

Weak Plume Impingement (Turning) Region

Quantification of convective heat transfer from weak fire plumes impinging on ceiling surfaces has been an area of research activity for many years. In the turning region, a widely used correlation is derived by Yu and Faeth, from experiments with small pool fires (convective heat release rates, $\dot{Q}_c$, from 0.05 to 3.46 kW; ceiling heights, H, less than 1 m). This correlation gives convective heat flux to the ceiling, $\dot{q}''$, as

$$\frac{\dot{q}''H^2}{\dot{Q}_c} = \frac{31.2}{\mathrm{Pr}^{3/5}\,\mathrm{Ra}^{1/6}} = \frac{38.6}{\mathrm{Ra}^{1/6}} \tag{16}$$

where Pr is the Prandtl number, and the plume Rayleigh number, Ra, is given by

$$\mathrm{Ra} = \frac{g\dot{Q}_c H^2}{3.5 p \nu^3} = \frac{0.027\dot{Q}_c H^2}{\nu^3} \tag{17}$$

for gases similar to air, having ambient absolute pressure, p, and kinematic viscosity, ν. It is recommended that when these expressions are applied to actual heat-transfer problems, the ceiling height be corrected for the location of the virtual point source for the plume.

Note that the heat-flux parameter on the left side of Equation 16 is proportional to the classic heat-transfer Stanton number and that the Rayleigh number is proportional to the cube of the plume Reynolds number, Re (defined in terms of centerline velocity, characteristic plume diameter, $2b$, and kinematic viscosity at the plume centerline temperature).

Equation 16 has been established for mainly weak plumes with Rayleigh numbers from 10^9 to 10^{14}. Kokkala[18] has verified this impingement zone heat-transfer correlation, using up to 10 kW natural gas flames, for flame heights up to 70 percent of the ceiling height. For greater flame height to ceiling height ratios, Kokkala[18] finds that heat-transfer rates are many times higher than predicted, partly due to thermal radiation.

Alpert[19] performed small-scale (0.3-m ceiling height) experiments at elevated air pressures, which allow Rayleigh numbers greater than 2×10^{15} to be achieved while maintaining somewhat better control of ambient disturbances than in 1-atm experiments. Results of these experiments essentially confirm the predictions of the correlation in Equation 16, as well as an expression recommended for the plume impingement region by Cooper.[8] The latter expression yields nondimensional ceiling heat transfer, in terms of the plume Reynolds number defined by Alpert,[19] as follows:

$$\frac{\dot{q}''H^2}{\dot{Q}_c} = 49 \times \mathrm{Re}^{-1/2} = 105\left(\frac{\dot{Q}_c^{1/3}H^{2/3}}{\nu}\right)^{-1/2} \tag{18}$$

Although Equations 16 and 18 have identical dependence of impingement heat flux on fire heat release rate and ceiling height, heat-flux values from Equation 18 are about 50 percent higher, since this expression is derived from data on turbulent jets.

Ceiling Jet Region

Outside of the turning region, the convective flux to the ceiling is known to drop off sharply with increasing radial distance from the plume axis. The experiments of Yu and Faeth[10] described in the preceding section were also used to determine this radial variation in ceiling jet convective flux. Their own data, as well as data from small-scale experiments (ceiling heights of 0.5 to 0.8 m) by Alpert[15] and by Veldman[11] are all consistent with the following correlation that is given in Reference 10:*

$$\frac{\dot{q}''H^2}{\dot{Q}_c} = 0.04\left(\frac{r}{H}\right)^{-1.3} \qquad \text{for } 0.2 \le \frac{r}{H} < 2.0 \tag{19}$$

An alternate derivation of Equation 19 can be obtained by using Alpert's correlation for ceiling jet excess temperature (Equation 3) and Alpert's theory for average ceiling jet velocity (Equation 11) with the Reynolds/Colburn analogy, as discussed in References 10 and 11. From the Reynolds/Colburn analogy, the heat-transfer coefficient at the ceiling, h, should be related to ceiling jet average velocity and density as follows:

$$\frac{h}{\rho_\infty U c_p} = \mathrm{Pr}^{-2/3}\frac{f}{2} \tag{20}$$

where Pr is the Prandtl number and f is the ceiling friction factor. By using Equation 11 for average ceiling jet velocity, U, the ceiling heat-transfer coefficient becomes

$$h = 0.246\, f\left(\frac{\dot{Q}_c}{H}\right)^{1/3}\left(\frac{r}{H}\right)^{-0.69} \qquad \text{for } 0.17 \le \frac{r}{H} < 4.0 \tag{21}$$

With $f = 0.03$, Equation 21 is identical to the simplified expression listed in Beyler's extensive compilation.[16] The nondimensional heat flux to a ceiling at ambient temperature can then be expressed as follows, since $\dot{q}'' = h\Delta T$, with ΔT given by Equation 3:

$$\frac{\dot{q}''H^2}{\dot{Q}_c} = 1.323f\left(\frac{r}{H}\right)^{-1.36} \qquad \text{for } 0.2 \le \frac{r}{H} < 4.0 \tag{22}$$

*Note that there is a typographical error in the exponent of r/H in Equation 17 of this reference.

Equations 19 and 22 are in good agreement for a friction factor of 0.03, which is comparable with the value of 0.02 deduced from the theory of Reference 4.

Sloped Ceilings

There have been very few studies of the ceiling jet flow that results from plume impingement on a flat ceiling that is not horizontal, but is inclined at some angle, θ, to the horizontal. One such study, by Kung et al.,[20] obtained measurements showing pronounced effects in the velocity variation along the steepest run from the point of impingement of a strong plume, both in the upward and downward directions. In the upward direction, the rate of velocity decrease with distance, r, from the intersection of the plume vertical axis with the ceiling was reduced significantly as the ceiling slope increased. In the downward direction, the flow separated from the ceiling and turned upward at a location, $-r$, denoted by Kung et al.[20] as the penetration distance. These results were the outcome of experiments with 0.15- and 0.228-m-diameter pan fires located 0.279 to 0.889 m beneath an inclined 2.4-m square ceiling and were limited to convective heat release rates in the range of 3 to 13 kW.

Following Heskestad and Hamada,[6] Kung et al. developed correlations by scaling near-maximum excess temperature and velocity, as well as radial distance along the ceiling, in terms of the quantities in the undeflected plume at the impingement point. These correlations take the following form:

$$\frac{\Delta T}{\Delta T_p} = \exp\left[(0.12\sin\theta - 0.42)\left(\frac{r}{b} - 1\right)^{0.7}\right] \quad (23)$$

$$\frac{U}{V_p} = \exp\left[(0.79\sin\theta - 0.52)\left(\frac{r}{b} - 1\right)^{0.6}\right] \quad (24)$$

for $r/b \geq 1$ (upward direction from the impingement point) and $\theta = 0 - 30°$;

$$\frac{\Delta T}{\Delta T_p} = (0.15\sin\theta + 0.11)\left(\frac{r}{b}\right) + 0.97 - 0.06\sin\theta \quad (25)$$

$$\frac{U}{V_p} = (0.21\sin\theta + 0.10)\left(\frac{r}{b}\right) + 0.99 - 1.17\sin\theta \quad (26)$$

for $r/b < 0$ (downward direction from the impingement point), valid only for $\theta = 10 - 30°$, and for ΔT and $U \geq 0$.

In Equations, 23, 24, 25, and 26, the characteristic plume radius is proportional to that defined in Equation 15 but with a slightly different magnitude, namely,

$$b = 0.548[(c_p\rho_\infty)^{4/5}T_\infty^{3/5}g^{2/5}]^{-1/2}\frac{T_p^{1/2}\dot{Q}_c^{2/5}}{\Delta T_p^{3/5}} \quad (27)$$

Equation 26 shows that the ceiling jet velocity first becomes zero in the downward direction at values of r/b equal to -5.6, -3.5, and -2.0 for ceiling slopes of 10°, 20°, and 30°, respectively.

Time-Dependent Fires

Quasi-Steady Assumption

For time-dependent fires, all estimates from the previous section may still be used, but with the constant heat release rate, $\dot{Q}$, replaced by an appropriate time-dependent $\dot{Q}(t)$. In making this replacement, a "quasi-steady" flow has been assumed. This assumption implies that when a change in heat release rate occurs at the fire source, full effects of the change are immediately felt everywhere in the flow field. In a room-size enclosure, under conditions where the fire is growing slowly, this assumption is reasonable. However, in other cases, the time for the heat release rate to change significantly may be comparable to or less than the time, $t_f - t_i$, for gas to travel from the burning fuel to a detector submerged in the ceiling jet. The quasi-steady assumption may not be appropriate in this situation, unless the following condition is satisfied, depending on the accuracy desired:

$$\frac{\dot{Q}}{d\dot{Q}/dt} > t_f - t_i \quad (28)$$

where t_i is an ignition reference time.

The quasi-steady assumption, together with the strong plume-driven ceiling jet analysis of Heskestad and Hamada,[6] has been used by Kung et al.[21] to correlate ceiling jet velocity and temperature induced by growing rack-storage fires. Although gas travel times for these large-scale experiments may amount to many seconds, Equation 28 shows that a sufficiently small fire-growth rate allows a quasi-steady analysis to be used.

Testing has shown that the heat release rate during the growth phase of many fires can often be characterized by simple time-dependent polynomial or exponential functions. The most extensive research and analysis have been performed with heat release rates that vary with the second power of time.

Power-Law Fire Growth

The growth phase of many fires can be characterized by a heat release rate increasing proportionally with a power, p, of time measured from the ignition reference time, t_i, as follows:

$$\dot{Q} = \alpha(t - t_i)^p \quad (29)$$

Figure 2-2.3 shows one case where the heat release rate for a burning foam sofa during the growth phase of the fire, more than 80 s (t_i) after ignition,[22] can be represented by the following equation:

$$\dot{Q} = 0.1736(t - 80)^2 \quad (30)$$

Heskestad[23] used the general power-law behavior given by Equation 29 to propose a set of theoretical modeling relations for the transient ceiling jet flow that would result from such a time-varying heat release rate. These relations were validated in an extensive series of tests conducted by Factory Mutual Research Corporation,[24,25] where measurements were made of maximum ceiling jet

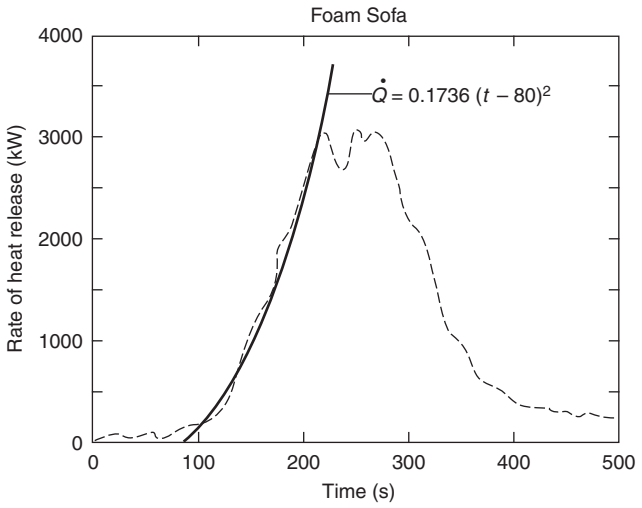

Figure 2-2.3. ***Heat release rate history for a burning foam sofa.[22]***

temperatures and velocities during the growth of fires in three different sizes of wood crib. Subsequent to this original experimental study, Heskestad and Delichatsios[26] corrected the heat release rate, $\dot{Q}$, computed for the crib tests and also generalized their results to other types of fuels by using the more relevant, convective heat release rate, $\dot{Q}_c$. The resulting dimensionless correlations for maximum ceiling jet temperatures and velocities are given by

$$\Delta T_2^* = 0 \qquad t_2^* \le (t_2^*)_f \tag{31}$$

$$\Delta T_2^* = \left(\frac{t_2^* - (t_2^*)_f}{0.126 + 0.210 r/H} \right)^{4/3} \qquad t_2^* > (t_2^*)_f \tag{32}$$

$$\frac{U_2^*}{\sqrt{\Delta T_2^*}} = 0.59 \left(\frac{r}{H} \right)^{-0.63} \tag{33}$$

where

$$t_2^* = \frac{t - t_i}{(A\alpha_c H^{-4})^{-1/5}} \tag{34}$$

$$U_2^* = \frac{U}{(A\alpha_c H)^{1/5}} \tag{35}$$

$$\Delta T_2^* = \frac{(T - T_\infty)/T_\infty}{(A\alpha_c)^{2/5} g^{-1} H^{-3/5}} \tag{36}$$

$$A = \frac{g}{\rho_\infty c_p T_\infty} \tag{37}$$

$$\alpha_c = \frac{\dot{Q}_c}{(t - t_i)^2} \tag{38}$$

$$(t_2^*)_f = 0.813 \left(1 + \frac{r}{H} \right) \tag{39}$$

and where dimensionless variables are indicated with the superscript asterisk.

Notice that in Equation 32 the dimensionless time, t_2^*, has been reduced by the time $(t_2^*)_f$. This reduction accounts for the gas travel time, $t_f - t_i$, between the fire source and the location of interest along the ceiling at the specified r/H. For dimensionless times after ignition less than $(t_2^*)_f$, the initial heat front has not yet arrived at r/H, so the gas temperature is still at the ambient value, as shown in Equation 31. In dimensional terms, the gas travel time is given by the following, after using the definition of t_2^* in Equation 39:

$$t_f - t_i = H^{4/5} \frac{0.813(1 + r/H)}{(A\alpha_c)^{1/5}} \tag{40}$$

Substitution of Equation 29 into Equation 28 shows that for power-law fire growth, the quasi-steady assumption will always be valid beginning at a sufficiently long time after ignition. For the specific case of t^2 fire growth, substitution of Equation 38 and the expression for the gas travel time, Equation 40, into Equation 28 results in the following requirement if a quasi-steady analysis is to be appropriate:

$$\frac{t - t_i}{2} > H^{4/5} \frac{0.813(1 + r/H)}{(A\alpha_c)^{1/5}} \tag{41}$$

In the limit of very large values of $t - t_i$, Equation 41 will always be satisfied and a quasi-steady limit is achieved, as shown by an alternative method in Reference 24. The value of the quasi-steady excess temperature, $(\Delta T_2^*)_{qs}$, in this limit of $t_2^* \gg (t_2^*)_f$ becomes, from Equation 32

$$(\Delta T_2^*)_{qs} = \left(\frac{t_2^*}{0.126 + 0.210 r/H} \right)^{4/3} \tag{42}$$

The preceding correlations of ceiling jet temperatures and velocities are the basis for the calculated values of fire detector spacing found in NFPA 72®, *National Fire Alarm Code®*, Appendix B, "Engineering Guide for Automatic Fire Detector Spacing."[27] In NFPA 72, three or four selected fire heat release rates assumed to increase proportionally with the square of time are used as the basis for the evaluation. These fire heat release rate histories are chosen to be representative of actual fires involving different commodities and geometric storage arrangements. The chosen release-rate histories are as follows:

Slow, $\dot{Q} = 0.00293 t^2$ (43)

Medium, $\dot{Q} = 0.01172 t^2$ (44)

Fast, $\dot{Q} = 0.0469 t^2$ (45)

Ultrafast, $\dot{Q} = 0.1876 t^2$ (46)

where $\dot{Q}$ is in kW and t is in s.

EXAMPLE:

Sofa fire: Consider how the following calculation demonstrates a use of the correlation (Equations 32 and 33) for calculating the ceiling jet maximum temperature and velocity produced by a t^2 fire growth.

A foam sofa, of the type analyzed in Figure 2-2.3, is burning in a showroom 5 m below a suspended ceiling. The showroom temperature remote from the fire remains at 20°C at floor level as the fire begins to grow. Determine the gas temperature and velocity at the position of a ceiling-mounted fire detector submerged in the ceiling jet flow 4 m away from the fire axis when the convective heat release rate (assumed to equal the total heat release rate) first reaches 2.5 MW.

Figure 2-2.3 shows that the heat release rate from the sofa first reaches 2.5 MW (2500 kW) at about 200 s after ignition. Using the analytic formula for the time-dependent heat release rate, Equation 30, the time from the virtual ignition of the sofa at 80 s to reach 2500 kW is

$$2500 = 0.1736(t - 80)^2$$
$$(t - 80) = 120 \text{ s}$$

In this problem, the low-level heat release rate up to 80 s after actual ignition of the sofa is ignored. Thus, the sofa fire can be treated as having started at $t = 80$ s and grown to 2.5 MW in the following 120 s. Equations 34 through 39 are used to evaluate parameters of the problem, using the dimensionless correlations for ceiling jet temperature and velocity.

For the sofa fire in the showroom example, $T_\infty = 293$ K, $\rho = 1.204$ kg/m^3, $c_p = 1$ kJ/kg·K, $g = 9.8$ m/s^2, $\alpha_c = 0.1736$ kW/s^2, $A = 0.0278$ m^4/kJ·s^2, $r = 4$ m, $H = 5$ m, $(t_2^*)_f = 1.46$, $t - t_i = 120$ s, and $t_2^* = 11.40$. For the conditions of interest, $t_2^* > (t_2^*)_f$, so the correlation (Equation 32) is used to evaluate the dimensionless ceiling jet temperature:

$$\Delta T_2^* = \left[\frac{11.40 - 1.46}{0.126 + 0.210(4/5)}\right]^{4/3}$$
$$\Delta T_2^* = 109.3$$

Equation 33 is used to calculate the dimensionless ceiling jet velocity

$$U_2^* = 0.59(4/5)^{-0.63}\sqrt{109.3}$$
$$= 7.10$$

The dimensional excess temperature and velocity are calculated using Equations 36 and 35, respectively, to yield

$$\Delta T = 147 \text{ K}$$
$$T = 147 \text{ K} + 293 \text{ K} = 440 \text{ K} = 167°\text{C}$$
$$U = 3.37 \text{ m/s}$$

The corresponding gas temperature calculated with the quasi-steady analysis of Equation 42 instead of the t^2 fire analysis is 197°C.

EXAMPLE:

Rack storage: Yu and Stavrianidis[28] were interested in predicting activation times of quick-response sprinklers protecting high rack storage of plastics. Since the sprinklers are activated typically in less than 1 min by the ceiling jet flow, information on flow temperature and velocity shortly after ignition is required. The objective was to correlate properties of the ceiling jet induced by fires in 2- to 5-tier-high rack storage, consisting of polystyrene cups packaged in corrugated paper cartons on pallets. When this fuel array is ignited at its base, the initial growth period ($t - t_i \approx 25$ s) can be characterized as heat release rates increasing by the third power of time, as follows:

$$\dot{Q}_c = \alpha_c(t - t_i)^3 \tag{47}$$

where $\alpha_c = 0.0448$. Because of upward and lateral flame propagation during the transient rack-storage fire, the virtual origin elevation, z_o, of the plume changes during the course of fire growth, as follows:

$$z_o = -2.4 + 0.095\dot{Q}_c^{2/5} \tag{48}$$

thereby complicating the effort to correlate ceiling jet properties. Nevertheless, Yu and Stavrianidis were able to develop correlations based on the following dimensional temperature and velocity variables, which are similar to those first proposed by Heskestad[23] for power-law fire growth:

$$\Delta\hat{T}_m = \alpha_c^{-1/3}(H - z_o)^{1/3}\frac{\Delta T_m}{T_\infty} \tag{49}$$

$$\hat{U}_m = \alpha_c^{-1/6}(H - z_o)^{-1/3}U_m \tag{50}$$

where the maximum ceiling jet excess temperature, $\Delta\hat{T}_m$, and velocity, $\hat{U}_m$, variables depend on the following heat release rate and radial distance parameters, respectively:

$$X = \alpha_c^{-1/6}(H - z_o)^{-2/3}\dot{Q}_c^{1/3} \tag{51}$$

$$\hat{R} = \frac{r}{H - z_o} \tag{52}$$

The exact form of the preceding correlations, in terms of detailed formulas, is provided in Reference 28.

In addition to maximum excess gas temperature and velocity, Yu and Stavrianidis[28] also measured the depth of the ceiling jet, in terms of the distance below the ceiling where the velocity and excess temperature are $1/e$ of the respective maximum values. Results show the ceiling jet depth based on velocity to be very similar to that based on excess temperature and both depths to be fairly insensitive to the transient fire growth process. Typical values for the ratio of ceiling jet temperature depth to effective ceiling height, $\ell_T/(H - z_o)$, for radial positions, $r/(H - z_o)$ of 0.217, 0.365, 1.75, and 4.33 are about 0.07, 0.1, 0.14, and 0.2, respectively.

Confined Ceilings

Channel Configuration

Previous discussions of ceiling jets in this chapter have all dealt with unconfined radial spread of the gas flow away from a ceiling impingement point. In practice this flow may be interrupted by ceiling beams, or corridor walls, creating a long channel that partially confines the

flow. Knowledge of the resultant ceiling jet flows is important in determining fire detector response times. For the channel configuration, the flow near the impingement point will remain radial (i.e., axisymmetric), but after spreading to the walls or beams that bound the ceiling, the flow will become generally parallel with the confining boundary. Delichatsios[29] has developed correlations for steady-state ceiling jet temperature and velocity, which apply to the channel flow between beams and down corridors. In the case of corridors, the correlations apply when the corridor half-width, ℓ_b, is greater than 0.2 times the ceiling height, H, above the fire source. Note that this value of ℓ_b corresponds approximately to the outer radius of the ceiling jet turning region. In the case of beams, the flow must also be contained fully so that only a flow in a primary channel results, without spillage under the beams to the adjoining secondary channels. For the latter condition to be satisfied, the beam depth, h_b, must be greater than the quantity $(H/10)(\ell_b/H)^{-1/3}$. Downstream of where the ceiling jet flow is parallel to the beams or corridor walls and in the absence of spillage, Delichatsios[29] determined that the average excess ceiling jet temperature and velocity within the primary channel are given by the following:

$$\frac{\Delta T}{\Delta T_p} = \mathrm{a}\left(\frac{H}{\ell_b}\right)^{1/3} \exp\left[-6.67\,\mathrm{St}\,\frac{Y}{H}\left(\frac{\ell_b}{H}\right)^{1/3}\right] \tag{53}$$

$$U = 0.102\sqrt{H\Delta T}\left(\frac{H}{\ell_b}\right)^{1/6} \tag{54}$$

under the conditions:

$$Y > \ell_b$$

$$h_b/H > 0.1(\ell_b/H)^{-1/3}$$

$$\ell_b/H > 0.2$$

$$0.5 < \frac{Y}{H}\left(\frac{\ell_b}{H}\right)^{1/3} < 3.0$$

where

ΔT_p = excess temperature on the plume centerline defined previously in Equation 14

Y = distance along the channel measured from the plume impingement point

St = Stanton number, whose value is recommended to be 0.03

Based on the minimum value of $\ell_b/H = 0.2$, the limit on h_b/H implies that the beam depth to ceiling height ratio must be at least 0.17 for the fire gases to be restricted to the primary channel. The constant a in Equation 53 is determined by Delichatsios to be in the range 0.24 to 0.29. This equation is based on the concept that the channel flow has undergone a hydraulic jump, which results in greatly reduced entrainment of cooler, ambient air from below. Reductions in ceiling jet temperature or velocity are then mainly due to heat losses to the ceiling and would thus be dependent on ceiling composition to some extent.

Additional detailed measurements of the ceiling jet flow in a primary beamed channel have been obtained by Koslowski and Motevalli.[30] Their data generally validate the Delichatsios beamed ceiling correlation (Equation 53) and ceiling jet flow behavior, but additional measurements for a range of beam depth to ceiling height ratios has allowed the correlation to be generalized. Furthermore, Koslowski and Motevalli recast the correlation in terms of the nondimensional heat release rate defined by Heskestad and Delichatsios (Equations 6 and 7), instead of centerline plume conditions at the ceiling, with the following result:

$$\Delta T_0^* = \mathrm{C}\left(\frac{H}{\ell_b}\right)^{1/3} \exp\left[-6.67\,\mathrm{St}\,\frac{Y}{H}\left(\frac{\ell_b}{H}\right)^{1/3}\right] \tag{55}$$

where Stanton number is recommended to be 0.04, rather than 0.03, and the constant, C, has the following dependence on the ratio of beam depth, h_b, to ceiling height, H:

$$\mathrm{C} = -25.38\left(\frac{h_b}{H}\right)^2 + 13.58\,\frac{h_b}{H} + 2.01 \quad \text{for } 0.5 \le \frac{Y}{H} \le 1.6 \tag{56}$$

To derive Equation 56, Koslowski and Motevalli vary the h_b/H ratio from 0.07 up to 0.28. In so doing, they note that C increases steadily with this ratio until leveling off near h_b/H equals 0.17, determined by Delichatsios as the condition for the fire gases to be restricted to the primary channel. Between values of h_b/H of 0.07 (or even much less) and 0.17, spillage from the primary channel to adjacent secondary channels is steadily reduced, thereby increasing temperatures in the primary channel. Characteristics of the ceiling jet flow in the secondary channels, as well as the primary channel, have also been studied by Koslowski and Motevalli.[31]

General Enclosure Configurations

The analyses in preceding sections for unconfined ceiling jet flows may be sufficient for large industrial or commercial storage facilities. In smaller rooms, or for very long times after fire ignition in larger industrial facilities, a quiescent, heated layer of gas will accumulate in the upper portion of the enclosure. This heated layer can be deep enough to totally submerge the ceiling jet flow. In this case, temperatures in the ceiling jet can be expected to be greater than if the ceiling jet were entraining gas from a cooler, ambient-temperature layer. It has been shown by Yu and Faeth[10] that the submerged ceiling jet also results roughly in a 35 percent increase in the heat transfer rate to the ceiling.

There are analytical formulas to predict temperature and velocity in such a two-layer environment, in which the ceiling jet is contained in a heated upper layer and the fire is burning in a lower, cool layer. This type of prediction, which has been developed by Evans,[32,33] Cooper,[34] and Zukoski and Kubota,[35] can best be used to check the proper implementation of readily available numerical

models (e.g., zone or field/CFD) of fire-induced flows in enclosures. An example of a zone model to predict activation of thermal detectors by a ceiling jet submerged in a heated layer is the algorithm developed by Davis.[36] This model, which assumes that thermally activated links are always located below the ceiling at the point of maximum ceiling jet temperature and velocity, is based partly on a model and thoroughly documented software developed by Cooper.[37]

Formulas to predict the effect of the heated upper layer in an enclosure are based on the assumption that the ceiling jet results from a fire contained in a uniform environment at the heated upper-layer temperature. This substitute fire has a heat release rate, $\dot{Q}_2$, and location below the ceiling, H_2, differing from those of the real fire. Calculation of the substitute quantities $\dot{Q}_2$ and H_2, depends on the heat release rate and location of the real fire, as well as the depths and temperatures of the upper and lower layers within the enclosure.

Following the development by Evans,[33] the substitute source heat release rate and distance below the ceiling are calculated from Equations 57 through 60. Originally developed for the purpose of sprinkler and heat detector response time calculations, these equations are applicable during the growth phase of enclosure fires.

$$\dot{Q}^*_{l,2} = \left(\frac{1 + C_T \dot{Q}^{*\,2/3}_{l,1}}{\xi C_T - 1/C_T} \right)^{3/2} \tag{57}$$

$$Z_{l,2} = \left\{ \frac{\xi \dot{Q}^*_{l,1} C_T}{\dot{Q}^{*\,1/3}_{l,2} \left[(\xi - 1)(\beta^2 + 1) + \xi C_T \dot{Q}^{*\,2/3}_{l,2} \right]} \right\}^{2/5} Z_{l,1} \tag{58}$$

$$\dot{Q}_{c,2} = \dot{Q}^*_{l,2} \rho_{\infty,2} c_{p\infty} T_{\infty,2} g^{1/2} Z^{5/2}_{l,2} \tag{59}$$

$$H_2 = H_1 - Z_{l,1} + Z_{l,2} \tag{60}$$

Further explanation of variables is contained in the nomenclature section.

Cooper[34] has formulated an alternative calculation of substitute source heat release rate and distance below the ceiling that provides for generalization to situations in which portions of the time-averaged plume flow in the lower layer are at temperatures below the upper-layer temperature. In these cases, only part of the plume flow may penetrate the upper layer sufficiently to impact on the ceiling. The remaining portion at low temperature may not penetrate into the hotter upper layer. In the extreme, when the maximum temperature in the lower-layer plume flow is less than the upper-layer temperature, none of the plume flow will penetrate significantly into the upper layer. This could be the case during the decay phases of an enclosure fire, when the heat release rate is small compared to earlier in the fire growth history. In this calculation of substitute fire-source quantities, the first step is to calculate the fraction of the plume mass flow penetrating the upper layer, m^*_2, from Equations 61 and 62.

$$m^*_2 = \frac{1.04599\sigma + 0.360391\sigma^2}{1 + 1.37748\sigma + 0.360391\sigma^2} \tag{61}$$

where

$$\sigma = \left(\frac{\xi}{\xi - 1} \right) \left[\frac{1 + C_T (\dot{Q}^*_{l,1})^{2/3}}{\xi} - 1 \right] \tag{62}$$

Then, analogous to Equations 58, 59, and 60 of the previous method:

$$Z_{l,2} = Z_{l,1} \xi^{3/5} (m^*_2)^{2/5} \left(\frac{1 + \sigma}{\sigma} \right)^{1/3} \tag{63}$$

$$\dot{Q}_{c,2} = \dot{Q}_{c,1} \left(\frac{\sigma m^*_2}{1 + \sigma} \right) \tag{64}$$

$$H_2 = H_1 - Z_{l,1} + Z_{l,2} \tag{65}$$

The last step is to use the substitute source values of heat release rate and distance below the ceiling, as well as heated upper-layer properties for ambient conditions, in the correlations developed for ceiling jet flows in uniform environments.

To demonstrate the use of the techniques, the previous example in which a sofa was imagined to be burning in a showroom may be expanded. Let all the parameters of the problem remain the same except that at 200 s after ignition ($t - t_i = 120$ s), when the fire heat release rate has reached 2.5 MW, a quiescent heated layer of gas at a temperature of 50°C is assumed to have accumulated under the ceiling to a depth of 2 m. For this case, the two-layer analysis is needed to determine the ceiling jet maximum temperature at the same position as calculated previously (a radial distance of 4 m from the plume impingement point on the ceiling).

All of the two-layer calculations presented assume quasi-steady conditions. From Equation 41 with the values of parameters in the single-layer calculation, it can be shown that the time after sofa ignition must be at least 31 s for a quasi-steady analysis to be acceptable. Since the actual time after ignition is 120 s, such an analysis is appropriate. It will be assumed that this finding will carry over to the two-layer case.

Using Equations 57 through 60 from the work of Evans,[33] values of the heat release rate and position of the substitute fire source that compensates for the two-layer effects on the plume flow can be calculated. The dimensionless heat release rate of the real fire source evaluated at the position of the interface between the upper and lower layers is as follows:

$$\dot{Q}^*_{l,1} = \frac{\dot{Q}}{\rho_\infty c_{p\infty} T_\infty g^{1/2} Z^{5/2}_{l,1}} \tag{66}$$

For an actual heat release rate of 2500 kW, ambient temperature of 293 K, and distance between the fire source and the interface between the lower and upper layers of 3 m, Equation 66 becomes

$$\dot{Q}^*_{l,1} = \frac{2500}{1.204 \times 1 \times 293 \times 9.8^{1/2} \times 3^{5/2}} = 0.1452$$

Using the ratio of upper-layer temperature to lower-layer temperature, $\xi = 323/293 = 1.1024$ and the constant, $C_T = 9.115$, the dimensionless heat release rate for the substitute fire source is

$$\dot{Q}^*_{I,2} = 0.1179$$

Using the value for the constant $\beta^2 = 0.913$,, the position of the substitute fire source relative to the two-layer interface is

$$Z_{I,2} = 3.161$$

Now, from Equations 59 and 60, the dimensional heat release rate and position relative to the ceiling are found to be

$$\dot{Q}_2 = 2313 \text{ kW} \qquad H_2 = 5.161 \text{ m}$$

The analogous calculations for substitute fire-source heat release rate and position following the analysis of Cooper,[34] Equations 61 through 65, are

$$\sigma = 23.60$$
$$m^*_2 = 0.962$$
$$Z_{I,2} = 3.176$$
$$\dot{Q}_2 = 2308 \text{ kW}$$
$$H_2 = 5.176 \text{ m}$$

These two results are essentially identical for this type of analysis.

Since it has been shown that the quasi-steady analysis is appropriate for this example, the dimensionless maximum temperature in the ceiling jet flow, 4 m from the impingement point, can now be calculated from $(\Delta T^*_2)_{qs}$ in Equation 42. Using the ceiling height above the substitute source, this equation yields the result:

$$(\Delta T^*_2)_{qs} = \left[\frac{11.40}{0.126 + 0.210(4/5.161)}\right]^{4/3} = 134.4$$

For the given time after ignition of 120 s and the assumed t^2 fire growth, the calculated $\dot{Q}_2$ value implies that α equals 0.1606, instead of the original sofa fire growth factor of 0.1736. Substitution of this new α in Equation 36, along with H_2 and the upper-layer temperature as the new ambient value, yields the following dimensional excess temperature at the 4-m radial position in the ceiling jet:

$$\Delta T = \frac{134.4 \times 323 \times (0.0278 \times 0.1606)^{2/5}}{9.8 \times 5.161^{3/5}}$$
$$\Delta T = 190 \text{ K}$$
$$T = 190 \text{ K} + 323 \text{ K} = 513 \text{ K} = 240°\text{C}$$

This is 73°C above the temperature calculated previously using the quasi-steady analysis and a uniform 20°C ambient, demonstrating the effect of flow confinement on gas temperature.

Ceiling Jet Development

At the beginning of a fire, the initial buoyant flow from the fire must spread across the ceiling, driven by buoyancy, to penetrate the cooler ambient air ahead of the flow. Research studies designed to quantify the temperatures and velocities of this initial spreading flow have been initiated.[38] At a minimum, it is useful to become aware of the many fluid mechanical phenomena embodied in a description of the ceiling jet flow in a corridor up to the time when the ceiling jet is totally submerged in a quiescent, warm upper layer. Borrowing heavily from a description of this flow provided by Zukoski et al.,[38] the process is as follows.

A fire starts in a small room with an open door to a long corridor having a small vent near the floor at the end opposite the door. As the fire starts, smoke and hot gases rise to form a layer near the fire room ceiling. The layer is contained in the small room by the door soffit [see Figure 2-2.4(a)]. As the fire continues, hot gas from the room begins to spill out under the soffit into the hallway. The fire grows to a relatively constant heat release rate.

The outflowing gas forms a short, buoyant plume [see Figure 2-2.4(b)] that impinges on the hallway ceiling, producing a thin jet that flows away from the fire room in the same manner that the plume within the room flows over the interior ceiling. The gas flow in this jet is supercritical, analogous to the shooting flow of liquids over a weir. The velocity of the gas in this flow is greater than the speed of gravity waves on the interface between the hot gas and the cooler ambient air. The interaction of the leading edge of this flow with the ambient air ahead of it produces a hydraulic, jumplike condition, as shown in Figure 2-2.4(c). A substantial amount of ambient air is entrained at this jump. Downstream of the jump, the velocity of the gas flow is reduced and mass flow is increased due to the entrainment at the jump. A head is formed at the leading edge of the flow. Mixing between this ceiling-layer flow and the ambient cooler air occurs behind this head.

The flow that is formed travels along the hallway ceiling [see Figures 2-2.4(c) and 2-2.4(d)] with constant velocity and depth until it impinges on the end wall [see Figure 2-2.4(e)]. A group of waves are reflected back toward the jump near the fire room, traveling on the interface. Mixing occurs during the wall impingement process [see Figure 2-2.4(f)], but no significant entrainment occurs during the travel of the nonbreaking reflected wave. When these waves reach the jump near the fire room door, the jump is submerged in the warm gas layer, eliminating the entrainment of ambient lower-layer air at this position [see Figure 2-2.4(g)].

After several wave reflections up and down the corridor along the interface, the wave motion dies out, and a ceiling layer uniform in depth is produced. This layer slowly grows deeper as the hot gas continues to flow into the hallway from the fire room.

It is clear from the preceding description that quantification of effects during development of a submerged ceiling jet flow is quite complex.

Analysis and experiments have been performed to understand better the major features of a developing ceil-

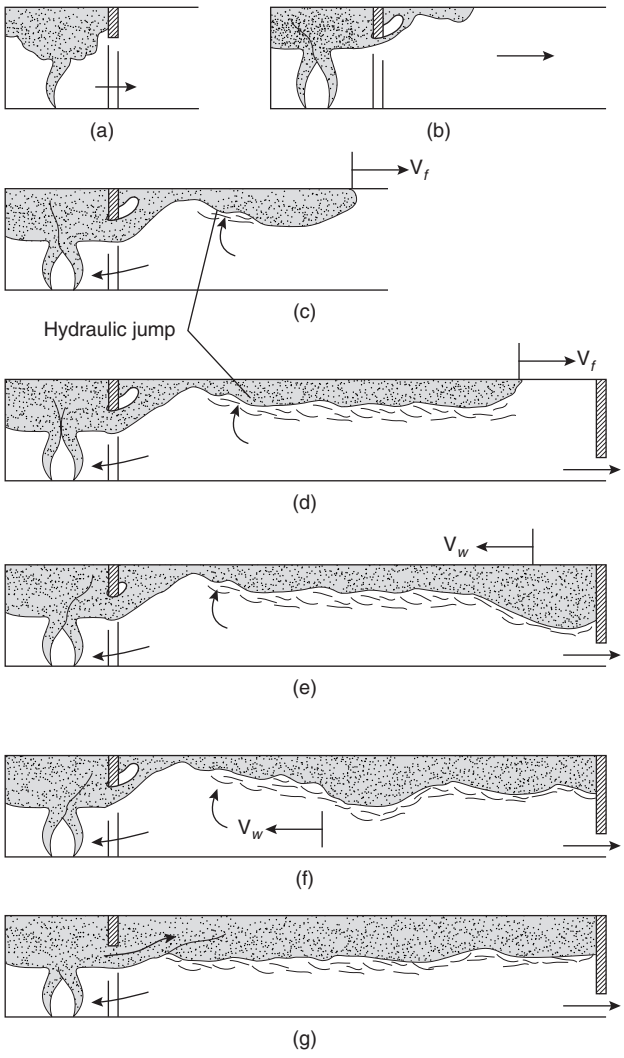

Figure 2-2.4. ***Transient ceiling jet flow in a room and corridor.[38]***

ing jet flow in a corridor.[39,40] One such study[41] contains a description somewhat different from that already given.

Summary

Reliable formulas are available to predict maximum gas temperatures and velocities and approximate temperature/velocity profiles in fire-driven ceiling jet flows beneath unobstructed ceilings for both steady and power-law fire growth. These predictive formulas, which also apply to certain situations where the ceiling jet flow is confined by beams or corridor walls, are very useful for verifying that detailed, numerical enclosure fire models have been implemented properly. The predictive techniques are the basis for acceptable design of fire detection systems, as exemplified by Appendix B of NFPA 72, *National Fire Alarm Code*.[27]

Nomenclature

A	$g/(\rho_\infty c_p T_\infty)$ (m^2/kg)
a	constant in Equation 53, equal to 0.24 to 0.29
b	effective plume radius at the intersection with the ceiling elevation (m)
C_T	constant, related to plume flow, equal to 9.115 (Reference 14)
c_p	heat capacity at constant pressure (J/kg·K)
f	ceiling friction factor
g	gravitational acceleration (m/s^2)
H	ceiling height above fire source (m)
h	heat transfer coefficient ($kW/m^2 \cdot K$)
h_b	depth of beams in a primary beam channel (m)
ℓ_b	half-width for corridor or primary beam channel (m)
ℓ_T	ceiling jet thickness based on $1/e$ depth of excess temperature profile (m)
m_2^*	fraction of fire-plume mass flux penetrating upper layer
p	ambient air pressure (Pa); also, as exponent of time for general power-law fire growth
Pr	Prandtl number
$\dot{Q}$	total heat release rate (kW)
$\dot{Q}_c$	convective heat release rate (kW)
$\dot{Q}_0^*$	$\dot{Q}/(\rho_\infty c_p T_\infty \sqrt{g} H^{5/2})$
$\dot{q}''$	rate of heat transfer per unit area (heat flux) to the ceiling surface (kW/m^2)
R	radial distance to detector (m)
$\hat{R}$	$r/(H - z_o)$
Ra	Rayleigh number
Re	Reynolds number
r	radial distance from axis of fire plume (m)
St	Stanton number, $h/(\rho U c_p)$
T	ceiling jet gas temperature (K)
T_∞	ambient air temperature (K)
T_p	peak gas temperature in plume at the intersection with ceiling elevation (K)
ΔT	excess gas temperature, $T - T_\infty$ (K) or (°C)
t	time (s)
U	ceiling jet gas velocity (m/s)
V_p	maximum plume velocity at the intersection with ceiling elevation (m/s)
Y	distance along channel or corridor, measured from plume axis (m)
Z_I	distance of layer interface above the real or substitute fire source (m)
z	distance above top surface of fire source (m)
z_o	position of virtual point-source origin of plume with respect to fire source (m)
$d\dot{Q}/dt$	rate of change of heat release rate with time (kW/s)

Greek

- α growth parameter for t^2 fires (kW/s^2)
- β^2 constant related to plume flow, equal to 0.913 (Reference 14)
- ν kinematic viscosity (m^2/s)
- θ angle of inclination of the ceiling with respect to the horizontal (degrees)
- ρ gas density (kg/m^3)
- σ parameter defined in Equation 62
- ξ ratio of temperatures, $T_{\infty,2}/T_{\infty,1}$

Subscripts

- 0 based on steady-state fire source
- 1 associated with lower layer
- 2 associated with upper layer; or parameter associated with t^2 fire growth
- ∞ ambient, outside ceiling jet or plume flows
- c convective fraction
- f associated with gas travel time delay
- I value at the interface position between the heated upper layer and cool lower layer
- i reference value at ignition
- p associated with plume flow
- q_s quasi-steady flow condition

Superscripts

- * dimensionless quantity
- ^ quantity related to transient rack-storage fire

CHAPTER 3

Vent Flows

Howard W. Emmons

Introduction

Fire releases a great amount of heat which causes the heated gas to expand. The expansion produced by a fire in a room drives some of the gas out of the room. Any opening through which gas can flow out of the fire room is called a *vent.*

The most obvious vents in a fire room are open doors and open or broken windows. Ventilation ducts also provide important routes for gas release. A room in an average building may have all of its doors and windows closed and if ventilation ducts are also closed, the gas will leak around normal closed doors and windows and through any holes made for pipes or wires. These holes will act as vents. (If a room were hermetically sealed, a relatively small fire would raise the pressure in the room and burst the window, door, or walls.)

Gas will move only if it is pushed. The only forces acting on the gas are the gas pressure and gravity. Since gravity acts vertically, it might seem that gas could only flow through a hole in the floor or ceiling. Gravity, however, can produce horizontal pressure changes, which will be explained in detail below. A gas flow that is caused directly or indirectly by gravity is called a *buoyant flow.*

When a pressure difference exists across a vent, fluid (liquid or gas) will be pushed through. Precise calculation of such flows from the basic laws of nature can only be performed today by the largest computers. For fire purposes, and all engineering purposes, calculations are carried out with sufficient precision using the methods of hydraulics. Since these formulas are only approximate, they are made sufficiently accurate (often to within a few percent) by a flow coefficient. These coefficients are determined by experimental measurements.

Dr. Howard W. Emmons was professor emeritus of mechanical engineering at Harvard University. His research has focused on heat transfer, supersonic aerodynamics, numerical computation, gas turbine compressors, combustion, and fire. Dr. Emmons died in 1998.

Calculation Methods for Nonbuoyant Flows

If a pressure drop, $\Delta p = p_1 - p_2$, exists across a vent of area, A, with a fluid density, ρ, the flow through the vent has (see Figure 2-3.1)[1]

Velocity $$V = \sqrt{\frac{2\Delta p}{\rho}} \quad (1)$$

Volume flow $$Q = CA\sqrt{\frac{2\Delta p}{\rho}} \quad (2)$$

and

Mass flow $$\dot{m} = CA\sqrt{2\rho\Delta p} \quad (3)$$

In these formulas the SI units are Δp = (Pa) = (N/m^2), A = (m^2), ρ = (kg/m^3), V = (m/s), Q = (m^3/s), $\dot{m}$ = (kg/s).

If the flow of water from a fire hose or sprinkler (Figure 2-3.2) is to be calculated and the pressure, p_g, is read on a gauge (in lb/in^2) at the entrance to the nozzle where

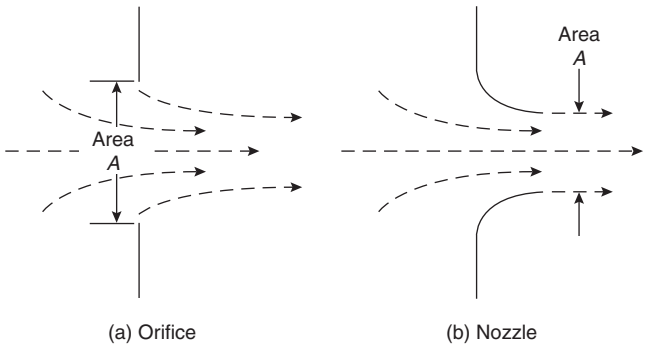

Figure 2-3.1. ***Most fire vents are orifices.***

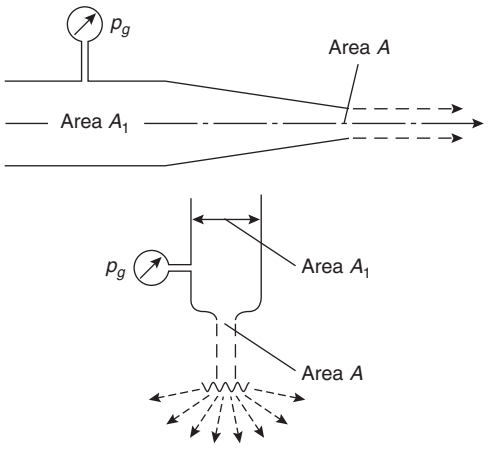

Figure 2-3.2. ***A hose nozzle and a sprinkler nozzle.***

the area is A_1, the previous formulas provide the velocity, volume flow, and mass flow by using

$$\Delta p = \frac{6895 p_g}{1 - (A/A_1)^2} \tag{4}$$

where A = area of vent and A_1 = area of supply pipe.

The factor 6895 converts pressure in lb/in^2 to Pascals while the factor $[1 - (A/A_1)^2]$ corrects Δp for the dynamic effect of the inlet velocity in the supply hose or pipe.

In the atmosphere, the pressure at the ground is p_a, which is just sufficient to support the weight of the air above. If the air density is ρ_a, the pressure, p, at height, h, is less than p_a by the weight of the air at height, h. Thus the pressure difference is

$$\Delta p = p_a - p = \rho_a g h \tag{5}$$

It is sometimes convenient when considering fire gases to use $h = \Delta p/\rho_a g$, the pressure head, in meters of ambient air, in the velocity and flow rate formulas given above.

The previous discussion supposes that the flowing fluid is of constant density. For liquids this is true for all practical situations. The density of air or fire gases will not change significantly during the flow through the vent so long as the pressure change is small, so they can also be treated as constant density fluids.

If the pressure drop is large, the equations become more complicated.[2] If the pressure and density upstream of the vent are p_1, ρ_1 while the pressure after the vent is p_2, the equations for velocity and mass flow become

$$V = \sqrt{\frac{2p_1}{\rho_1}} \left\{ \frac{\gamma}{\gamma - 1} \left(\frac{p_2}{p_1} \right)^{2/\gamma} \left[1 - \left(\frac{p_2}{p_1} \right)^{(\gamma-1)/\gamma} \right] \right\}^{1/2} \tag{6}$$

$$\dot{m} = CA\sqrt{2\rho_1 p_1} \left\{ \frac{\gamma}{\gamma - 1} \left(\frac{p_2}{p_1} \right)^{2/\gamma} \left[1 - \left(\frac{p_2}{p_1} \right)^{(\gamma-1)/\gamma} \right] \right\}^{1/2} \tag{7}$$

where $\gamma = c_p/c_v$.

The value of γ depends upon the complexity of the molecules of the flowing gas. For fire gases (which always contain a large amount of air) the value of γ will fall between 1.33 and 1.40. For most fire purposes the diatomic gas value (air) of 1.40 is sufficiently accurate.

The mass flow given by the previous equation has a maximum at

$$\frac{p_2}{p_1} = \left(\frac{2}{\gamma + 1} \right)^{\gamma/(\gamma-1)} \tag{8}$$

For $\gamma = 1.40$, the maximum flow is reached for a downstream pressure $p_2 = 0.528 p_1$. For all lower back pressures the flow remains constant at its maximum

$$\dot{m} = CA\sqrt{\rho_1 p_1} \left[\gamma \left(\frac{2}{\gamma + 1} \right)^{(\gamma+1)(\gamma-1)} \right]^{1/2} \tag{9}$$

With these equations, the mathematical description of the rate of flow of liquids and gases through holes is complete as soon as the appropriate flow coefficients are known. The coefficients, found by experiment, correct the formulas for the effect of the fluid viscosity, the nonuniformity of the velocity over the vent, turbulence and heat transfer effects, the details of nozzle shape, the location of the pressure measurement points, and so forth. The corrections also depend upon the properties and velocity of the fluid. The most important coefficient corrections for any given vent geometry is the dimensionless combination of variables which is called the Reynolds number, Re, and

$$\mathrm{Re} = \frac{VD\rho}{\mu} \tag{10}$$

where

V = velocity of the fluid given by the previous equations

D = diameter of the nozzle or orifice

ρ = density of the fluid approaching the vent

μ = viscosity of the fluid approaching the vent

A door or window vent is almost always rectangular, not circular. The D to be used in the Reynolds number should be the hydraulic diameter

$$D = \frac{4A}{P} \tag{11}$$

where

A = area of the vent

P = perimeter of vent

For a rectangular vent, a wide and b high, $A = ab$, $P = 2(a + b)$.

$$D = \frac{2ab}{(a + b)} \tag{12}$$

The experimental values of the flow coefficients for nozzles and orifices are given in Figure 2-3.3.[2] Flow coefficients for nozzles are near unity while for orifices are approximately 0.6; the reason for this can be seen from

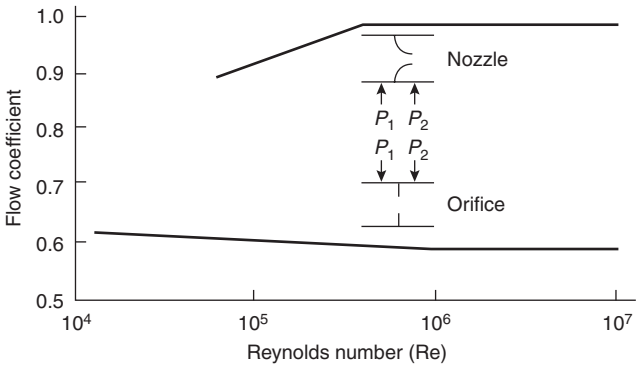

Figure 2-3.3. ***Orifice and nozzle flow coefficients.***

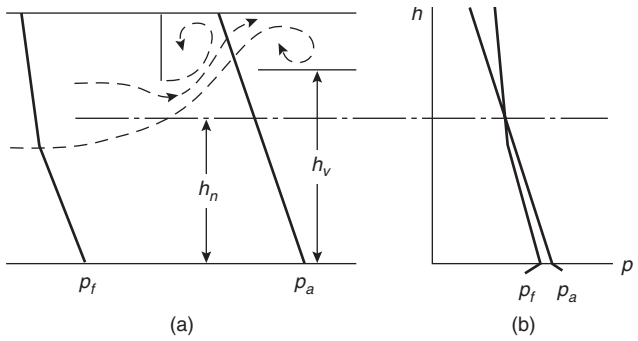

Figure 2-3.4. ***Pressure gradients: (a) each side of a door; (b) superimposed on a pressure versus height graph.***

Figure 2-3.1, wherein the flow from an orifice separates from the edge of the orifice and decreases to a much smaller area, in fact about 0.6 of the orifice area.

For most fire applications the Reynolds number will be about 10^6. Sprinklers and fire nozzles are small but the velocity is quite high. Conversely, ventilation systems of buildings are larger but have a lower velocity. Finally, doors and windows in the areas of a building not too near the fire are still larger but the velocity is still smaller. For most purposes the flow coefficient can be set as $C = 0.98$ for a nozzle and $C = 0.60$ for an orifice.

Buoyant Flows through Vertical Vents

A fire in a room causes gases to flow out through a vent by two processes. The heating of the air in a room causes the air to expand, pushing other air out through all available vents and hence throughout the entire building. At the same time, the heated air, with products of combustion and smoke, rises in a plume to the ceiling. When the hot layer of gas at the ceiling becomes deep enough to fall below the top of a vent, some hot gas will flow out through the vent. As the fire grows, the buoyant flow out will exceed the gas expansion by the fire. Thus the pressure in the fire room at the floor will fall below atmospheric, and outside air will flow in at the bottom. A familiar sight develops, where smoke and perhaps flames issue out the top of a window while fresh air flows in near the bottom. This buoyant flow mechanism allows a fire to draw in new oxygen so essential for its continuation.

For these buoyantly driven flows to occur, there must be a pressure difference across the vent. Figure 2-3.4 illustrates how these pressure differences are produced. The pressure difference at the floor is

$$\Delta p_f = p_f - p_a \tag{13}$$

where

p_f = pressure at the floor inside the room in front of the vent

p_a = pressure at the floor level outside of the room just beyond the vent

The pressure at height y is less than the pressure at the floor and can be found by the following hydrostatic equations:

Inside
$$p_1 = p_f - \int_0^y \rho_1 g \, dy \tag{14}$$

Outside
$$p_2 = p_a - \int_0^y \rho_2 g \, dy \tag{15}$$

The pressure difference at height, h, is

$$\Delta p = p_1 - p_2 = \Delta p_f + \int_0^h (\rho_2 - \rho_1) g \, dy \tag{16}$$

Since the outside density, ρ_2, is greater than the inside density, ρ_1, the integral is positive so that Δp is often positive (outflow) at the top of the vent and negative (inflow) at the bottom. The flow properties at the elevation, h, are the same as previously given.

$$V = \sqrt{\frac{2\Delta p}{\rho}} \tag{17}$$

$$\frac{Q}{A} = C\sqrt{\frac{2\Delta p}{\rho}} \tag{18}$$

$$\frac{\dot{m}}{A} = C\sqrt{2\rho\Delta p} \tag{19}$$

Since they are not the same at different heights in the vent, the volume and mass flow are given as flow per unit area.

Measuring Vent Flows in a Fire Experiment

Sufficient measurements must be made to evaluate ρ and Δp to allow use of Equation 19. There are four different available methods which differ in simplicity, accuracy, and cost.

Method 1: The dynamic pressure distribution can be measured in the plane of the vent. This measurement re-

quires a sensitive pressure meter. The pressure difference is almost always less than the atmospheric pressure difference between the floor, p_f, and the ceiling, p_c. For a room 2.5 m in height the atmospheric pressure difference is

$$p_f - p_c = \rho_a g H = 1.176 \times 9.81 \times 2.5$$
$$= 28.84 \text{ Pascals} \quad (3.0 \text{ mm } H_2O)$$

This is only

$$\frac{p_f - p_c}{p_a} = \frac{28.84}{101{,}325}$$
$$= 0.00028 \quad \text{fraction of atmospheric pressure}$$

Thus the buoyantly driven flow velocities induced by a room fire could be as high as

$$V = \sqrt{\frac{2\Delta p}{\rho}} = \sqrt{\frac{2 \times 28.84}{1.176}} = 7.00 \text{ m/s} \quad (23 \text{ ft/s})$$

Since the pressure varies with height and time, a series of pressure probes are required and each should have its own meter or a rapid activation switch. Although standard pitot tubes are the most accurate dynamic pressure probes, they are sensitive to flow direction and would have to be adjusted at each location for the direction of the local flow, especially for outflow and inflow. The probe orientation would need to be continually changed as the fire progressed.

A single string of fixed orientation pressure probes arranged vertically down the center of the door increases convenience of the measurement but forces a decrease in accuracy. The out-in flow problem is avoided by use of bidirectional probes in place of pitot tubes.[3] (See Figure 2-3.5.) These probes give velocities within 10 percent over an angular range of ±50 degrees of the probe axis in any direction.

Determination of the local velocity also requires the measurement of the local gas density. The density of fire gases can be determined from measured gas temperatures with sufficient accuracy by the ideal gas law

$$\rho = \frac{Mp}{RT} \tag{20}$$

where

M = avg. molecular weight of flowing gas

$R = 8314 \dfrac{\text{J}}{\text{kg mol K}}$ = universal gas constant

As noted previously, the pressure changes only by a very small percentage throughout a building so its effect on gas density is negligible.

Fire gases contain large quantities of nitrogen from the air and a variety of other compounds. The average molecular weight of the mixture will be close to but somewhat larger than that of air. Incomplete knowledge of the actual composition of fire gas prevents high accuracy calculations. For most fire calculations, it is accurate enough

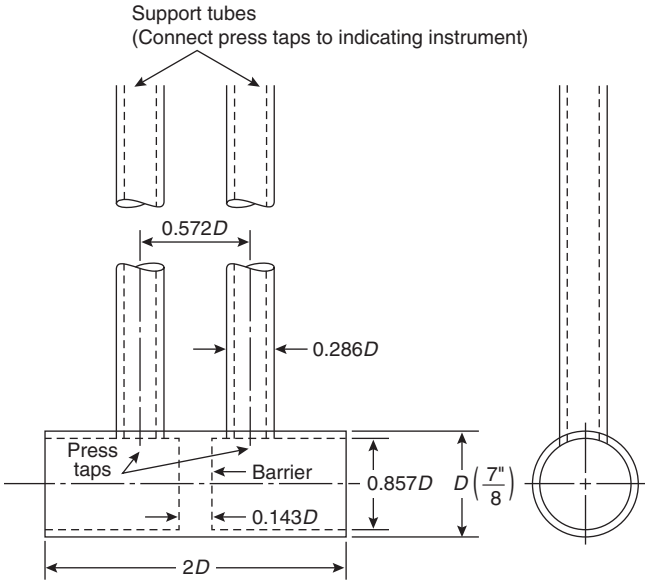

Figure 2-3.5. ***A bidirectional flow probe.***

to neglect the effect of the change of molecular weight from that of air ($M_a = 28.95$). Density of gas is determined primarily by its temperature (which may vary by a factor of 4 in a fire). Thus

$$\rho = \frac{352.8}{T} \frac{\text{kg}}{\text{m}^3} \tag{21}$$

where T = temperature in Kelvin (= °C + 273)

A string of thermocouples must be included along with the bidirectional probes to measure vent flows. For higher accuracy, aspirated thermocouples must be used or a correction made for the effect of fire radiation.[3] The temperature, and hence the gas density, will vary over the entire hot vent outflow. To determine the temperature distribution so completely would require an impracticably large number of thermocouples. Fortunately the temperature in the vent is a reflection of the temperature distribution in the hot layer inside the room, which normally is stratified, and hence varies most strongly with the distance from the ceiling. Thus a string of thermocouples hanging vertically on the centerline of the vent is usually considered to be the best that can be done in a practical fire test. Special care must be exercised to keep the test fire some distance away from the entrance to the vent. Since a fire near a vent has effects at present unknown, fire model calculations of real fire vent flows under such conditions will be of unknown accuracy. The velocity distribution vertically in the vent is given by

$$V = 0.93\sqrt{\frac{2\Delta p}{\rho}} \tag{22}$$

where ρ follows from Equation 21 using the temperature distribution *in the vent* with a calibration factor of 0.93 for

the bidirectional probes.[4] Using ρ from Equation 21 gives the directly useful forms

$$\begin{aligned} V &= 0.070\sqrt{T\Delta p} \qquad \Delta p\left(\frac{\text{N}}{\text{m}^2}\right) \\ V &= 5.81\sqrt{T\Delta p} \qquad \Delta p\left(\frac{\text{lb}}{\text{in}^2}\right) \end{aligned} \quad \text{pressure measured with bidirectional probe} \tag{23}$$

where

V is in (m/s) $\qquad \left[V\left(\frac{\text{ft}}{\text{s}}\right) = 3.281 V\left(\frac{\text{m}}{\text{s}}\right) \right]$

T is in (K)

Except for very early stages of a room fire, there will be flow out at the top ($V, \Delta p > 0$) and flow in at the bottom ($V, \Delta p < 0$).* Thus there is a position in the vent at which $V = 0$; this is the vertical location where the pressure inside is equal to that outside. This elevation, h_n, is called the neutral axis. Defining the elevation of the vent sill as h_b ($h_b = 0$ for a door) and the elevation of the soffit as h_t, the flows are given by

$$\text{Flow out} \qquad \dot{m}_u = C\int_{h_n}^{h_t} \rho V b \, dy \tag{24}$$

$$\text{Flow in} \qquad \dot{m}_d = C\int_{h_b}^{h_n} \rho V b \, dy \tag{25}$$

where

b = width of the vent

C = experimentally determined flow coefficient (= 0.68)[7]

These equations in the most convenient form are

$$\text{Flow out} \qquad \dot{m}_u = 16.79\int_{h_n}^{h_t} b\sqrt{\frac{\Delta p}{T_V}}\, dy \quad \text{(kg/s)} \tag{26}$$

$$\text{Flow in} \qquad \dot{m}_d = 16.79\int_{h_b}^{h_n} b\sqrt{\frac{\Delta p}{T_V}}\, dy \quad \text{(kg/s)} \tag{27}$$

where

Δp = pressure drop in Pascals measured with bidirectional probe as a function of y

b = width of the vent in m

T_V = vertical distribution of temperature (K) in the vent

If the bidirectional probe pressures are measured in psi, the coefficient 16.79 must be replaced by 1394.

Method 2: A somewhat simpler but less accurate procedure to measure vent flows requires the measurement of the pressure difference at the floor (or some other height). One pressure difference measurement together with the vertical temperature distribution measurement, T_1, *inside the room* (about one vent width in from the vent) and T_2, *outside the vent* (well away from the vent flow) provides the density information required to find the pressure drop at all elevations (Equation 16).

$$\Delta p = \Delta p_f + 3461\int_0^y \left(\frac{1}{T_2} - \frac{1}{T_1}\right) dy \tag{28}$$

For most fires, Δp_f will be negative; that is, the pressure at the floor inside the fire room will be less than the pressure outside. This is only true for a fire room with a normal size vent (door, window). For a completely closed room the inside pressure is well above the outside pressure. Since the temperature inside the fire room is higher than that outside, Equation 28 gives a Δp which becomes less negative, passes through zero at the neutral axis, h_n, and becomes positive at higher levels in the fire room. The vertical location of the neutral axis is therefore readily found from Equation 28.

The calculation of the pressure distribution requires measurement of the temperature distribution both inside, T_1, and outside, T_2, of the vent. However, calculation of the flow requires a knowledge of the density distribution in the vent itself. Thus a third thermocouple string is required to measure the temperature distribution, T_V, in the vent. The desired flow properties[6] are

Velocity

$$V = \sqrt{\frac{2\Delta p}{\rho}} = 4.43\sqrt{T_V\int_{h_n}^{y}\left(\frac{1}{T_2} - \frac{1}{T_1}\right) dy} \quad \text{(m/s)} \tag{29}$$

Flow out

$$\begin{aligned} \dot{m}_u &= C\int_{h_n}^{h_t} \rho b V \, dy \\ &= 1063\int_{h_n}^{h_t} b\left[\frac{1}{T_V}\int_{h_n}^{y}\left(\frac{1}{T_2} - \frac{1}{T_1}\right) dy\right]^{1/2} dy \end{aligned} \tag{30}$$

Flow in

$$\begin{aligned} \dot{m}_d &= C\int_{h_b}^{h_n} \rho b V \, dy \\ &= 1063\int_{h_b}^{h_n} b\left[\frac{1}{T_V}\int_{h_b}^{y}\left(\frac{1}{T_2} - \frac{1}{T_1}\right) dy\right]^{1/2} dy \end{aligned} \tag{31}$$

where

b = width of the vent at height y

Δp = calculated from Equation 16 using the temperatures (and thus densities) *inside and outside of the room*

ρ = density computed from the temperature *in the vent*

(Note that for inflow Δp is negative. Therefore the equation takes the square root of the magnitude $|\Delta p|$ while its sign gives the flow direction.)

*Equation 23 should be written $V = (\text{sign}\ \Delta p)K\sqrt{T|\Delta p|}$ since when $\Delta p < 0$ the absolute value must be used to avoid the square root of a negative number and the sign of the velocity changes since the flow is in and not out.

Method 3: The use of a sensitive pressure meter can be avoided entirely by visually (or better, photographically) locating the bottom of the outflow *in the vent* during the test. This is at the position of the neutral axis, h_n, where $\Delta p = 0$. Method 3 is the same as Method 2 except that the neutral axis location is found directly by experiment, rather than being deduced from the pressures. The distribution of pressure drop across the vent is found by integrating Equation 16 above ($\Delta p > 0$) and below ($\Delta p < 0$) h_n using the density distribution *inside,* ρ_1, and *outside,* ρ_2, *the room.* The flow properties are computed as before from Equations 29 through 31.

Method 4: A simpler but less accurate method uses the fair assumption that the gas in the fire room soon separates into a nearly uniform hot layer of density, ρ, with a nearly uniform cold layer below density, ρ_d. This separation with appropriate notation is shown in Figure 2-3.6. In this approximation the appropriate flow formulas[7] are

$$\text{Outflow} \qquad V_u = \left(2g\frac{\rho_a - \rho}{\rho}y\right)^{1/2} \tag{32}$$

where y is distance above the neutral plane

$$\dot{m}_u = \frac{\sqrt{8}}{3}Cb\sqrt{g\rho(\rho_a - \rho)}(h_v - h_n)^{3/2} \tag{33}$$

The inflow by this two-layer method depends upon d, which is small and cannot be determined with sufficient accuracy because of the effect of gas motions in the fire room.

The neutral axis may be found in several ways:

1. It may be located visually or photographically during the test.
2. It may be found from the vent temperature distribution by locating [visually on a plot of $T_V(y)$] the position just below the most rapid temperature rise from bottom to top of the vent.

The low temperature, T_d, of the two-layer model is taken as the gas temperature just above the vent sill. The high temperature, T_u, is chosen so that the two-layer model has the same total mass (i.e., the same mean density) in the vent as the real flow.*

$$\left(\frac{1}{T}\right) = \frac{1}{h_v}\int_0^{h_v}\frac{dy}{T} = \frac{h_n}{h_v T_d} + \frac{h_v - h_n}{h_v T_u} \tag{34}$$

The densities ρ_a and ρ are found using Equation 21 from the temperatures T_a and T_u, respectively.

The outflow velocity and mass flow are found from Equations 32 and 33.

An estimate of the air inflow rate can be found if the test has included the measurement of the oxygen concentration in the gases leaving the fire room. The gas outflow rate is equal to the inflow rate plus the fuel vaporized, except for the effect of transient variations in the hot layer depth. Thus

$$\dot{m}_d = \dot{m}_u\left(\frac{1 + y_{O_2}\lambda}{1 + 0.23\lambda}\right) \tag{35}$$

where λ = effective fuel-air ratio.

The flow coefficient to be used for buoyant flows is 0.68 as determined by specific experiments designed for the purpose. For nonbuoyant flows (nozzles and orifices), the flow coefficients are determined to better than 1 percent and presented as a function of the Reynolds number as in Figure 2-3.3. This accuracy is possible because the fluid can be collected and measured (by weight or volume).

For buoyant flows the experiments are much more difficult because the hot outflow and cold inflow cannot be collected and weighed. The best fire-gas vent flow coefficient measurements to date[5,6] have ±10 percent accuracy with occasional values as bad as ±100 percent (for inflow). The most accurate buoyant flow coefficients were measured not for fire gases but for two nonmiscible liquids (kerosene and water).[7] In this case the two fluids could be separated and measured, and the value 0.68 was found except for the very low flow rates (near the beginning of a fire). When buoyant flow coefficients can be measured within a few percent accuracy, they will be a function of the Reynolds number, $\text{Re} = Vh_v\rho/\mu$; the Froude number, $\text{Fr} = V^2\rho_a/gh_v(\rho - \rho_a)$; and the depth parameter, h_n/h_v.

The best option now available is to use $C = 0.68$ and expect ±10 percent errors in flow calculations.

Note that all of the above four methods require a knowledge of h_n, the dividing line between outflow above and inflow below. It would be useful to have a simple formula by which h_n could be calculated without any special measurements. What determines h_n?

The fire at the start sends a plume of heated gas toward the ceiling and, by gas expansion, pushes some gas out of the vent. The hot plume gases accumulate at the ceiling with little, if any, flowing out the vent. After a

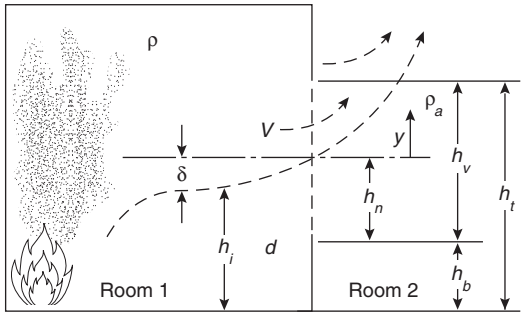

Figure 2-3.6. ***Buoyant flow out of the window of a fire room.***

*Sometimes the mean temperatures, $\overline{T}$, of the two-layer model and the real flow are also used and both h_n and T_u are determined (using T_d as above). The requirement of identical $\overline{T}$ is arbitrary, sometimes leads to impractical results, and is not recommended.

time, dependent on the size of the room, the hot layer depth becomes so large that its lower surface falls below the top of the vent. Hot gas begins to flow out.

When a fire has progressed to a second room, there is a hot layer on each side of a connecting vent. Thus, (with two layers on each side) there are as many as four different gas densities: $\rho_{d_1} > \rho_1$, densities below and above in room 1, and $\rho_{d_2} > \rho_2$, densities below and above in room 2. There are also four pertinent levels: h_b, sill height (0 if the vent is a door); h_t, soffit height; h_{i_1}, interface height in room 1; h_{i_2}, interface height in room 2. There are many different flow situations possible depending upon these eight values.

The pressure variation from floor to ceiling in each room depends upon the densities and layer heights in that room. In addition, the pressure difference between the two rooms (at the floor, for example) may have any value depending upon the fire in each room, all the room vents, and especially the vent (or vents) connecting the two rooms. Figure 2-3.7 shows a few of the possible pressure distributions. The pressure distribution in room 1 is shown with a dotted line while that in room 2 is shown as a solid line.

In Figure 2-3.7(a), there are no hot layers, the pressure in room 1 at every level is higher than that in room 2, and the flow is everywhere out (positive) (room 1 to room 2).

In Figure 2-3.7(b), a common situation exists. The density in room 2 is uniform (perhaps the outside atmosphere). Room 1 has a hot layer and a floor pressure difference such that there is outflow at the top, inflow at the bottom, and a single neutral axis somewhat above the hot-cold interface in the room.

In Figure 2-3.7(c), the flow situation is similar to that in Figure 2-3.7(b), although there are hot layers in both rooms (but with a neutral axis above the interface in room 1 and below the interface in room 2).

In Figure 2-3.7(d), the densities (slopes of pressure distribution lines) are somewhat different than those in Figure 2-3.7(c) (the hot layer in room 2 is less deep but hotter than that in room 1). Consequently there are two neutral axes with a new small inflow layer at the top, three flow layers in all—two in and one out.

In Figure 2-3.7(e), the densities and floor level pressure difference are such that there are four flow layers, two out and two in, with three neutral axes.

These five cases do not exhaust the possible vent flow situations.

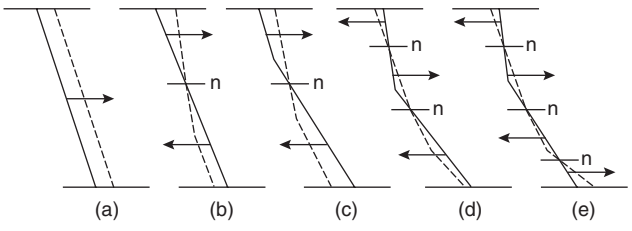

Figure 2-3.7. ***Some selected two-layer vent pressure drop distributions. Dotted line is pressure distribution in room 1; solid line is pressure distribution in room 2.***

Figure 2-3.7(a, b) account for all cases early in a fire and all cases of vents from inside to outside of a building. They are also the only cases for which experimental data is available. The case illustrated in Figure 2-3.7(c) is common inside a building after a fire has progressed to the point that hot layers exist in the two rooms on each side of a vent. The cases illustrated in Figures 2-3.7(d, e) have not been directly observed but probably account for an occasional confused flow pattern. (In fact, the above discussion assumes two distinct layers in each room.) The layers are seldom sharply defined and in this case there may be many neutral axes, or regions, with a confusing array of in-out flow layers. These confused flow situations are probably not of much importance in a fire since they seldom occur and when they do they don't last very long.

The previous discussion of the possible two-layer flow situation is very important for the zone modeling of a fire. Fire models to date are all two-layer models (a three- or more layer model will present far more complex vent flows than those pictured in Figure 2-3.7). In fire computation by a zone model, such as cases (d) and (e) in Figure 2-3.7 will be unimportant to fire development. However, since these situations can arise, they should be handled via fire computation; that is, by computing the flow layer by layer. Each layer has a linear pressure variation from sill, interface, or neutral axis up to the next interface, neutral axis, or soffit.

By use of the pressure drop at the floor and the room densities on each side of the vent in Equation 16, the position, h_i, of all layers and the sill, interfaces, neutral axes, and soffit will be known. Thus, for each layer (defined as j) the pressure drop at the bottom, Δp_j, and at the top, Δp_{j+1}, will be known. Since the room densities are constant in each room for each layer, the vent pressure drop will vary linearly from Δp_j to Δp_{j+1}. The flow in each layer from room 1 to room 2, found by integration,[8] is given by

$$\dot{m}_i = (\text{sign } \alpha) C \frac{\sqrt{8}}{3} b (h_{j+1} - h_j) \sqrt{\rho} \times \left(\frac{|\Delta p_j| + \sqrt{|\Delta p_j \Delta p_{j+1}|} + |\Delta p_{j+1}|}{\sqrt{|\Delta p_j|} + \sqrt{|\Delta p_{j+1}|}} \right) \qquad (36)$$

where

$\alpha = \left(\frac{\Delta p_j + \Delta p_{j+1}}{2} \right)$ whose sign determines the in-out direction of the flow

ρ = density of the gas flowing in the flow layer i

Thus

$$\rho = \begin{cases} \text{density in room 1 at height } h_j^+ & \text{if } \alpha > 0 \\ \text{density in room 2 at height } h_j^+ & \text{if } \alpha < 0 \end{cases}$$

This flow calculation appears complex but can be coded quite easily for computer use and then used to calculate all the possible cases.

Although all vent flows can now be calculated, the path of each layer of gas flow when it enters a room is still needed for fire modeling. If the two-layer model is to be

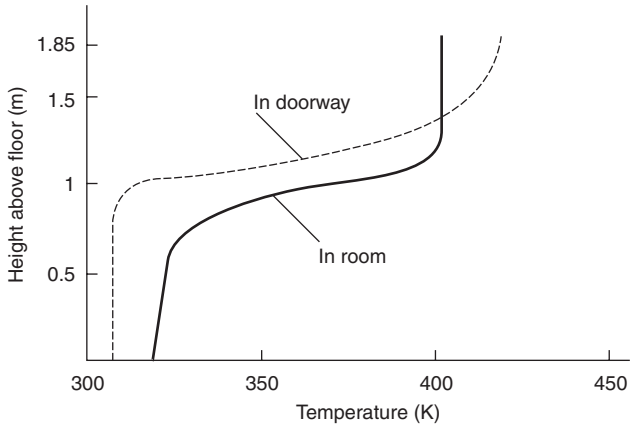

Figure 2-3.8. ***Sample fire room and doorway temperature distributions.***

preserved, each inflow must mix with the hot layer or the cold layer, or be divided between them. No information is yet available as to the best solution of this problem.

To illustrate these various methods of flow calculation, some test data from a steady burner fire in a room at the U.S. Bureau of Standards[6] is used. Some typical data are shown in Figure 2-3.8. Accurate results, even in a steady-state fire, are difficult to obtain and questions about the data in this figure will be noted as appropriate. The vent temperatures were measured by small diameter bare thermocouples for which there is some unknown radiation correction. This unknown correction may account for the top vent temperature being higher than that in the fire room.

The vent was 1.83 m high, 0.737 m wide and the outflow measured with bidirectional probes (not corrected for flow angle) was 0.588 kg/sec for a fire output of 0.63 kW. The ambient temperature was 21.3°C (= 294.3 K). This flow was determined by using Method 1.

Method 2 uses the known location of the neutral axis and requires the integration of Equations 30 and 31. In this way the data of Figure 2-3.8 gives outflow of 0.599 kg/s, 1.8 percent higher compared to Method 1 and inflow of 0.652 kg/s. A measured (by bidirectional probes) inflow is not given, but it seems odd that the inflow is greater than the outflow since inflow must be smaller than the outflow by the mass rate of fuel burned at steady state.

Data for use of Method 3 are not available.

Method 4 requires the selection from Figure 2-3.8, of a neutral axis location and inlet temperature. In the figure the rapid temperature rise *in the vent* begins at about 1 m. Hence this height is chosen as the neutral axis. The lowest inlet temperature is T_d = 308 K. By computing $(1/T_V)$ the average value was found to be $(1/T_V) = 2.875 \times 10^{-3}$. Now by Equation 34

$$2.875 \times 10^{-3} = \frac{1.00 - 0}{1.83 \times 308} + \frac{1.83 - 1.00}{1.83 T_u}$$

Thus T_u = 411.9 K. The corresponding density is ρ = 352.8/411.9 = 0.8565 kg/m^3. From the ambient temperature, T_a, we find ρ_a = 352.8/294.3 = 1.199 kg/m^3. Thus the outflow by Equation 33 is

$$\dot{m}_u = \frac{\sqrt{8}}{3} 0.68 \times 0.737 [9.81 \times 0.8565 (1.199 - 0.8565)]^{1/2} \times (1.83 - 1)^{3/2} = 0.607 \text{ kg/s}$$

This value is 3.2 percent higher compared to Method 1.

Buoyant Flows through Horizontal Vents

Unlike nonbuoyant flows through orifices or flow through vents in a vertical wall, very little quantitative work has been done on flow through vents in horizontal (floors or flat roofs) or slightly sloped (inclined roofs) surfaces. The following discussion is included to clarify the present status of our knowledge and to provide flow calculation formulas of unknown accuracy in lieu of nothing.

Consider the flow through a hole in a horizontal surface. The velocity and flow rate are determined by the pressure drop from the upstream side of the vent to the *vena contracta.* Therefore, the buoyancy of the fluid from the vent to the *vena contracta* influences the flow. Thus, for upward flow of the lower fluid the velocity is given by

$$v_H = \left[\frac{2}{\rho_H} (gh\Delta\rho + \Delta p) \right]^{1/2} \tag{37}$$

where

$\Delta\rho = \rho_c - \rho_H$

$\Delta p = p_H - p_c$ measured at the vent's lower and upper surfaces

h = the vertical distance from the vent lower surface to the *vena contracta* (about equal to the orifice diameter D)

If the unidirectional flow were down, the velocity would be

$$v_c = -\left[\frac{2}{\rho_c} (gh\Delta\rho - \Delta p) \right]^{1/2} \tag{38}$$

The magnitude of the buoyancy effect is 8.6 Pascals (for a fire density ratio of 4 to 1 and a 1-m diameter horizontal vent), and a buoyant velocity of 4 m/s (about 1/6 of the velocity) is produced by the fire room buoyancy. The plume above the *vena contracta* stirs the fluid on the upper surface but does not influence the flow.

As the flow nears zero, the interface between the lower (hot) and upper (cold) gases becomes flat and is unstable. The unidirectional flow is replaced by simultaneous up and down flows usually oscillating in time and location.

At present there are no measurements of effective values of *h.* There are only a couple of quantitative studies of horizontal vent flows in which the pressure drop-flow information has been adequately measured.[9,10] These are for very small holes (a diameter of 2 in. or less), and in many cases the holes were fitted with a short pipe. Ceiling or roof holes in fires are usually irregular in shape and have

a length to "diameter" ratio of 0.13 or less. There are a number of studies[11,12,13] of rooms with a ceiling hole with a fire either under the hole or on a wall. These supply interesting fire data but are not useful as horizontal vent studies, since the results do not include adequate orifice pressure and flow measurements. Epstein and Kenton[9] have measured the transfer of fluid from the lower to the upper chambers using water below and a brine above (density ratio 1.1 or less). They found that, at zero net volume flow (the lower chamber was closed except for a ceiling hole 2 in. in diameter or less), the fluid transfer to the upper chamber was

$$\frac{Q_H}{[D^5 g(\Delta\rho/\bar{\rho})]^{1/2}} = 0.055 \tag{39}$$

while the unidirectional volume flow, q, that just prevented reverse flow was

$$\frac{q}{[D^5 g(\Delta\rho/\bar{\rho})]^{1/2}} = 0.20 \tag{40}$$

The unidirectional volume flows that follow from the velocity Equations 37 and 38 are

$$\frac{Q_H}{[D^5 g(\Delta\rho/\rho_H)]^{1/2}} = \frac{\pi}{8} C_D \left(\frac{h}{D} + \frac{\Delta p}{\Delta\rho g D}\right)^{1/2} \tag{41}$$

$$\frac{Q_C}{[D^5 g(\Delta\rho/\rho_c)]^{1/2}} = \frac{\pi}{8} C_D \left(\frac{h}{D} - \frac{\Delta p}{\Delta\rho g D}\right)^{1/2} \tag{42}$$

If we assume that when $Q_H = q$, the flooding value, then $\Delta p/\Delta\rho g D$ has the value for which $Q_C = 0$. Then $\Delta p/\Delta\rho g D = h/D$, and by Equations 40 and 41

$$\frac{\Delta p}{\Delta\rho g D} = 0.045 \tag{43}$$

With this value as the limit of unidirectional flow, $-.045 < \Delta p/\Delta\rho g D < .045$ is the pressure range in which flows occur simultaneously in both directions. There is no current theory nor measurements to compute these low flows so each flow squared up and down are assumed to vary linearly in this range. The resultant flows are

$$\dot{m} = cD[2\rho_H(\Delta\rho g D + \Delta p)]^{1/2} \quad \text{for } \Delta p > .045\Delta\rho g D \tag{44}$$

$$\left.\begin{aligned} \dot{m}_u &= cD[23.22\rho_H(.045\Delta\rho g D + \Delta p)]^{1/2} \\ \dot{m}_D &= -cD[23.22\rho_c(.045\Delta\rho g D - \Delta p)]^{1/2} \end{aligned}\right\} \begin{array}{l}\text{simultaneous} \\ \text{up-down} \\ \text{flow for} \\ -.045\Delta\rho g D \\ < \Delta p < \\ .045\Delta\rho g D\end{array} \tag{45}$$

$$\dot{m} = -cD[2\rho c(\Delta\rho g D - \Delta p)]^{1/2} \quad \text{for } p < -.045\Delta\rho g D \tag{46}$$

Note: The use of the dimensionless form $\Delta p/\Delta\rho g D$ has been changed in Equations 44 thru 46 so that numerical computations when there is no density change ($\Delta\rho = 0$) does not encounter division by zero.

Equations 44 through 46 describe the positive upward flow through a horizontal vent over the entire pressure range from $-\infty$ inflow to $+\infty$ outflow. This theory is shown in Figure 2-3.9 for a density ratio of 2 with coordinates using the average density.

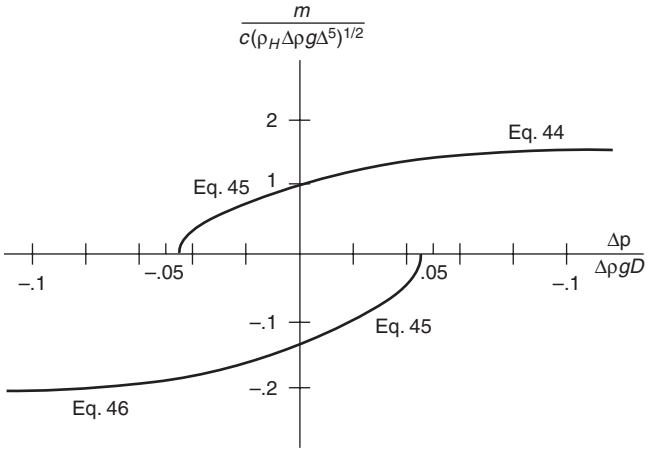

Figure 2-3.9. ***Theory of flow based on Equations 44 through 46.***

The theory of Cooper[14] omitted the buoyancy effect on the vertical flow and was developed before the Epstein flood data were available. However, in view of present horizontal vent data uncertainty, it is a useful alternative.

Accuracy of Vent Flow Calculations

For nonbuoyant flows (using nozzles or orifices in a straight run of pipe made and calibrated with a specific geometry over a known Reynolds number range) one easily obtains 2 percent accuracy. Thus, Equations 1 through 9 are capable of high accuracy.

For vents in vertical walls with limited internal room fire circulations, the best methods of measurement may get 5 percent accuracy. However, in real fires, induced circulations are often severe and unknown. Thus, errors of 10 percent or higher must be expected. Even if flow instrumentation is located in the vent itself, there is never enough to really account for variations over the vent surface and time fluctuations originating in the fire phenomena inside the fire room.

For vents in a horizontal surface, the accuracy is completely unknown. Equations 45 through 48 reproduce the water-brine experiments in small holes. The experimental accuracy is 10 percent. However, for a real fire, the errors are probably much higher. A typical case is a hole in the ceiling burned through by the flames from below. The hole geometry is very irregular and is completely unknown. Furthermore, a fire directly below the hole supplies hot gas with a considerable vertical velocity. Also, the ceiling jet flow often provides considerable cross flow.

Full-scale experimental results determining the effects of fire circulation, large density ratios, and large Reynolds numbers are needed. The present formulas are given as "better than nothing."

Vents as Part of the Building Flow Network

A building is an enclosed space generally with floors, walls that divide the space both vertically and horizontally into rooms, corridors, and stairwells. A fire that starts at any place in the building causes gas expansion, which raises the local pressure and pushes air throughout the building through all pathways leading to the outside. If a window is open in the room of fire origin, and there is little or no wind, little flow moves through the remainder of the building. If there is no open window, the flow will move toward cracks and leaks wherever they may be in the building. All these flows are initially nonbuoyant. The flow through the building is simply flow through a complex system of pipes and orifices. As the fire grows larger, hot gas flows buoyantly out of the place of origin, while cold gas flows in below. Thus, while the net flow (out-in) is just sufficient to accommodate the fire gas expansion, the actual volumetric hot gas outflow may be 2.5 times larger than the inflow. A layer of hot gas moves along the ceiling of connected spaces and at the first opportunity proceeds up a stairwell or other ceiling (roof) opening into regions above.[15] The accumulating hot gas will help spread the fire while the newly created hot fire gases build a new hot layer in the adjacent spaces. The flow and pressure drop across each vent will then progress through a succession of situations as previously discussed. The flow throughout the building is therefore determined by the vent and flow friction drops along *all* of the available flow paths from the fire to the outside of the building.

The vent flow calculation procedures described in this section are sufficiently accurate and general to compute the required flow-pressure drop relations for building flow networks (except slow buoyant flows through horizontal vents).

Nomenclature

A	area (m^2)
a	length (m)
b	width (m)
C	flow coefficient
D	orifice diameter (m)
Fr	Froude number
g	gravity constant (m/s^2)
h	height (m)
M	molecular weight (kg/kg mol)
$\dot{m}$	mass flow rate (kg/s)
P	perimeter (m)
p	pressure (Pa)
Q	volume flow rate (m^3/s)
R	gas constant (J/kg mol K)
Re	Reynolds number
T	temperature (K)
V	velocity (m/s)
y	vertical coordinate (m)
Δ	increment of
δ	depth (see Figure 2-3.6) (m)
$\gamma = c_p/c_v$	isentropic exponent
ρ	density (kg/m^3)
μ	viscosity ($N \cdot s/m^2$)

Subscripts

a	atmosphere
b	sill of vent
c	ceiling of room
d	lower
f	floor
g	gauge
i	hot-cold interface
j	index of layer
n	neutral axis
O_2	oxygen
t	soffit of vent
u	upper
v	in the vent
1	upstream of orifice
2	downstream of orifice

CHAPTER 4

Visibility and Human Behavior in Fire Smoke

Tadahisa Jin

Background

This chapter presents the scientific basis for establishing safety evacuation countermeasures, that is, evacuation plans, escape signs, and so forth in case of fire. The data were obtained in Japan, but should provide more general guidance internationally. In particular, issues of physical and physiological effects of fire smoke on evacuees are addressed. The chapter consists of three sections: (1) visibility, (2) characteristics of human behavior, and (3) development of an intensive system for escape guidance in fire smoke.

In Japan, since the 1960s, an increasing number of people have been killed by smoke in fire-resistant buildings. Toxic gases and/or depletion of oxygen in fire smoke are the final causes of death of those victims. However, many evacuees are trapped in an early stage of fire by relatively thin smoke, and loss of visibility is an indirect but fatal cause of death. For this reason, the relations between the visibility and optical density of fire smoke were examined experimentally, and practical equations were proposed.

For further understanding of human behavior in fire smoke, many investigations were conducted by interviewing evacuees and analyzing questionnaires. Also, experimental research was carried out with subjects under limited fire smoke conditions and the threshold of fire smoke density for safe evacuation was examined.

Through many field investigations of fires, it is found that an effective guidance sign system is required for safe evacuation in fire smoke. Development of conspicuous exit signs, using a flashing light source was one means of improving evacuation in smoke-filled conditions.

A new type of escape guidance in fire smoke by continuously traveling, flashing light sources was developed, and its effectiveness was examined in a smoke-filled corridor. These innovative technologies for safe evacuation are now in practical use in Japan. A form of this is already found in floor lighting of passenger aircraft cabins.

Tadahisa Jin was born in 1936 in Japan. He received his doctor of engineering degree from Kyoto University in 1975. He joined the Fire Research Institute in 1962 and has worked in the field of visibility and human behavior in fire smoke. In 1996, he joined the Fire Protection Equipment and Safety Center of Japan and is technical advisor for the improvement of new fire protection equipment.

Visibility in Fire Smoke

Introduction

There has been much research on visibility in fog in the past, whereas relatively little research has been carried out on visibility in fire smoke. This difference is due mainly to the physical characteristics of these composite particles. Fog is composed of water mist and the individual particles are spherical. The particle size is also relatively stable in time and space. These simple characteristics enable a visibility model in fog to be developed. On the other hand, the characteristics of fire smoke, that is composition, shape, and size of the particles, depend on the combustible materials involved and the conditions of combustion. These characteristics are also highly dependent on surrounding flow and temperature fields and vary with time.

Figure 2-4.1 shows the result of measuring the relationship between visibility and smoke density on the extinction coefficient obtained from experiments performed in Japan.[1] A large difference is shown in data though the correlation is roughly between both. There are two reasons for the decrease in visibility through smoke: (1) luminous fluxes from a sign and its background are interrupted by smoke particles and reduce its intensity when reaching the eyes of a subject, and (2) luminous flux scattered from the general lighting of corridors or rooms by smoke particles

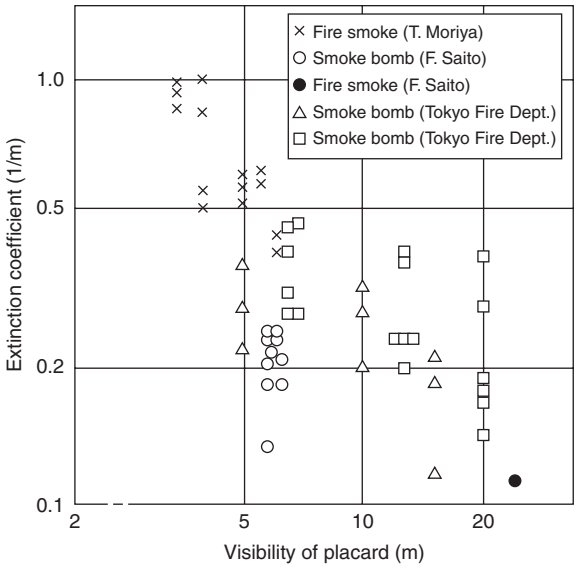

Figure 2-4.1. ***Relation between visibility of the placard-type signs and extinction coefficient by the experiments performed in Japan.***

in the direction of a subject's eyes is superimposed on the reduced flux mentioned in (1).

The human eye can distinguish a sign from the background in smoke only when the difference of intensity between the flux from the sign and that from the background is larger than some threshold value, that is, when the following equation can be established between the intensity of luminous flux from a sign (including scattered flux) B_e, the intensity of luminous flux (including scattered flux) from the background B_b, and the threshold value δ_c:

$$\left| \frac{B_e - B_b}{B_b} \right| \geq \delta_c$$

The value (the threshold contrast of signs) varies depending on the intensity of luminous flux from the background and the properties of smoke, but particularly when discussing the visibility in a meteorological fog, a constant value $\delta_c = 0.02$ is normally employed for both day and night.

Smoke Density and Visibility

Development of a mathematical visibility model based on physical parameters has attracted some researchers, but it is very complicated and tends to be of little practical use. A simple visibility model for signs seen through fire smoke is proposed by Jin as Equation 1:[2]

$$V \approx \frac{1}{C_s} \ln\left(\frac{B_{EO}}{\delta_c k L}\right) \quad (1)$$

where

V = visibility of signs at the obscuration threshold (m)

C_s = smoke density expressed by the extinction coefficient (1/m)
(hereafter, smoke density will be expressed by the extinction coefficient in 1/m)*

B_{EO} = brightness of signs (cd/m^2)

δ_c = contrast threshold of signs in smoke at the obscuration threshold (0.01 ~ 0.05)

$k = \sigma_s/C_s$ (0.4 ~ 1.0) and $C_s = \sigma_S + \sigma_{ab}$ (σ_S: scattering coefficient; σ_{ab}: absorption coefficient)

L = 1/π of mean illuminance of illuminating light from all directions in smoke (1 m/m^2)

For placard-type (reflecting) signs, Equation 1 can be modified to

$$V \approx \frac{1}{C_s} \ln\left(\frac{\alpha}{\delta_c k}\right) \quad (2)$$

where

α = reflectance of sign.

The signs in a smoke-filled chamber were observed from outside through a glass window. The results are shown in Figure 2-4.2. This shows the relation between the visibility of self-illuminated signs at the obscuration threshold and the density of smoldering smoke (white) or flaming smoke (black). In the range of the visibility of 5 to 15 m, the product of the visibility, V, at the obscuration threshold and the smoke density, C_s, is almost constant.

The visibility in black smoke is somewhat better than in white smoke of the same density; this remarkable difference in visibility is not recognized among smokes from various materials. For reflecting signs, the product of the visibility and smoke density is almost constant, too. The product depends mainly on the reflectance of the sign and the brightness of illuminating light. The visibility, V, at the obscuration threshold of signs is found to be

$$V = \frac{(5 \sim 10)}{C_s} \text{ (m)} \quad \text{for a light-emitting sign} \quad (3)$$

and

$$V = \frac{(2 \sim 4)}{C_s} \text{ (m)} \quad \text{for a reflecting sign} \quad (4)$$

The visibility of other objects such as walls, floor, doors, stairway, and so forth in an underground shopping mall or a long corridor varies depending on the interior and its contrast condition; however, the minimum value for reflecting signs may be applicable.

---

*Note that the extinction coefficient (C_s) can be obtained by the following equation:

$$C_s = \frac{1}{L} \ln\left(\frac{I_o}{I}\right)$$

where

I_o = the intensity of the incident light

I = the intensity of light through smoke

L = light path length (m)

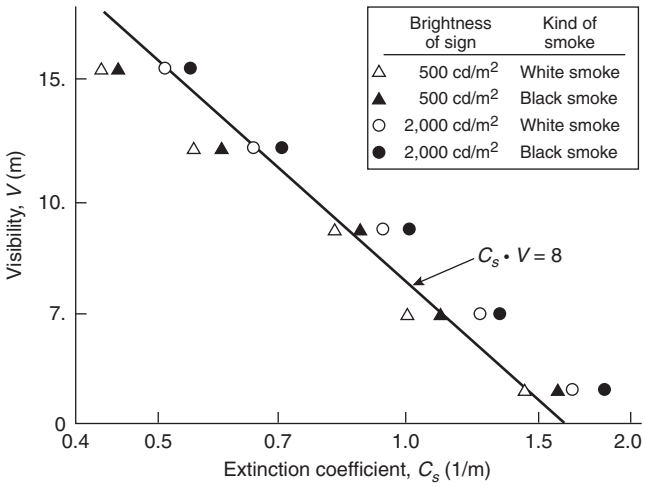

Figure 2-4.2. ***Relation between the visibility of self-illuminated signs at the obscurity threshold and smoke density (extinction coefficient).***

Visibility of Signs through Irritant Smoke and Walking Speed

A 20-m-long corridor was filled with smoke corresponding to an early stage of fire; a highly irritant white smoke was produced by burning wood cribs with narrow spacing between the sticks, and a less irritant black smoke was produced by burning kerosene. The subjects were instructed to walk into the corridor from one end, or to record the places where they saw a lighted FIRE EXIT sign (previous signs before 1982) at another end, or to read the words on the signs.[2,3]

For the obscuration threshold of the sign, the following relation can be found $C_S \cdot V \cong$ constant. However, for visibility at the legible threshold of words, this relation can only apply to nonirritant smoke, as shown in Figure 2-4.3.

The visibility in irritant smoke decreases sharply at a smoke density exceeding a certain level. In thick irritant smoke, the subjects could only keep their eyes open for a short time and tears ran so heavily that they could not see the words on the signs. However, in this case when the exit signs are very simple or sufficiently familiar to the occupants to be recognized at a glance, this irritant effect of smoke may not cause so much trouble in locating the exits.

The smoke irritation reduces the visibility for evacuees and consequently there will be a possibility of needless unrest or panic. The smoke hazards of concern are found not only in such psychological reactions, but also in evacuees' actions, especially walking speed.[4,5]

In this experiment, walking speed in the smoke was determined as shown in Figure 2-4.4. Both smoke density and irritation appear to effect the walking speed. This figure shows that the walking speed in nonirritant smoke decreases gradually as the smoke density increases. However, in the irritant smoke, the speed decreases very rapidly in the same range of smoke density levels. From this observation, the sharp drop in walking speed is explained by the subjects' movements: they could not keep their eyes open and they walked inevitably zigzag or step by step along the side wall.

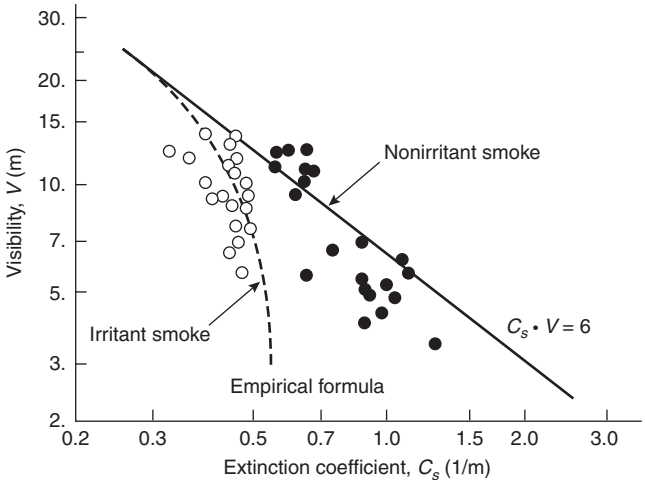

Figure 2-4.3. ***Visibility of the FIRE EXIT sign (signs of the type used before 1982) at the legible threshold of the words in irritant and nonirritant smoke.***

Decrease of Visual Acuity in Irritant Smoke

Further laboratory studies were conducted to determine the relationship between visual acuity and the smoke irritant effect in a room filling with a high irritant smoke.[3] Visual acuity indicates the ability of the human eye to distinguish two points very close together. A visual acuity of 1.0 is defined as the conditions under which a 1.5 mm gap between two points can be distinguished from a distance of 5 m. The visual acuity is 0.5 when the gap can be distinguished from only 2.5 m. Usually, visual acuity is obtained from the Landolts ring test chart. This has been an international standard since 1909 when it was established by the International Association for Ophthalmology.

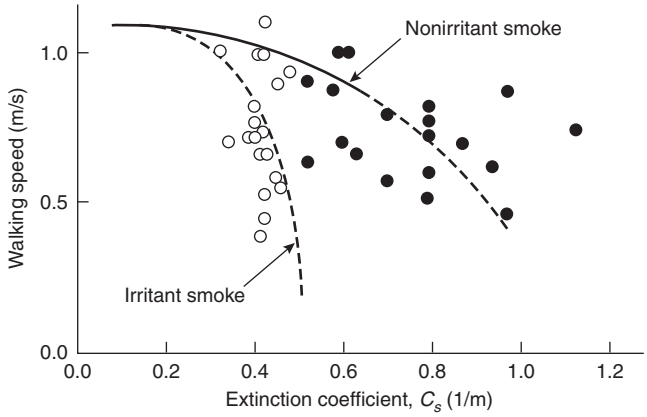

Figure 2-4.4. ***Walking speed in fire smoke.***

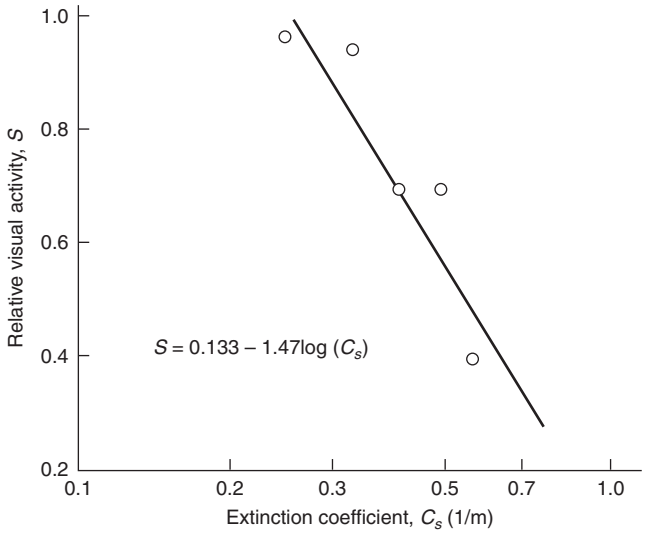

Figure 2-4.5. ***Decrease of relative visual acuity due to smoke irritant effect.***

Weber-Fechner's law gives the relationship between an impact on human sensitivity and its response; the response of human sensitivity is logarithmically proportional to the impact intensity.[6] This well-known theory is applied to the series of experiments, that is,

$$S = A - B \log C_S$$

where

S = relative visual acuity as the response
C_S = extinction coefficient as the impact
A, B = experimental constants

The relative visual acuity, S, and C_S data are plotted on a semi–log chart as shown in Figure 2-4.5 in the region of $C_S > 0.25$ 1/m. The data plotted in this figure indicate an approximately linear relationship, then the decrease of visual acuity due to the smoke irritant effect is expressed as

$$S = 0.133 - 1.47 \log C_S \quad (5)$$

The drop of visual acuity through smoke seems to be caused mainly by two factors. One is the apparent decrease of the visual acuity due to the physical effect of smoke particles obscuring the object. The other is the physiological irritant effect of smoke. Thus the visibility through smoke is expressed by the next approximations:

$$V_1 = C/C_S \qquad (0.1 \leq C_s < 0.25 : \text{in nonirritant region}) \quad (6)$$

$$V_2 = (C/C_S)(0.133 - 1.47 \log C_S) \quad (C_S \geq 0.25: \text{in irritant region}) \quad (7)$$

The empirical constant C in the equations depends on several experimental conditions; the brightness of objects and their surroundings, the contrast between them, and the kinds of objects present. The obtained relationships Equations 6 and 7 are applied to the series of experiments on visibility through smoke, and the results are presented in Figure 2-4.3 with dash-dotted line. The theoretical curves approximately agree with the experimental data when the constant is set to be 6.0. The visibility through other kinds of smoke besides the irritant white smoke from smoldering wood may be considered to vary in the intermediate region between Equations 6 and 7.

Visibility of Colored Signs

Measurement of spectral extinction properties of smoke: Figure 2-4.6 shows the change of the relative spectral extinction coefficient (ratio of spectral extinction coefficient to that at a wavelength of 700 μm) with time for smoldering wood smoke. It indicated that reduction of the longer wavelength (red light) is small compared with the shorter wavelength (blue light) in fire smoke. However, this reduction (gradients of the curve in the figure) changes with time. The inversion results from change in the size of smoke particles.

The relative spectral extinction properties have also been measured for the smoldering smoke from polystyrene foam and polyvinyl chloride. Compared with the properties of wood, the time for the gradient inversion is longer for the smoke of these materials. The relative spectral extinction properties of flaming wood smoke are shown in Figure 2-4.7. There is no inversion of the gradient of these curves. There is little or no change in the spectral extinction with time for smoke from flaming PVC, polystyrene, or kerosene.

Ratio visibility of red light to that of blue light: Let us assume that the smoke density at which fire escape is still possible is 0.5/m, and that the time for such smoke density to develop in a building is about 10 min after ignition.

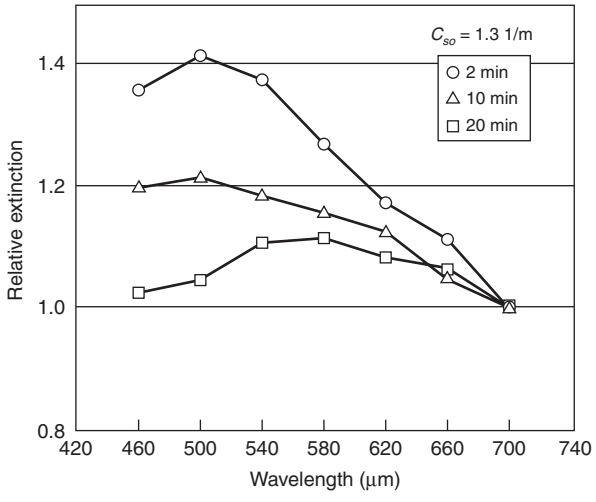

Figure 2-4.6. ***The change of the relative spectral extinction coefficient with time for smoldering smoke from wood.*** C_{s0} ***= Initial smoke density.***

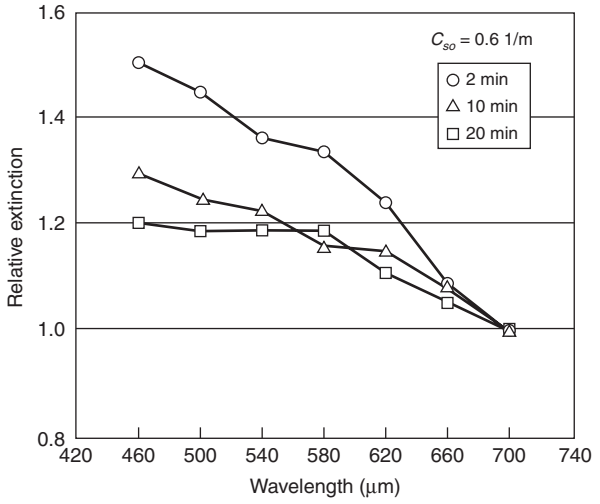

Figure 2-4.7. ***The change of the relative spectral extinction with time for flaming wood smoke. C_{s0} = initial smoke density.***

The visibilities of blue light through smoke will be compared with that of red using a calculation with the following assumptions:

1. The wave length is 657 nm for red light and 483 nm for blue light.
2. The same brightness can be obtained for both lights with a luminance meter with spectral luminous efficiency.
3. The contrast threshold at the obscuration threshold is the same for both red and blue lights.

Under the above assumptions, the ratio of visibility of a red-lighted sign, V_{red}, to that of a blue-lighted sign, V_{blue}, can be expressed by

$$\frac{V_{red}}{V_{blue}} \approx \frac{C_{s,blue}}{C_{s,red}}$$

where $C_{s,blue}$, $C_{s,red}$ are the extinction coefficients for blue light and red light, respectively.

The ratios of sign, V_{red} to V_{blue} for various smokes (10 min after generation and for the initial extinction coefficient, $C_{s0} \approx 0.5$ 1/m) are given in Table 2-4.1. This table shows that the visibilities of red-lighted signs are 20 to 40 percent larger for smoldering smoke and 20 to 30 percent larger for flaming smoke than those of blue-lighted signs. This fact indicates that visibility varies by only a few tens of percent at the most by changing the color while keeping the brightness constant. If we require to double the visibility of a conventional sign, there is no other way but to increase the brightness by a significant factor (see Equation 1).

Table 2-4.1 ***Values of V_{red}/V_{blue} for Fire Smoke***

Smoldering Smoke	V_{red}/V_{blue}	Flaming Smoke	V_{red}/V_{blue}
Wood	1.3	Wood	1.2
Polystyrene	1.4	Polystyrene	1.2
Polyvinyl chloride	1.2	Polyvinyl chloride	1.2
		Kerosene	1.3

Human Behavior in Fire Smoke

Emotional State in Fire Smoke

An attempt was made to monitor the subjects' emotional state of mind when exposed to fire smoke using a steadiness tester that is often employed in psychological studies.[4] A test chamber was used that has a floor area of 5 × 4 m, no windows, and floor-level illumination averaging 30 lx at the start of the experiment. White smoke was produced by placing wood chips in an electric furnace. The smoke generation rate was adjusted such that the extinction coefficient increased at the rate of 0.1 1/m per minute.

One subject sat at a table in the enclosure and manipulated the steadiness tester that was located on the table. The tester is faced with a metal plate in which four holes have progressively graded diameters as shown in Figure 2-4.8. The subject was told to thrust a metal stylus into holes in a specified order, trying not to touch the hole edges with the stylus. The smaller the hole size, the more concentration the subject needs to avoid contact. As the smoke density in the test room increased, fear of smoke and irritations to his or her eyes and throat hampered concentration more seriously, causing an increasing frequency of contact between the stylus and hole edges. About half of the 49 subjects subjected to the test consisted of researchers from the Fire Research Institute (former name of National Research Institute of Fire and Disaster): most of the remainder were housewives.

Figure 2-4.9 is the result of an attempt to determine the subjects' emotional variations on the basis of the num-

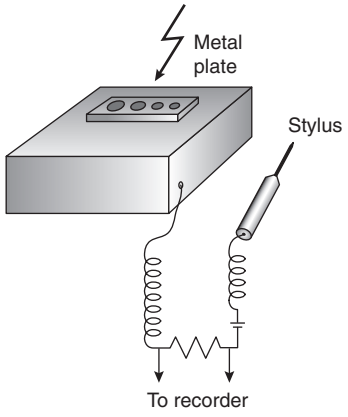

Figure 2-4.8. ***Sketch of a steadiness tester to monitor the subjects' emotional fluctuation.***

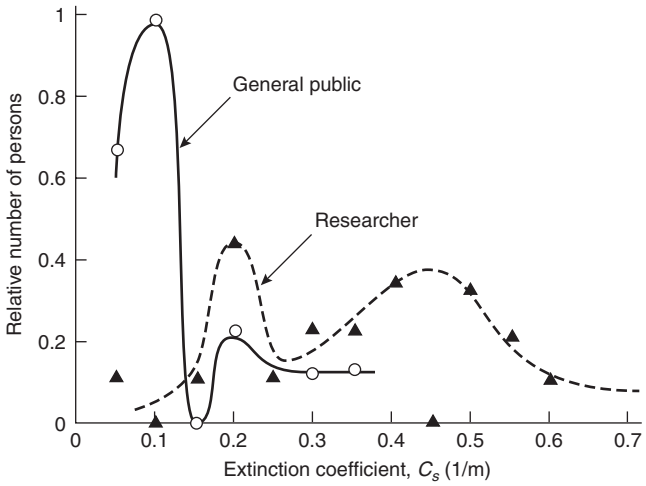

Figure 2-4.9. ***Number of emotionally affected subjects versus smoke density at the point of rapid increase in the number of contacts in the steadiness tester.***

ber of stylus contact on the steadiness tester. Curves with two peaks as shown were obtained for both groups of subjects. These peaks seem to attest to the following facts: other than the Institute researchers, most subjects began to be emotionally affected when the smoke density reached 0.1 1/m, but in a few others, emotional fluctuations did not begin to be pronounced until the smoke reached an extinction coefficient of $0.2 \sim 0.4$ 1/m. In contrast, most researchers began to show emotional fluctuations only when the smoke density reached $0.35 \sim 0.55$ 1/m although a small number of them responded at the lower smoke density of 0.2 1/m.

Interviews with some subjects were held after the experiment. Comments by many of the subjects representing the general public could be generalized like this: "Smoke itself didn't scare me much when it was thin, but irritation to my eyes and throat made me nervous. When I thought of the smoke still getting thicker and thicker, I was suddenly scared of what was going to happen next." In other words, these subjects were more afraid of what was going to happen next than they were physiologically unable to withstand the smoke.

Hence, the author believes that the data obtained from these subjects could reasonably be treated as equivalent to those that would be obtained from a group of unselected people who are unfamiliar with the internal geometry of a building on fire. The smoke density of 0.15 1/m, at which most of the subjects analyzed in Figure 2-4.9 began to feel uneasy, could be determined as the maximum smoke density for safe evacuation of a building to which the public have access.

In contrast, the Institute researchers who served as subjects said in the interview, "Irritation to my eyes was rather acute but the smoke didn't scare me because I had heard in the pretest briefing that it was harmless. But as the smoke grew denser, I began to feel more acute irritation in my eyes and throat, and when I got the signal to end the test (smoke extinction coefficient $0.5 \sim 0.7$ 1/m), irritation and suffocation were near the limit I could physiologically withstand. Toward the end of the test, visibility in the test room was so limited that I saw only a small floor area around my feet, and this made me a little nervous when I walked through the smoke."

Even though these researchers had some knowledge of smoke from the pretest briefing and were well informed of the geometry in the test room, most of them began to be emotionally affected when the smoke density exceeded 0.5 1/m. It could be reasoned that emotional instability of these subjects during the test resulted from physiological rather than psychological reasons.

These facts led the author to believe that the results of this experiment using Institute researchers as the subjects can be treated as data relevant to people who are well informed of the inside geometry of a building on fire. This means that the smoke density of 0.5 1/m, at which Figure 2-4.9 indicates most of the researchers began to lose steadiness, can be determined as the threshold where escape becomes difficult even for persons who are well familiar with the escape route in the building.

Visibility at these smoke densities is listed in Table 2-4.2, which indicates that those who know the inside geometry of the building on fire need a visibility of 4 m for safe escape while those who do not need a visibility of 13 m.

In Table 2-4.3, a comparison is made between some of the values of acceptable visibility or allowable smoke density proposed by researchers who have conducted many experiments on escape through fire smoke.[2] Wide variations in the proposed values are probably due to differences in the geometry of the places and the composition of the group escaping from fire.

Table 2-4.2 ***Allowable Smoke Densities and Visibility That Permits Safe Escape***

Degree of Familiarity with Inside Building	Smoke Density (extinction coefficient)	Visibility
Unfamiliar	0.15 1/m	13 m
Familiar	0.5 1/m	4 m

Table 2-4.3 ***Values of Visibility and/or Allowable Smoke Density for Fire Safe Escape Proposed by Fire Researchers***

Correct Answer Rate and Emotional Instability in Thick Fire Smoke

An experimental study was conducted in order to obtain data on emotional instability in thick, hot smoke (see Figure 2-4.10). Mental arithmetic and walking speed were adopted as indicators and the subjects were asked to complete a questionnaire to allow their response to smoke and heat to be assessed.[14]

The corridor was filled with white smoke generated by wood chips that were allowed to smolder in an electric furnace before each experiment. At the start of each experiment, the smoke density was adjusted to 1.2 1/m and 2 or 3 subjects entered into the corridor individually at the same smoke density condition. The temperature inside the corridor was about 20°C. At the inner positions A and B, subjects were exposed to radiant heat from an electrical radiator (12 kW at A and 3 kW at B) installed at ceiling level. The maximum heat fluxes at positions A and B, 1.5 m above the ground, were 2.4 kW/m² and 1.6 kW/m² respectively. The mean radiant temperature measured with a glove thermometer was about 82°C at A and 75°C at B.

In this experiment, a mental arithmetic test was adopted to estimate the degree of emotional instability under thick and hot smoke condition. The rate of correct answers to simple arithmetic questions was expected to decrease with increasing human emotional instability. This rate was adopted as an index of emotional instability. The mental arithmetic questions were recorded in an endless tape and 10 questions were put to the subject by a loudspeaker at each five answer positions (A to E). Thirty-one adults aged 20 to 51 (14 male, 17 female) participated in this experiment. The females were mainly housewives and the males were undergraduate students.

The smoke density was not the same at the beginning of each experiment. The values varied in the range of $C_S = 0.92 \pm 0.21$ 1/m. In the first experimental trials with thicker smoke, 17 subjects (6 male and 11 female) could reach the furthest position A, but the other 14 subjects (8 male and 6 female) turned back. The solid line in Figure 2-4.11 shows how the relative correct answer rate varied with distance reached from the entrance. The average rate of the 17 subjects who were able to reach position A fell to the lowest level just after entering the corridor (at position E) but tended to increase as they walked further into the corridor.

The subjects pointed out afterwards that they felt uneasy as they were walking forward. The results showed that the walking speed decreased in proportion to distance from the entrance. From these observations, the extent of the decrease in the relative correct answer rate which is due to psychological factors as the subjects walk forward is not known, but may be illustrated by the dashed line in Figure 2-4.11. The abrupt decrease in the correct answer rate just after entering the corridor can be explained by the physiological effect of the smoke on the subjects' eyes and throat. This discomfort eases with lapse of time due to conditioning and the correct answer rate can rise as the subject walks further into the corridor. This is illustrated in Figure 2-4.11 by the dashed and dotted line. The effect of radiant heat is apparent in the experimental data at positions A and B.

The experimental data obtained and shown in Figure 2-4.11 with the solid line appear to be composed of two kinds of smoke effect, physiological and psychological. The relation between these two effects, for example, whether a simple algebraic addition can explain the data or not, is a task for further investigations.

Figure 2-4.12 presents the mental arithmetic results in the absence of smoke. The data at position A drop to 10 percent below those at the other positions. This decrease is caused by the heat radiation from electric heat radiators installed at the ceiling. The same drop at position A is also apparently recognized under the smoke condition presented with a normal line in Figure 2-4.11. Nevertheless, there is no fall at position B. The maximum heat flux intensity was 2030 kcal/m²h (2.47 kW/m²) at 1.5 m above the floor at A and 1370 kcal/m²h (1.60 kW/m²) at B. This suggests that there is a threshold value of heat flux be-

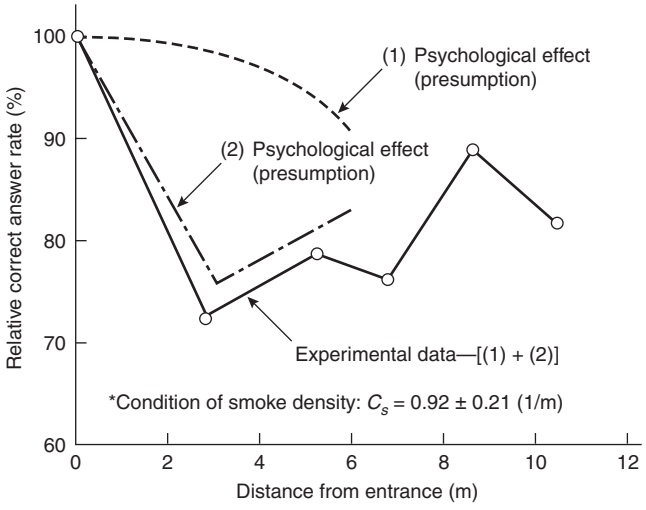

Figure 2-4.11. ***Relation between distance from entrance and correct answer rate: 17 subjects (6 males, 11 females) reached at the end of the corridor in the first trial.***

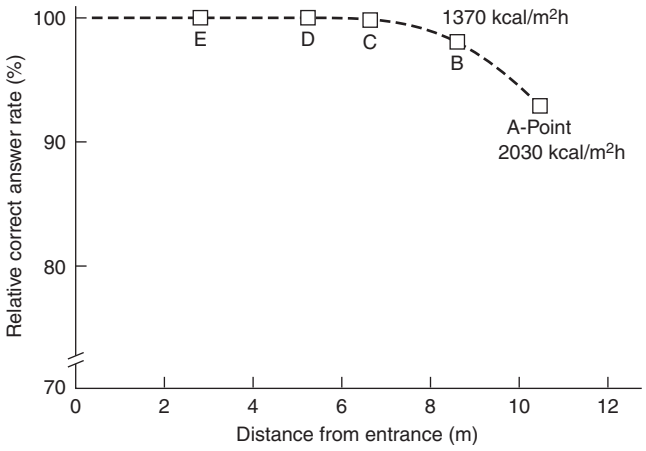

Figure 2-4.12. ***Relation between distance from entrance and correct answer rate with electric heater and without smoke: the electric heater is installed at positions A and B.***

tween 1.6 and 2.4 kW/m² above which decision making may be affected.

Some questions were asked of each subject after the experiment. One was related to the subject's response to the smoke: "What are the uncomfortable factors of smoke? Select three factors concerned with fire smoke from the following items." The result is shown in Table 2-4.4. Some variances between male and female were found. Physiological factors were mainly selected by males. Irritation of the eyes and/or throat was the first or the second selected item. Difficulty in breathing was selected as the second or the third uncomfortable factor. In comparison with the above answers from males, females tended to feel psychological discomfort. As well as physiological annoyance, the reduction in visibility was selected as the first cause of discomfort of females along with irritation and inhalation problems. The reduction in visibility was also cited as the second cause.

These experimental results indicate that the emotional instability in thick fire smoke is not necessarily caused by the same factors for males and females. Under thin smoke conditions, the smoke irritation and heat flux are selected as the first or the second factor, regardless of sex.

Table 2-4.4 ***Uncomfortable Factors of Fire Smoke***

	Male (n = 14)			Female (n = 18)

Intensive System for Escape Guidance

Improvement of Conspicuousness of Exit Sign by Flashing Light Source

An emergency exit sign, which indicates a location and/or direction of emergency exit and leads evacuees to a safe place swiftly, is important in case of fire or other emergencies. In Japan, three sizes of emergency exit sign are currently being used [40 cm(h) × 1200 cm(w); 20 cm(h) × 60 cm(w); and 12 cm(h) × 36 cm(w)]. However, the conspicuousness of an exit sign in a location where there are many other light sources was not known. In the first experiments, the conspicuousness of an "ordinary" exit sign in an underground shopping mall was measured during business hours. The experimental variables were the observation distance, size, and luminance of the sign. In the second series of experiments, the conspicuousness of a self-flashing type exit sign (flashing the lamp in the sign) was compared with that of an ordinary exit sign.[15] The type of emergency exit sign currently in use in Japan is shown in the photo in Figure 2-4.13.

Visibility and conspicuousness of exit sign: Prior to this study, another experimental study on visibility of exit signs had been carried out. In that experiment, the original type of exit sign was observed in a background without other light sources. Figure 2-4.14 shows one of the results concerned with the relation between visibility expressed by visual angle (defined by the height of the pictograph) and surface luminance. In this figure, visibility is represented on two discrimination levels; one is the level at which a person can distinguish the details of the pictograph and the other is the level at which only the direction

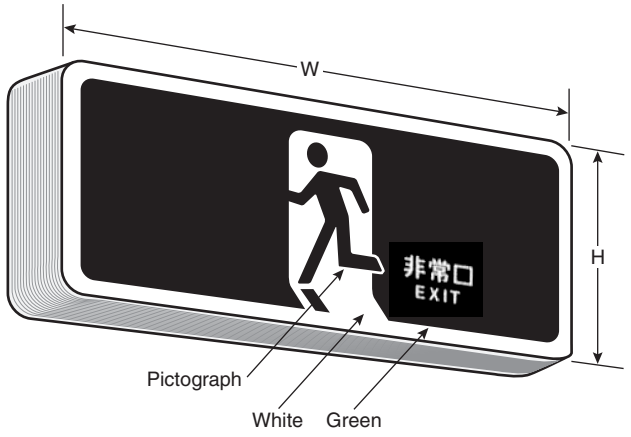

Figure 2-4.13. ***Emergency exit sign currently used in Japan.***

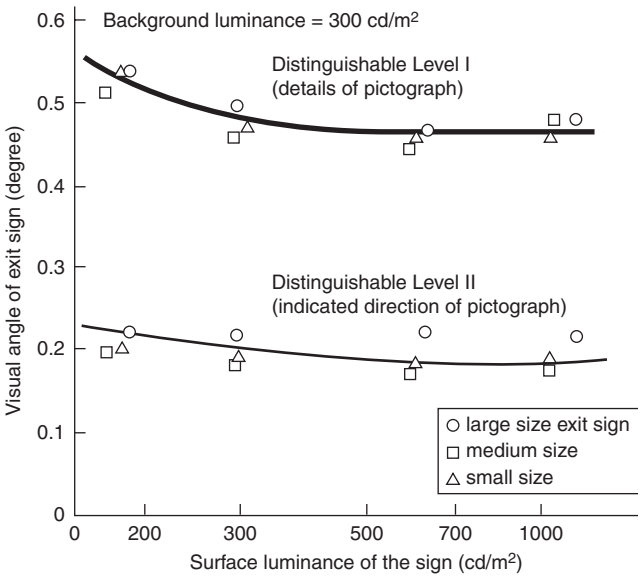

Figure 2-4.14. ***Relation between surface luminance of ordinary exit sign and visual angle associated with visibility.***

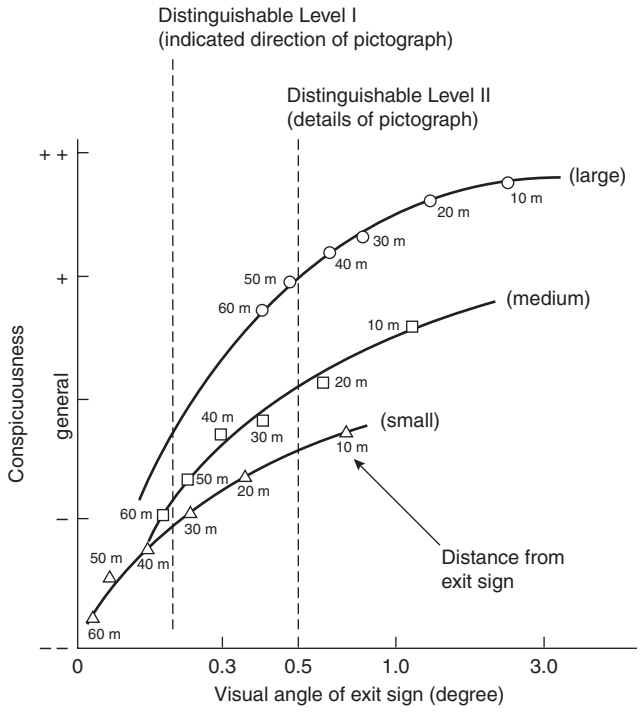

Figure 2-4.15. ***Relation between conspicuousness of ordinary type exit sign and visual angle.***

of the running person in the pictograph is distinguishable. This result indicates that visibility is almost constant when the luminance of the white part of the exit sign is more than 300 cd/m^2. This observation is true for every size of the exit sign. It is independent of the size of the sign when visibility is expressed in terms of the visual angle.

Figure 2-4.15 shows the relation between conspicuousness of ordinary exit signs and the visual angle according to the evaluation categories given in Table 2-4.5.[16] The larger-size exit sign is more conspicuous than the smaller one when the visual angle is the same. This indicates that conspicuousness depends on the relative scale of exit sign against the size of surrounding lights. In this sense, the visibility expressed in terms of visual angle does not always correspond rationally to conspicuousness.

Table 2-4.5 ***Categories for Evaluating Conspicuousness of Ordinary Type Exit Sign***

Evaluation Categories	(Marks in Fig. 2-4.15)
1. The exit sign is fairly conspicuous	(++)
2. The exit sign is slightly conspicuous	(+)
3. The exit sign is similar to the general level	(general)
4. The exit sign is less conspicuous	(–)
5. The exit sign is not conspicuous at all	(––)

Improvement of conspicuousness by flashing the light sources: Figure 2-4.16 shows the relation between conspicuousness of an ordinary exit sign and that of the self-flashing type exit sign using the categories for evaluation given in Table 2-4.6. In this figure the vertical interval between the dash-dotted line and the curves corresponds to the improvement of conspicuousness by the flashing light in the sign. For the medium-size exit sign, a self-flashing type sign is more effective to improve conspicuousness. However, the small-size exit sign of self-flashing type is not conspicuous enough when observed from a distance more than 20 m in the background with many other lights, because the exit sign is too small to be recognized as an exit sign, even though the flashing was expected to be much more conspicuous. The large exit sign is big enough to have sufficient conspicuousness without flashing even in the background with many competing light sources. Conspicuousness of the sign could also be improved by adding a flashing light source the same as a flashing-type sign.

In addition to the improvement achieved by adding a flashing light, the author has suggested the development of an acoustic guiding exit sign. Adding a speaker and voice recorded IC chip to the flashing exit sign can provide an announcement such as "Here is an Emergency Exit" when fire is detected by, for example, smoke detectors.[17]

Effect of Escape Guidance in Fire Smoke by Traveling Flashing of Light Sources

An escape guidance system has been developed for safe evacuation. This system indicates the appropriate escape directions by creating a row of flashing lights leading away from a hazardous area such as a fire in a

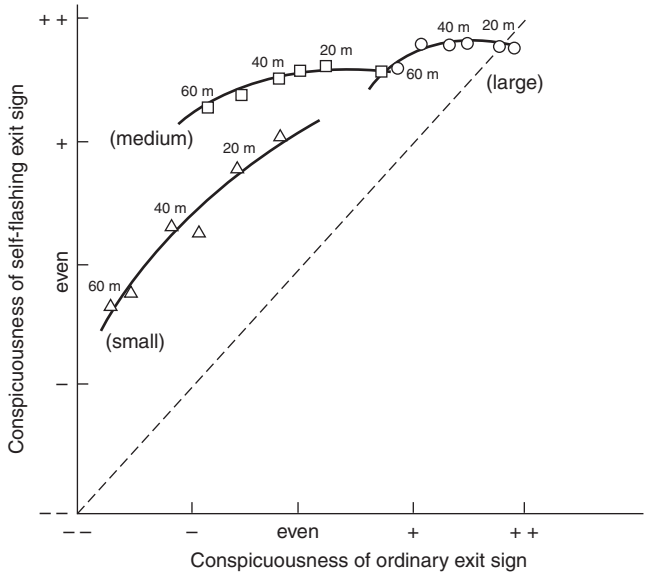

Figure 2-4.16. ***Relation between the conspicuousness of a self-flashing exit sign and that of an ordinary one.***

Table 2-4.6 ***Categories for Evaluating Conspicuousness of Self-Flashing Exit Signs***

Evaluation Categories *(as compared with the ordinary-type exit sign)*	(Marks in Fig. 2-4.16)

2. The flashing exit sign is slightly conspicuous	(+)
3. The flashing exit sign has similar conspicuousness	(general)
4. The flashing exit sign is less conspicuous	(–)
5. The flashing exit sign is not conspicuous	(– –)

building. A form of this is already found in the floor lighting of passenger aircraft cabins.

An experiment was carried out to evaluate this system using a portion of passageway (1.4 m wide, 6.3 m long, and 2.5 m high) filled with smoke. As lighting for the passageway, fluorescent lamps are provided under the ceiling, giving about 200 lx at the center of the passage in the absence of smoke. The flashing light unit boxes are set on the floor along the side of the right-hand wall at intervals of 0.5 m, 1.0 m, and 2.0 m as a test guidance system.[18]

The effectiveness of the escape guidance was evaluated by 12 subjects who walked in a line at a side of a row of flash-traveling green light sources located on the floor under various conditions, that is, the spacing and the traveling speed of flashing lights and smoke concentration. Under each condition, subjects walk along the system successively; however, only two or three subjects are inside the passageway at a time to maintain free walking speed.

The degree of effectiveness of escape guidance is classified into seven steps as follows, and the evaluations are made by filling one score from seven points into an observation sheet directly after each test run. These categories are adopted as a semantic differential scale for escape guidance.

Score	Effectiveness
7 point	very effective for escape guiding
5 point	fairly effective
3 point	a little effective
1 point	not effective

(Points 2, 4, and 6 correspond to the middle point between 1 and 3, 3 and 5, and 5 and 7 respectively.) In general, the effectiveness decreases with increasing smoke. The evaluation value of 4 point stands for less effective than fairly effective and more effective than a little effective, so we consider the value a threshold where practical effectiveness of escape guidance is secured.

The correlation between smoke concentration and the effect of escape guidance is shown in Figure 2-4.17. This indicates that this system is useful for evacuees to escape in thick smoke (up to an extinction coefficient of 1.0

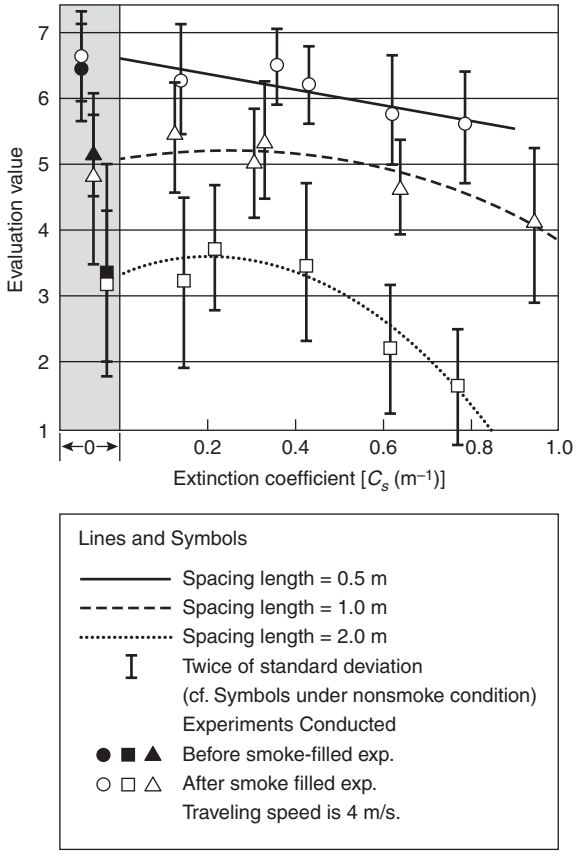

Figure 2-4.17. ***Relation between smoke density and the effect of escape guidance with variation of flashing light sources under a smoke condition.***

per meter) when the spacing length is 0.5 m and the flashing speed is 4 m/s. When the spacing length is set to be 1.0 m, the effectiveness decreases but it is still useful in smoke under 0.8 1/m. However, when the spacing is greater than 2.0 m, less effectiveness is expected even under a no-smoke condition and it decreases as the smoke density increases. The evaluation values in the meshed area to the left in Figure 2-4.17 were obtained before and after smoke inhalation, but under conditions of no smoke. This area shows stability of the evaluation, and no assimilation effects are observed.

From Figure 2-4.17, the effectiveness of flashing traveling signs in an ambient atmosphere is maintained up to a smoke density of 0.4 1/m. This result is very important for evaluating the escape guidance system from the viewpoint of safe evacuation. Visibility (observable distance) of normal exit signs drops rapidly from more than 10 m to 5 m, and the guidance effectiveness is also lost over the same range of smoke densities.[2] This relation between the visibility of ordinary exit signs and the smoke density is expressed in Figure 2-4.18.

Compared with the decrease in visibility of ordinary exit signs, the decrease in the effectiveness of the guidance system with increasing obscuration seems to be small, so that the new system is expected to maintain high and stable effectiveness of guidance escape, even in relatively dense smoke. It is known that the threshold of smoke density for safe evacuation of a building without emergency signs is under 0.5 1/m for evacuees who are familiar with the building and 0.15 1/m for strangers.[4]

The effectiveness of this escape guiding system is also illustrated by previous experimental observations mentioned in the section headed Correct Answer Rate and Emotional Instability in Thick Fire Smoke, that is, 7 subjects out of 31 participants could not proceed beyond 2.8 m from the exit, 3 subjects were stopped at 5.3 m, 3 subjects at 6.9 m, and 1 subject at 8.6 m in the corridor filled with thick smoke ($C_S = 0.92 \pm 0.21$). Many evaluation values at 0.2 1/m smoke density give higher values than those under a nonsmoke condition. It is considered that interference by the background lighting is weakened by the smoke and the evacuees are able to concentrate more on the flashing light. Therefore, in thinner smoke at the very beginning of fire, this type of guidance system can be expected to have a high effectiveness for safety evacuation, as well as in thick smoke.

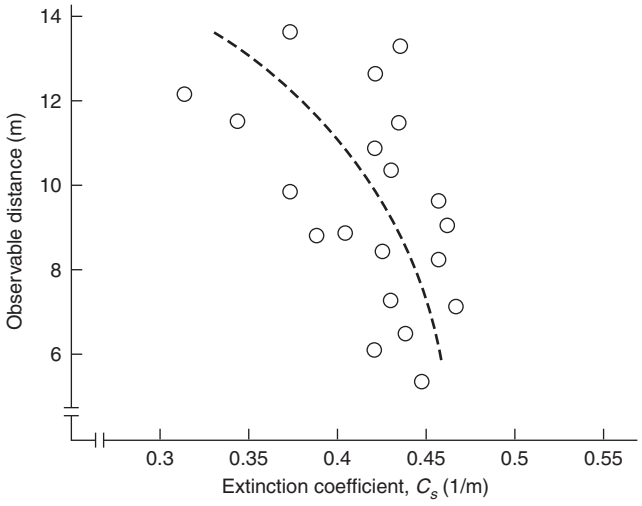

Figure 2-4.18. ***Relation between smoke density and visibility of exit sign.***

Clearly, the spacing between flashing light sources is a very important factor to maintain effectiveness. High effectiveness is expected, especially, when the spacing is less than 1 m. The relation between effectiveness and flashing light conditions in the presence of smoke is found to be almost the same as the relation under a nonsmoke condition.

Conclusion

The following are the major conclusions derived from these research activities:

1. Relation between smoke density and visibility in fire smoke was examined under various kinds of smoke, and simple equations were proposed for practical use.
2. The visibility in fire smoke depends on its irritating nature as well as the optical density of the smoke. Increasing irritating effect causes a rapid drop of visual acuity. A modification due to irritating effect was made for the visibility versus smoke density equation.
3. Evacuees begin to feel emotional instability in relatively thin smoke; however the threshold of smoke density varies with the subject. Through experiments and investigations, it was found that the level depended on the degree of evacuees' familiarity of the internal geometry of a building on fire. Evacuees in unfamiliar buildings tend to feel emotional instability in thinner smoke.
4. Ability of evacuees to think clearly when exposed to fire smoke decreases with increasing smoke density. Generally, this is caused by both psychological and physiological effects on evacuees. Also, in due course, hot smoke causes a further decrease of thinking ability.
5. Conspicuousness of the ordinary exit sign was improved by a flashing light source sign or by adding a flashing light source in conditions where there were many other light noises.
6. A new type of escape guidance in fire smoke by traveling flashing light sources toward exits was developed, and the effectiveness was examined in a smoke-filled corridor. This new system is expected to maintain high and stable escape guidance, even in relatively thick smoke.

CHAPTER 5

Effect of Combustion Conditions on Species Production

D. T. Gottuk and B. Y. Lattimer

Introduction

A complete compartment fire hazard assessment requires a knowledge of toxic chemical species production. Although combustion products include a vast number of chemical species, in practical circumstances the bulk of the product gas mixture can be characterized by less than ten species. Of these, carbon monoxide (CO) represents the most common fire toxicant. (See Section 2, Chapter 6.) Over half of all fire fatalities have been attributed to CO inhalation.[1,2] Concentrations as low as 4000 ppm (0.4 percent by volume) can be fatal in less than an hour, and carbon monoxide levels of several percent have been observed in full-scale compartment fires. A complete toxicity assessment should not only include the toxicity of CO but also include the synergistic effects of other combustion products, such as elevated CO_2 and deficient O_2 levels.

The transport of combustion products away from the room of the fire's origin is of the utmost importance, because nearly 75 percent of the fatalities due to smoke inhalation occur in these remote locations.[3] However, conditions close to the compartment of origin will govern the levels that are transported to remote locations. The research in this area has focused on characterizing species levels produced under a variety of conditions, both inside and nearby the compartment of fire origin.

Species product formation is affected by the compartment geometry, ventilation, fluid dynamics, thermal environment, chemistry, and mode of burning. The mode of burning and ventilation are two of the key conditions that dictate product formation. These conditions can be used to classify fires into three general categories (1) smoldering, (2) free- (or open-) burning fires, and (3) ventilation-limited fires. Smoldering is a slow combustion process characterized by low gas temperatures and no flaming. Under these conditions, high levels of CO can be generated. Section 2, Chapters 6 and 9, and Section 3, Chapter 4, discuss this mode of burning in detail; thus, it will not be discussed further here. Free-burning fires are flaming fires that have an excess supply of air. These well-ventilated fires (discussed in Section 3, Chapter 4) are generally of little concern in terms of generating toxic species. This chapter focuses primarily on the third category, ventilation-limited flaming fires. These fires consist of burning materials inside an enclosure, such as a room, in which airflow to the fire is restricted due to limited ventilation openings in the space. As a fire grows, conditions in the space will transition from overventilated to underventilated (fuel rich). It is normally during underventilated conditions that formation of high levels of combustion products, including CO, creates a major fire hazard.

This chapter discusses the production of species within a compartment fire and the transport of these gases out of the fire compartment to adjacent areas. Engineering correlations are presented along with brief reviews of pertinent work on species production in compartment fires. These sections provide the background and basis for understanding the available engineering correlations and the range of applicability and limitations. An engineering methodology is presented to utilize the information given in this chapter.

This chapter is organized according to the following outline:

- Basic Concepts
- Species Production within Fire Compartments
  - Hood Experiments
  - Compartment Fire Experiments

Dr. Daniel T. Gottuk is a senior engineer at the fire science and engineering firm of Hughes Associates, Inc. He received his Ph.D. from Virginia Tech in the area of carbon monoxide generation in compartment fires. He continues to work in the area of species generation and transport in compartment fires.

Dr. Brian Y. Lattimer is a research scientist at Hughes Associates, Inc. His research has focused on species formation and transport in building fires, fire growth inside compartments, flame spread, and heat transfer from flames.

Chemical Kinetics
Fire Plume Effects
Transient Conditions
Species Transport to Adjacent Spaces
Engineering Methodology

Basic Concepts

In a typical compartment fire, a two-layer system is created. The upper layer consists of hot products of combustion that collect below the ceiling, and the lower layer consists of primarily ambient air that is entrained into the base of the fire. (See Figure 2-5.1a.) Initially, the fire plume is totally in the lower layer, and the fire burns in an overventilated mode similar to open burning. Due to excess air and near-complete combustion, little CO formation is expected in this mode. (See Section 3, Chapter 4 for yields.) As the fire grows, ventilation paths in the room restrict airflow, creating underventilated (fuel-rich) burning conditions. It is generally under these conditions that products of incomplete combustion are created. Typically, the fire plume extends into the upper layer, such that layer gases recirculate through the upper part of the plume.

Depending on both the size of the room and the size of the fire, it is possible to have a fire plume that cannot be contained within the room, resulting in flame extension out of windows or doors. Flame extension can occur when the fire plume impinges on the ceiling and the ceiling jets are longer than the distance from the plume to outside vent openings (See Figure 2-5.1b). Flame extension is different from a second burning phenomenon outside of the fire compartment, called external burning, which is discussed below. The main point to understand is that flame extension outside of the fire compartment is a result of a fire that is too large to be contained in the room. Flame extension can occur during both over- and underventilated burning conditions. To estimate when flame extension may occur, the maximum heat release rate that can be supported by the compartment ventilation needs to be determined. Flame length correlations can then be used to determine whether flames will extend outside of the compartment.

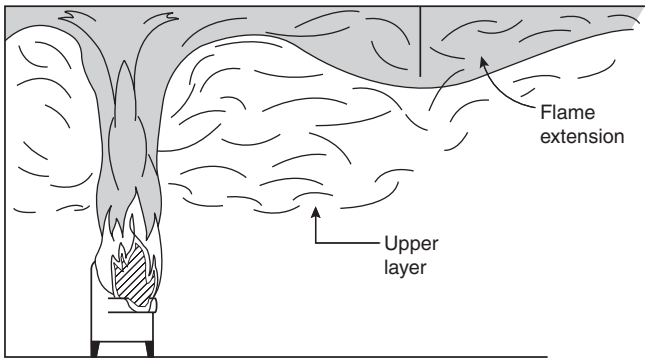

Figure 2-5.1b. ***A fire compartment with flame extension out of the doorway.***

As a fire progresses and the upper layer descends, the layer will spill below the top of doorways or other openings into adjacent areas. The hot, vitiated, fuel-rich gases flowing into adjacent areas can mix with air that has high O_2 concentrations to create a secondary burning zone outside of the compartment. (See Figure 2-5.1c.) This is referred to as external burning. External burning can also be accompanied by layer burning. Layer burning is the ignition of fuel-rich upper layer gases at the interface between the upper and lower layers. External burning and layer burning occur due to the buildup of sufficient fuel in an atmosphere that is able to mix with available oxygen. These phenomena can only occur during underventilated burning conditions. In some circumstances, external burning can decrease human fire hazard through the oxidation of CO and smoke leaving the fire compartment. (See the section in this Chapter on species transport to adjacent spaces.).

The occurrence of external burning has been predicted using a compartment layer ignition model developed by Beyler.[4] (See Section 2, Chapter 7.) Beyler derived a relationship called the ignition index to predict the ignition of gases at the interface of the upper and

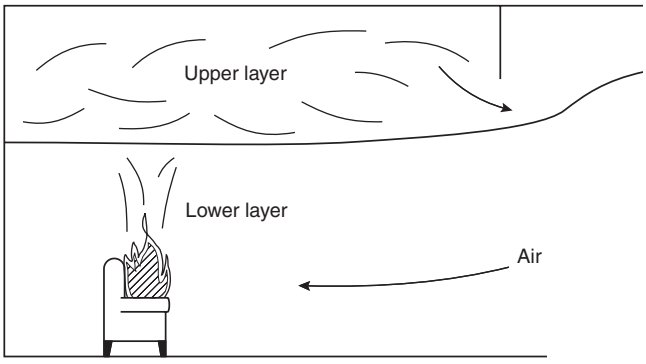

Figure 2-5.1a. ***An overventilated compartment fire with the fire plume below the layer interface.***

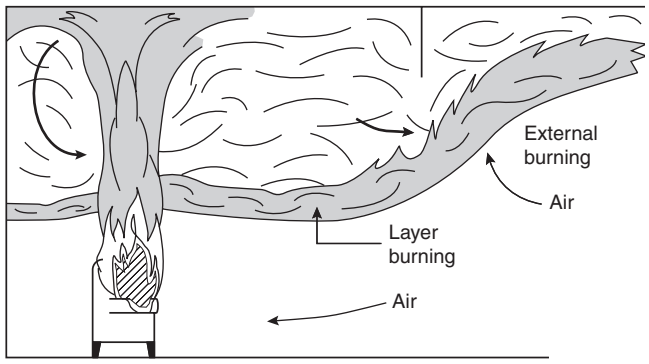

Figure 2-5.1c. ***An underventilated compartment fire with external burning of fuel-rich upper layer gases.***

lower layers inside a compartment. The ignition index, I, is defined as

$$I = \sum_j \frac{\left(C_j/100\right)\Delta H_{c,j}}{\int_{T_o}^{T_{SL,j}} n_{prod} C_p dT} \geq 1.0 \quad (1)$$

where

j = fuel species of interest
C_j = volume concentration of fuel j when fuel stream is stoichiometrically mixed with oxidant stream
$\Delta H_{c,j}$ = heat of combustion of the species j (kJ/g·mol)
$T_{SL,j}$ = adiabatic flame temperature at the stoichiometric limit for fuel species j (K)
T_o = temperature of the gas mixture prior to reaction (K)
n_{prod} = number of moles of products of complete combustion per mole of reactants (stoichiometric mixture of fuel and oxidant streams)
C_p = heat capacity of products of complete combustion (kJ/g·mol K)

The use of the ignition index is discussed in detail in Section 2, Chapter 7 of this book. An ignition index greater than 1.0 indicates that ignition is expected if the mixture contains sufficient fuel.

Species Yields

The generation of fire products in compartment fires can be quantified in terms of species yields, Y_i, defined as the mass of species i produced per mass of fuel burned (g/g):

$$Y_i = \frac{m_i}{m_f} \quad (2)$$

Similarly, oxygen is expressed as the depletion of O_2, (i.e., D_{O_2}), which is the grams of O_2 consumed per gram of fuel burned:

$$D_{O_2} = \frac{m_{O_2}}{m_f} \quad (3)$$

The normalized yield, f_i, is the yield divided by the theoretical maximum yield of species i for the given fuel, k_i. For the case of oxygen, f_{O_2} is the normalized depletion rate, where k_i is the theoretical maximum depletion of oxygen for the given amount of fuel. As a matter of convenience, the use of the term yield throughout this chapter will also include the concept of oxygen depletion. As in Section 3, Chapter 4, the normalized yield is also aptly referred to as the "generation efficiency" of compound i. By definition, the normalized yields range from 0 to 1, and are thus good indicators of the completeness of combustion. For example, under complete combustion conditions the normalized yields of CO_2, H_2O and O_2 are 1. As a fire burns more inefficiently, these yields decrease. The use of normalized yields is also useful for establishing mass balances. The conservation of carbon requires that

$$f_{CO} + f_{CO_2} + f_{THC} + f_{resid.C} = 1 \quad (4)$$

where f_{THC} is the normalized yield of gas-phase total hydrocarbons and $f_{resid.C}$ is the normalized yield of residual carbon, such as soot in smoke, or high molecular weight hydrocarbons that condense out of the gas sample.

For two-layer systems the yield of all species except oxygen can be calculated as follows:

$$Y_i = \frac{X_{i_{wet}}(\dot{m}_f + \dot{m}_a)M_i}{\dot{m}_f M_{mix}} \quad (5)$$

where

$X_{i_{wet}}$ = the wet mole fraction of species i
$\dot{m}_a$ = the mass air entrainment rate into the upper layer
$\dot{m}_f$ = the mass loss rate of fuel
M_i = the molecular weight of species i
M_{mix} = the molecular weight of the mixture (typically assumed to be that of air)

The depletion rate of oxygen is calculated as

$$D_{O_2} = \frac{0.21\dot{m}_a M_{O_2}/M_a - X_{O_2\,wet}(\dot{m}_f + \dot{m}_a)M_{O_2}/M_{mix}}{\dot{m}_f} \quad (6)$$

The normalized yield, f_i, is simply calculated by dividing the yield by the maximum theoretical yield

$$f_i = \frac{Y_i}{k_i} \quad (7)$$

Typical operation of common gas analyzers requires that water be removed from the gas sample before entering the instrument. Consequently, the measured gas concentration is considered dry and will be higher than the actual wet concentration. Equation 8 can be used to calculate the wet mole fraction of species i, $X_{i_{wet}}$, from the measured dry mole fraction, $X_{i_{dry}}$. As can be seen from Equation 8, the percent difference between $X_{i_{dry}}$ and $X_{i_{wet}}$ is on the order of the actual H_2O concentration which, depending on conditions, is typically 10 to 20 percent by volume.

$$X_{i_{wet}} = (1 - X_{H_2O_{wet}})X_{i_{dry}} \quad (8)$$

Reliable water concentration measurements are difficult to obtain. Therefore, investigators have calculated wet species concentrations using the above relationship with the assumption that the molar ratio, C, of H_2O to CO_2 at any equivalence ratio is equal to the calculated molar ratio at stoichiometric conditions.[5,6] Based on this assumption, Equation 9 can be used to calculate wet species concentrations from dry concentration measurements.

$$X_{i_{wet}} = \frac{X_{i_{dry}}}{1 + CX_{CO_{2_{dry}}}} \quad (9)$$

Equivalence Ratio

The concept of a global equivalence ratio (GER) can be used to express the overall ventilation of a control volume, such as a fire compartment. However, due to the complex interaction between the plume and the upper

and lower layers, as well as the potential extension of the fire beyond the initial compartment, a unique definition for the GER does not exist. Therefore, if one uses the term GER, it must be associated with a defined control volume.

The first efforts in developing the GER concept were based on hood experiments[7–11] (e.g., as in Figure 2-5.2) in which the idea of a plume equivalence ratio was introduced. The plume equivalence ratio, ϕ_p, is the ratio of the mass of fuel burning, m_f, to the mass of oxygen entrained, m_a, into the fire plume (below the upper layer) normalized by the stoichiometric fuel-to-oxygen ratio, r_{O_2}.

$$\phi_p = \frac{m_f/m_{O_2}}{r_{O_2}} \tag{10a}$$

Since oxygen is typically entrained into a fire plume via air, ϕ_p is commonly defined as

$$\phi_p = \frac{m_f/m_a}{r} \tag{10b}$$

where m_a is the mass of air entrained into the plume (in the lower layer) and r is the stoichiometric mass fuel-to-air ratio. As discussed in the section on species production within fire compartments, this simple characterization of the equivalence ratio well represented the global conditions that existed in the first hood and compartment fire experimental configurations.

In order to more accurately describe the time integrated conditions within the upper layer, a second equivalence ratio was defined for this control volume.[7,10,11] The upper layer equivalence ratio, ϕ_{ul}, is the ratio of the mass of the upper layer that originates from fuel sources, to the mass of the upper layer that originates from any source of air into the upper layer, divided by the stoichiometric fuel-to-air ratio.

The two equivalence ratios (ϕ_p and ϕ_{ul}) are not necessarily the same. As a fire grows, the upper layer composition represents a collective time history of products. In an ideal two layer fire, where all air enters the upper layer through the plume, ϕ_{ul} is the same as ϕ_p only during steady burning conditions. If the burning rate of the fire changes quickly compared to the residence time of the gases in the upper layer, the upper layer equivalence ratio lags behind the plume equivalence ratio. The residence time, t_R, can be defined as the time required for a unit volume of air to move through the upper layer volume, and can be characterized according to Equation 11.

$$t_R = \frac{V_{ul}\rho_{ul}}{\dot{m}_{exhaust}} \tag{11}$$

where

$\dot{m}_{exhaust}$ = mass flow rate of gases out of the layer
ρ_{ul} = density of the upper layer gases
V_{ul} = volume of the upper layer

For example, consider a compartment fire burning with a plume equivalence ratio of 0.5 with upper layer gases that have a residence time of 20 seconds. If the fire grows quickly such that ϕ_p increases to a value of 1.5 in about 5 seconds, ϕ_{ul} would now lag behind (less than 1.5). The fuel rich (ϕ_p = 1.5) gas mixture from the plume is effectively diluted by the upper layer gases since there has not been sufficient time (greater than 20 seconds) for the layer gases to change over. The result is that ϕ_{ul} will have a value between 0.5 and 1.5. Another instance when ϕ_{ul} can differ from ϕ_p is when additional fuel or air enters the upper layer directly. An example of this would be the burning of wood paneling in the upper layer.

The calculation of ϕ_{ul} can be a complex task. Either a fairly complete knowledge of the gas composition is needed[7] or time histories of ventilation flows and layer residence times are needed, to be able to calculate ϕ_{ul}. Toner[7] and Morehart[12] present detailed methodologies for calculating ϕ_{ul} from gas composition measurements. Equation 12 can be used to calculate ϕ_{ul} if the mass flow rates can be expressed as a function of time.

$$\phi_{ul} = \frac{1\int_{t-t_R}^{t} \dot{m}_f(t')\,dt'}{r\int_{t-t_R}^{t} \dot{m}_a(t')\,dt'} \tag{12}$$

Although termed the upper layer equivalence ratio, ϕ_{ul} actually represents the temporal aspect of the equivalence ratio no matter what the control volume. For instance, the control volume may be the whole compartment, as shown in Figure 2-5.1. In this case, the compartment equivalence ratio, ϕ_c, is defined as the ratio of the mass, m_f, of any fuel entering or burning in the compartment to the mass, m_a, of air entering the compartment normalized by the stoichiometric fuel-to-air ratio.

In a compartment fire, air is typically drawn into the space through a door or window style vent. If all of the air drawn into the compartment is entrained into the lower layer portion of the plume, then the plume equivalence ratio can be an adequate representation of the fire environment. However, if layer burning occurs, or multiple vents cause air to enter the upper layer directly, the use of

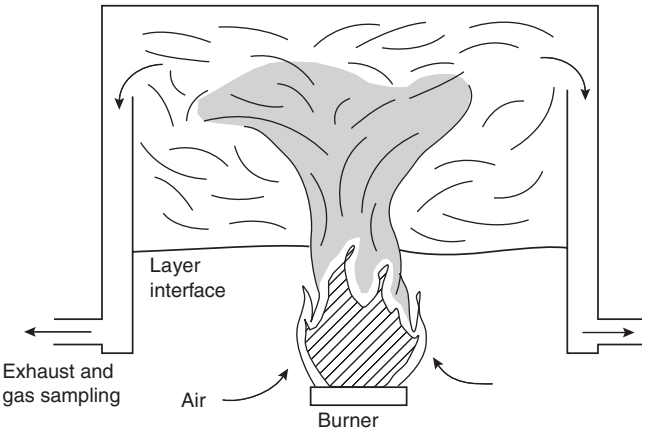

Figure 2-5.2. ***Schematic of the two-layer system created in the hood experiments of Beyler.[8,9]***

a compartment equivalence ratio is more appropriate. As a practical note, for fires within a single compartment, the equivalence ratio is calculated (and experimentally measured) based on the instantaneous fuel mass loss rate, $\dot{m}_f$, and air flow rate, $\dot{m}_a$, into the compartment (Equation 13a).

$$\phi = \frac{\dot{m}_f/\dot{m}_a}{r} \tag{13a}$$

As noted previously, r is defined as the stoichiometric fuel-to-air ratio. Unfortunately, the ratio r is sometimes defined as the air-to-fuel ratio, r_a. Therefore, consideration must be given to values obtained from tabulated data. Keeping with the nomenclature of this chapter, the equivalence ratio can also be expressed as

$$\phi = \frac{\dot{m}_f}{\dot{m}_a} \cdot r_a = \frac{\dot{m}_f}{\dot{m}_a} \frac{r_o}{Y_{O_{2,air}}} \tag{13b}$$

where

r_a = mass air-to-fuel ratio
r_o = oxygen-to-fuel mass ratio
$Y_{O_{2,air}}$ = mass fraction of oxygen in air (0.23)

The formulation of Equation 13b allows direct use of r_o values tabulated for various fuels in Table C-2 of this handbook. Another useful expression for ϕ can be derived from Equation 13b by multiplying the numerator and denominator by the fuel heat of combustion, Δh_c, and recognizing that the heat release per mass of oxygen consumed, E, is equal to Δh_c over r_o, yielding

$$\phi = \frac{\dot{Q}}{\dot{m}_a} \cdot \frac{1}{EY_{O_{2,air}}} = \frac{\dot{Q}}{\dot{m}_a} \cdot \frac{1}{3030} \tag{13c}$$

where

$\dot{Q}$ = ideal heat release rate of the fire (kW)
$\dot{m}_a$ = air flow rate, (kg/s)
$E \approx$ 13,100 kJ/kg (Reference 33)

Note that Q is the ideal heat release rate, which is determined by multiplying the mass loss rate by the heat of combustion, and is not limited by the amount of air flowing into the compartment or control volume. To date, Equation 13c has not been utilized in the literature and therefore has not been well established. However, it offers a convenient means to calculate the equivalence ratio without the need to know the fuel chemistry.

The equivalence ratio is an indicator of two distinct burning regimes, overventilated (fuel lean) and underventilated (fuel rich). Overventilated conditions are represented by equivalence ratios less than one, while underventilated conditions are represented by equivalence ratios greater than one. An equivalence ratio of unity signifies stoichiometric burning which, in an ideal process, represents complete combustion of the fuel to CO_2 and H_2O with no excess oxygen. During underventilated conditions there is insufficient oxygen to completely burn the fuel; therefore, products of combustion will also include excess fuel (hydrocarbons), carbon monoxide, and hydrogen. It follows that the highest levels of CO production in flaming fires is expected when underventilated conditions occur in the compartment on fire. This basic chemistry also suggests that species production can be correlated with respect to the equivalence ratio. Although the not-so-ideal behavior of actual fires prevents accurate theoretical prediction of products of combustion, experimental correlations have been established.

A simple model for the most complete combustion of a fuel can be represented by the following expressions:[8]

$$f_{CO_2} = f_{O_2} = f_{H_2O} = 1 \qquad \text{for } \phi < 1 \tag{14a}$$
$$f_{CO_2} = f_{O_2} = f_{H_2O} = 1/\phi \qquad \text{for } \phi > 1 \tag{14b}$$
$$f_{CO} = f_{H_2} = 0 \qquad \text{for all } \phi \tag{14c}$$
$$f_{THC} = 0 \qquad \text{for } \phi < 1 \tag{14d}$$
$$f_{THC} = 1 - 1/\phi \qquad \text{for } \phi > 1 \tag{14e}$$

These expressions assume that for $\phi > 1$, all excess fuel can be characterized as unburned hydrocarbons. Since compartment fire experiments have shown that significant levels of both CO and H_2 are produced at higher equivalence ratios, Expression 14c is not always representative, and reveals a shortcoming of assuming this simple ideal behavior. However, for the products of complete combustion (CO_2, O_2 and H_2O), this model serves as a good benchmark for comparison of experimental results.

EXAMPLE 1:

Consider a piece of cushioned furniture to be primarily polyurethane foam. The nominal chemical formula of the foam is $CH_{1.74}O_{0.323}N_{0.07}$. Calculate the stoichiometric fuel-to-air ratio, the maximum yields of CO, CO_2, and H_2O, and the maximum depletion of O_2.

SOLUTION:

For complete combustion of the fuel to CO_2 and H_2O, the following chemical equation can be written

$$CH_{1.74}O_{0.323}N_{0.07} + 1.2735(O_2 + 3.76N_2) \rightarrow 1.0CO_2 + 0.87H_2O + 4.823N_2$$

The molecular weight of the fuel, M_f, = 1(12) + 1.74(1) + 0.323(16) + 0.07(14) = 19.888.

The stoichiometric fuel-to-air ratio is

$$r = \frac{(1\text{mole fuel})(M_f)}{(\text{moles of air})(M_a)} = \frac{19.888}{1.2735(4.76)(28.8)}$$
$$r = 0.1139$$

The stoichiometric air-to-fuel ratio is

$$\frac{1}{r} = 8.78$$

The maximum yield of CO (i.e., k_{CO}), is calculated by assuming that all carbon in the fuel is converted to CO. Therefore, the number of moles of CO formed, n_{CO},

equals the number of moles of carbon in one mole of fuel. For the polyurethane foam, $n_{CO} = 1$.

$$k_{CO} = \frac{n_{CO}(M_{CO})}{n_f(M_{fuel})} = \frac{(1)(28)}{(1)(19.888)} = 1.41$$

Similarly, k_{CO_2} and k_{H_2O} are calculated as

$$k_{CO_2} = \frac{(1)(44)}{19.888} = 2.21$$

$$k_{H_2O} = \frac{(0.87)(18)}{19.888} = 0.787$$

The maximum depletion of oxygen, k_{O_2}, refers to the mass of oxygen needed to completely combust one mole of fuel to CO_2 and H_2O. This is the same as the stoichiometric requirement of oxygen.

$$k_{O_2} = \frac{n_{O_2}(M_{O_2})}{n_f M_f} \frac{(1.2735)(32)}{(1)19.888} = 2.05$$

EXAMPLE 2:

The fuel specified in Example 1 is burning at a rate of 9 g/s and entraining air at a rate of 56 g/s. Measurements of the upper layer gas composition reveal dry concentrations of 3.7 percent by volume CO, 14.3 percent CO_2, and 0.49 percent O_2. Correct the concentrations for the water removed during the gas analysis process (i.e., calculate the wet concentrations).

SOLUTION:

In order to use Equation 9 to calculate the wet mole fractions, the stoichiometric molar ratio of H_2O to CO_2 for *C* needs to be calculated. This ratio is simply obtained from the stoichiometric chemical equation in Example 1.

$$C = \frac{n_{H_2O}}{n_{CO_2}} = \frac{0.87}{1} = 0.87$$

Once *C* is obtained, the wet mole fractions can be calculated as

$$X_{CO_{wet}} = \frac{0.037}{1 + 0.87(0.143)} = 0.033$$

$$X_{CO_{2wet}} = \frac{0.143}{1 + 0.87(0.143)} = 0.127$$

$$X_{O_{2wet}} = \frac{0.0049}{1 + 0.87(0.143)} = 0.0044$$

The estimated mole fraction of water is

$$X_{H_2O} = CX_{CO_{2wet}} = 0.87(0.127) = 0.11$$

Therefore, the corrected gas concentrations on a percent volume basis are 3.3 percent CO, 12.7 percent CO_2, and 0.44 percent O_2.

EXAMPLE 3:

Continuing from Example 2, calculate the yields and normalized yields for each species measured. The wet mole fractions are $X_{CO_{wet}} = 0.033$, $X_{CO_{2wet}} = 0.127$, and $X_{O_{2\,wet}} = 0.0044$.

SOLUTION:

Using Equations 5 and 7, the yield and normalized yield of CO, CO_2, and H_2O can be calculated. The maximum yields calculated in Example 1 are $k_{CO} = 1.41$, $k_{CO_2} = 2.21$, $k_{H_2O} = 0.787$, and $k_{O_2} = 2.05$.

$$Y_{CO} = \frac{X_{CO_{wet}}(\dot{m}_f + \dot{m}_a)M_{CO}}{\dot{m}_f M_a} = \frac{(0.033)(9 + 56)(28)}{9(28.8)} = 0.23$$

$$f_{CO} = \frac{Y_{CO}}{k_{CO}} = \frac{0.23}{1.41} = 0.16$$

$$Y_{CO_2} = \frac{(0.127)(9 + 56)(44)}{9(28.8)} = 1.40$$

$$f_{CO_2} = \frac{1.40}{2.21} = 0.63$$

$$Y_{H_2O} = \frac{(0.11)(9 + 56)(18)}{9(28.8)} = 0.50$$

$$f_{H_2O} = \frac{0.50}{0.787} = 0.63$$

The depletion of oxygen is calculated using Equation 6, assuming the molecular weight of the gas mixture, M_{mix}, to be approximately that of air.

$$D_{O_2} = \frac{0.21\dot{m}_a M_{O_2}/M_a - X_{O_{2wet}}(\dot{m}_f + \dot{m}_a)M_{O_2}/M_{mix}}{\dot{m}_f}$$

$$D_{O_2} = \frac{0.21(56)32/28.8 - 0.0044(9 + 56)32/28.8}{9}$$

$$D_{O_2} = 1.42$$

The normalized yield is calculated as

$$f_{O_2} = \frac{D_{O_2}}{k_{O_2}} = \frac{1.42}{2.05} = 0.69$$

Species Production within Fire Compartments

Hood Experiments

Beyler[8,9] was the first to publish major species production rates in a small-scale two-layer environment. The experiments performed consisted of situating a burner under a 1-m diameter, insulated collection hood. The result was the formation of a layer of combustion products in the hood similar to that found in a two-layer compartment fire. (See Figure 2-5.2.) By varying the fuel supply rates and the distance between the burner and layer interface, and, consequently, the air entrainment rate, a range of equivalence ratios was obtained. Layer gases were exhausted at a constant, metered flow rate from the periphery of the hood at a depth of 15 cm below the ceiling. The general procedure was to allow steady-state burning

conditions to develop, so the layer maintained a constant depth below the exhaust flow location. Tests revealed a reasonably well-mixed uniform layer both in temperature and chemical composition during the steady-state conditions. Gas analysis was performed on samples taken from the exhaust stream. Table 2-5.1 shows the physicochemical properties of the fuels tested.

Beyler's results show that species yields correlate very well with the plume equivalence ratio. Figure 2-5.3 shows normalized yields of major species for propane fires plotted against the plume equivalence ratio. The trends seen in these plots for propane are fairly representative of the other fuels tested. For overventilated conditions, the yield of CO_2 and H_2O and depletion of O_2 are at a maximum, and there is virtually no production of CO, H_2, or unburned hydrocarbons (*THC*). As underventilated burning conditions ($\phi \geq 1$) are approached, products of incomplete combustion (CO, H_2, and *THC*) are generated.

For comparison, the expressions for ideal complete combustion (Equations 14a through 14e) are shown on each plot in Figure 2-5.3. The CO_2 yield departs from Equation 14b as CO production increases at higher equivalence ratios. This departure, which is fairly independent of ϕ for $\phi > 1$, has been described by the yield coefficient.[5] The ratios of the normalized yield of CO_2, H_2O or normalized depletion of O_2 to the theoretical maximums expressed by Equations 14a through 14e are defined as the yield coefficients, B_{CO_2}, B_{H_2O} and B_{O_2}, respectively.[5]

$$B_{CO_2} = \frac{f_{CO_2}}{1} \qquad \text{for } \phi < 1 \qquad (15a)$$

$$B_{CO_2} = \frac{f_{CO_2}}{1/\phi} \qquad \text{for } \phi > 1 \qquad (15b)$$

$$B_{H_2O} = \frac{f_{H_2O}}{1} \qquad \text{for } \phi < 1 \qquad (16a)$$

$$B_{H_2O} = \frac{f_{H_2O}}{1/\phi} \qquad \text{for } \phi > 1 \qquad (16b)$$

$$B_{O_2} = \frac{f_{O_2}}{1} \qquad \text{for } \phi < 1 \qquad (17a)$$

$$B_{O_2} = \frac{f_{O_2}}{1/\phi} \qquad \text{for } \phi > 1 \qquad (17b)$$

These terms are useful in discussing characteristics of the combustion efficiency. For example, an O_2 yield of one indicates complete utilization of available O_2. In the case of CO_2 and H_2O, deviation from the model (as indicated by B_{CO_2} or $B_{H_2O} < 1$) is a measure of the degree of incomplete combustion. It can be seen from Figure 2-5.3 that the production of CO is primarily at the expense of CO_2 (i.e., B_{O_2} and B_{H_2O} remain nearly 1, while B_{CO_2} is about 0.8). Table 2-5.2 shows average yield coefficients for underventilated fires.

Figure 2-5.4 shows unnormalized CO yields plotted against the plume equivalence ratio for fuels tested by Beyler.[8,9] The correlations agree quite well for all fuels. Below an equivalence ratio of 0.6, minimal CO production is observed. Above ϕ_p equal to 0.6, carbon monoxide yield increases with ϕ_p and, for most fuels, tends to level out at equivalence ratios greater than 1.2. Toluene, which creates large amounts of soot, is anomalous compared to the other fuels studied. As can be seen in Figure 2-5.4, the CO yields from toluene fires remain fairly constant at about 0.09 for both overventilated and underventilated burning conditions.

It should be noted that Beyler originally presented all correlations with normalized yields, f_{CO}. However, better agreement is found between unnormalized CO yield-equivalence ratio correlations for different fuels, Y_{CO} (shown in Figure 2-5.4), rather than normalized yields. One point of interest though, is that when CO production is correlated as normalized yield, a more distinct separation of the data occurs for $\phi_p > 1$. The degree of carbon monoxide production (represented as f_{CO}) during underventilated conditions can be ranked by chemical structure

Table 2-5.1 ***Physicochemical Data for Selected Fuels***

Fuel	Empirical Chemical Formula of Volatiles	Empirical Molecular Weight	Maximum Theoretical Yields				
			k_{CO}	k_{CO_2}	k_{O_2}	k_{H_2O}	$1/r^c$

[a]Values have been calculated from data found in the cited references. Values for References 7–9 and 12 are from hood experiments, and values for Reference 5 are for a reduced-scale enclosure.

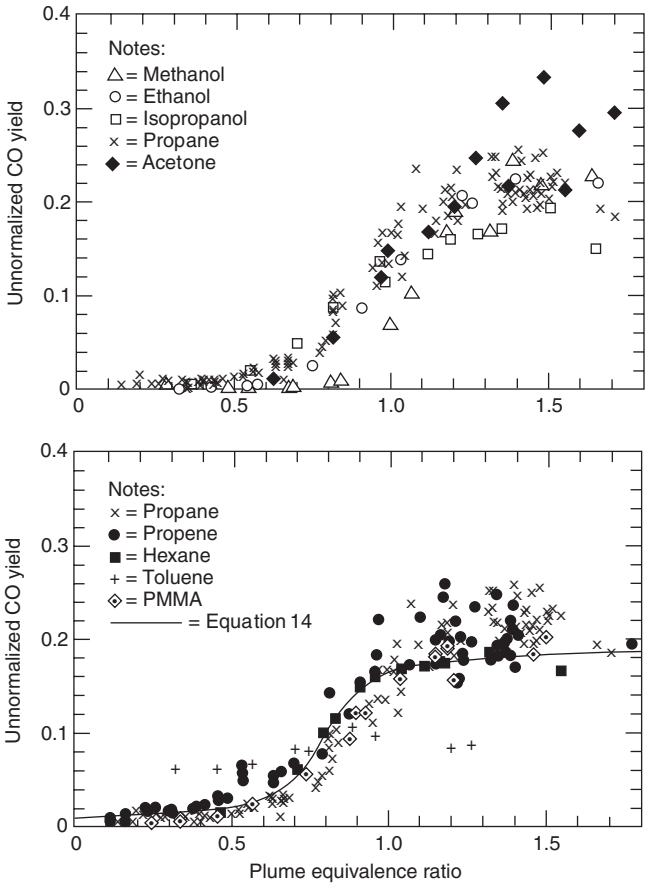

Figure 2-5.4. ***Unnormalized carbon monoxide yields as a function of the plume equivalence ratio for various fuels studied by Beyler in a hood apparatus.[8,9]***

according to oxygenated hydrocarbons > hydrocarbons > aromatics. This ranking is not observed for unnormalized yield correlations.

Toner et al.[7] and Zukoski et al.[10,11] performed similar hood experiments with a different experimental setup. The hood used was a 1.2 m cube, insulated on the inside with ceramic fiber insulation board. The layer in the hood formed to the lower edges where layer gases were allowed to spill out. Gas sampling was done using an uncooled stainless-steel probe inserted into the layer. Detailed gas species measurements were made using a gas chromatograph system. The upper layer equivalence ratio was determined from conservation of atoms using the chemical species measurements, the measured composition of the fuel, and the metered fuel flow rate. Natural gas flames with heat release rates of 20 to 200 kW on a 19-cm-diameter burner were studied. The layer in the hood was allowed to form and reach a steady-state condition before gas sampling was performed.

It was concluded that species concentrations were well correlated to the upper layer equivalence ratio, ϕ_{ul}, and insensitive to temperatures for the range studied (490 to 870 K). Since these experiments were conducted during steady-state conditions, with mean upper layer residence times of about 25 to 180 s, it can be concluded that ϕ_p and ϕ_{ul} were equal.

The data of Toner et al.[7] have been used to plot CO and CH_4 yields versus upper layer equivalence ratio in Figures 2-5.5 and 2-5.6, respectively. The correlations are qualitatively similar to the correlations obtained by Beyler for different fuels. An analysis of these test results also showed that normalized CO_2 and O_2 yield versus equivalence ratio data is represented reasonably well by Equations 15–17. Similar to Beyler's propane results, the average B_{O_2} value is about 1 and B_{CO_2} is 0.8 for underventilated burning conditions (the use of yield coefficients is discussed further in the section on engineering correlations).

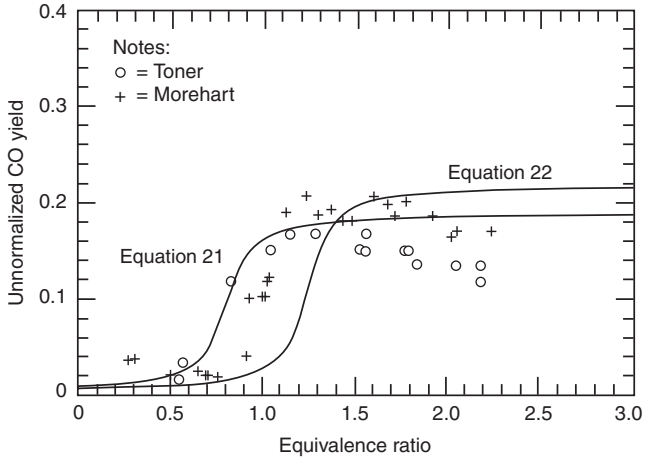

Figure 2-5.5. ***Unnormalized carbon monoxide yields as a function of equivalence ratio for methane fires studied by Toner et al.[7] and Morehart et al.[12] in hood experiments. Yields were calculated from data in References 7 and 12.***

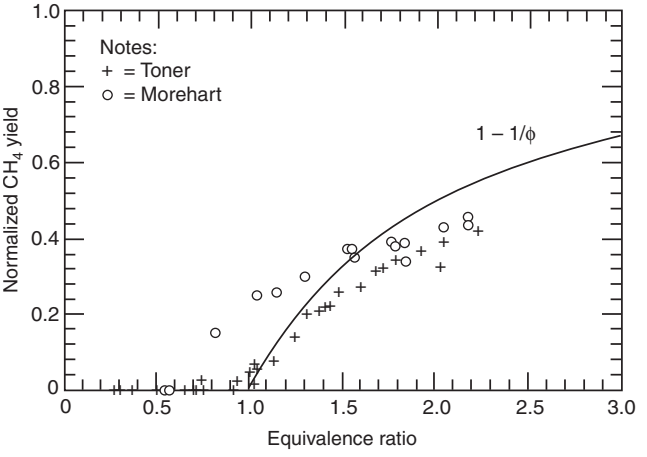

Figure 2-5.6. ***Normalized yields as a function of equivalence ratio for methane fires studied by Toner et al.[7] and Morehart et al.[12] in hood experiments. Yields were calculated from data in References 7 and 12.***

Toner compared the measured species concentrations to the calculated equilibrium composition of the reactants at constant temperature and pressure. The layer composition was modeled quite well by the chemical equilibrium composition for very overventilated conditions but not for underventilated conditions. His observance of CO production for near-stoichiometric and underventilated fires, at the expense of CO_2 production, led them to suggest that the oxidation of CO was "frozen out" before completion. (At low temperatures, there is insufficient energy for CO to chemically react to CO_2.)[7] Since the results showed that species production was independent of temperature for the range studied (490 to 870 K), Toner et al. concluded that, if a freeze-out temperature existed, it must be higher than 900 K. Work by Pitts[13] and by Gottuk et al.,[14] discussed later, shows that a freeze-out temperature does exist in the range of 800 to 900 K, depending on other factors.

Zukoski, Morehart, et al.[11] performed a second series of tests similar to that described above for Zukoski et al.[10] and Toner et al. Much of the same apparatus was used except for a different collection hood. The hood, 1.8 m square by 1.2 m high, was larger than that used by Toner et al. and was uninsulated.

Morehart et al.[12] experiments consisted of establishing steady-state burning conditions such that the burner-to-layer interface height was constant. A constant ϕ_p was maintained based on this constant interface height in conjunction with the fact that the mass burning rate of fuel was metered at a constant rate. Additional air was then injected into the upper layer at a known flow rate until a new steady-state condition was achieved. This procedure established a ϕ_{ul} that was lower than the ϕ_p, since ϕ_p was based on the ratio of the mass burning rate to the mass of air entrained into the plume from room air below the layer interface. By increasing the air supply rate to the upper layer, a range of ϕ_{ul} was established while maintaining a constant ϕ_p.

Although similar, the correlations obtained by Morehart et al. deviated from those obtained by Toner et al. Figures 2-5.5 and 2-5.6 compare the CO and CH_4 yields calculated from the data of Morehart et al. with the yields calculated from the data of Toner et al. For overventilated conditions, Morehart et al. observed higher CO and CH_4 yields, signifying that the fires conducted by Morehart et al. burned less completely. For underventilated methane fires, Morehart et al. observed lower CO, CO_2, and H_2O and higher CH_4 and O_2 concentrations than Toner et al. The only apparent differences between experiments was that Morehart found layer temperatures were 120 to 200 K lower for fires with the same equivalence ratio as those observed by Toner, that is, they ranged from 488 to 675 K. Due to the similarity in experimental apparatus, except for the hood, Morehart concluded that the temperature difference resulted from having a larger uninsulated hood.

Morehart studied the effect of increasing temperature on layer composition by adding different levels of insulation to the hood. Except for the insulation, the test conditions (e.g., ϕ of 1.45 and layer interface height) were held constant. Residence times of layer gases in the hood were in the range of 200 to 300 s. For the range of temperatures studied (500 to 675 K), substantial increases in products of complete combustion (i.e., CO_2 and H_2O) and decreases in fuel and oxygen occurred with increasing layer temperature. Upper layer oxygen mass fraction was reduced by approximately 70 percent and methane was reduced by 25 percent.[11,12] Excluding one outlier data point, CO concentrations increased by 25 percent. This is an important result. Although the gas temperatures were well below 800 K, an increase in the layer temperature resulted in more fuel being combusted to products of complete combustion and additional CO. (See section on chemical kinetics.)

Compartment Fire Experiments

The hood experiments performed by Beyler and Zukoski et al. differ from actual compartment fires in several ways. The hood setup allowed considerable radiation to the lab space below. Conversely, a real compartment would contain most of the radiation, thus resulting in higher wall and upper layer temperatures. Consequently, higher fuel mass loss rates for pool fires would be expected for an actual compartment fire. Also, the hood setup results in a lower layer that has an infinite supply of air which is neither vitiated nor heated. In a real compartment fire, the air supply is limited by ventilation openings (doors, windows, etc.) and the depth of the upper layer. The air that is entrained into the lower layer of an actual compartment fire can be convectively heated by hot compartment surfaces prior to fire plume entrainment. The hood experiments did not include any significant ceiling and wall flame jets. These dynamic flame structures enhance mixing of the upper layer in actual compartment fires and extend the flame zone beyond the plume. Lastly, the hood experiment correlations were developed from sustained steady-state burning conditions. Actual fires of interest are usually in a continual growth stage, and, thus, more transient in nature.

Tewarson reported that CO and CO_2 yields and O_2 depletion were correlated well by the air-to-fuel stoichiometric fraction (i.e., the reciprocal of the equivalence ratio) for wood crib enclosure fires.[15] Enclosure fire data was taken from previous work in the literature for cellulosic-base fiberboard and pine wood cribs burned in various compartment geometries, 0.21 to 21.8 m^3 in volume, with single and dual horizontal and vertical openings centered on the end walls. Additional data were obtained for pine wood cribs burned in a small-scale flammability apparatus that exposed the samples to variable external radiant heat fluxes with either natural or forced airflow from below.

The characteristics of the correlations presented by Tewarson are similar to the correlations developed by Beyler. The CO_2 yield and O_2 depletion are relatively constant for low equivalence ratios and decrease sharply as the equivalence ratio increases for underventilated conditions. The CO yield correlates with the equivalence ratio but with a fair amount of scatter in the data.

Due to the lack of measurements, the air entrainment rate used to calculate the mass air-to-fuel ratio was estimated from the ventilation parameter, $Ah^{1/2}$, where A is the cross-sectional area and h is the height of the vent. Although the general shape of the correlations are valid, the use of the ventilation parameter assumption causes the equivalence ratio data to be suspect. In addition, the elemental composition of the fuel volatiles for the wood was not corrected for char yield. A correction of this sort would tend to decrease the calculated equivalence ratio and increase the CO and CO_2 yields.

Gottuk et al.[5,16] conducted reduced-scale compartment fire tests specifically designed to determine the yield-equivalence ratio correlations that exist for various fuels burning in a compartment fire. A 2.2 m^3 (1.2 m × 1.5 m × 1.2 m high) test compartment was used to investigate the burning of hexane, PMMA, spruce, and flexible polyurethane foam. The test compartment was specially designed with a two-ventilation path system that allowed the direct measurement of the air entrainment rate and the fuel volatilization rate. The setup created a two-layer system by establishing a buoyancy-driven flow of air from inlet vents along the floor, up through the plume, and exhausting through a window-style exhaust vent in the upper layer. There was no inflow of air through the exhaust vent. The upper layer gas mixture was sampled using an uncooled stainless steel probe placed into the compartment through the center of the exhaust vent. This location for the probe was chosen after species concentration and temperature measurements, taken at several locations in the upper layer, showed a well-mixed, uniform layer.

Table 2-5.1 shows the physicochemical properties used for the four fuels. It should be noted that in determining properties of a fuel, such as maximum yields or the stoichiometric fuel-to-air ratio, the chemical formula must characterize the volatiles, not necessarily the base fuel. For liquid fuels or simple polymers, such as PMMA, the composition of the volatiles is the same as the base fuel. However, more complex fuels can char or contain nonvolatile fillers, as found in polyurethane foams. As a result, the composition of the volatiles differs from that of the base material. As an example, the composition of the wood volatiles used in this study was obtained by adjusting the analyzed wood composition for an observed average of 25 percent char.[5]

The results of these compartment tests showed similarities to Beyler's hood experiments. However, some significant quantitative differences exist. Figure 2-5.7 compares the CO yield correlations from Beyler's hood study and that of these compartment tests for hexane fires. This plot illustrates the primary difference observed between the hood and compartment hexane and PMMA fire test results. An offset exists between the rise in CO yield for the two studies. For the hood experiments, higher CO pro-

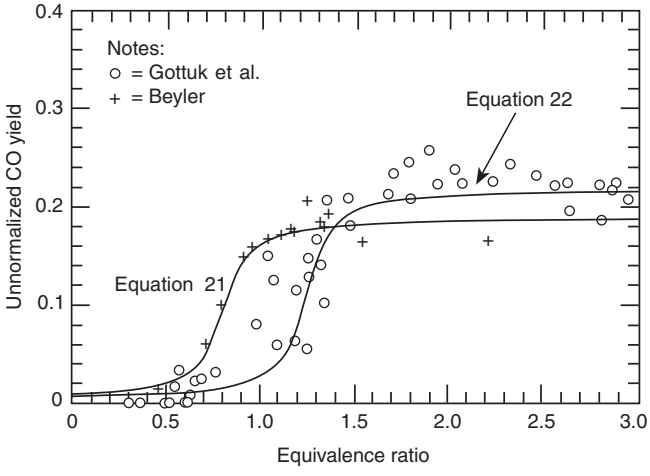

Figure 2-5.7. ***Comparison of unnormalized CO yield correlations for hexane fires in a compartment and under a hood apparatus. (Figure taken from Reference 5.)***

duction was observed for overventilated ($\phi_p < 1$) and slightly underventilated burning conditions. For the compartment fire experiments, negligible CO was produced until underventilated conditions were reached. Consistent with the increased CO production and the conservation of carbon, CO_2 yields were lower for the hood experiments compared to the compartment fires. The spruce and polyurethane compartment fires produced similar CO yield-equivalence ratio correlations to those observed by Beyler in hood experiments (i.e., high CO yields were observed for overventilated fires).

The differences in CO formation can be explained in terms of temperature effects. For the region of discrepancy between equivalence ratios of 0.5 and 1.5, upper layer temperatures in Beyler's hood experiments and the spruce and polyurethane compartment fire experiments were typically below 850 K, whereas temperatures for the hexane and PMMA fires were above 920 K (temperatures typically associated with postflashover fires).[17]

As is detailed in the section on chemical kinetics, the temperature range between 800 and 900 K is a transition range over which the oxidation of CO to CO_2 changes from a very slow to a fast reaction. That is, for upper layer temperatures below 800 K, the conversion of CO to CO_2 does not occur at an appreciable rate to affect CO yields. Since the oxidation of a fuel first results in the production of CO, which then further reacts to form CO_2, the low temperatures (< 800 K) prevent CO from oxidizing. This results in high CO yields. For temperatures greater than 900 K, the reactions that convert CO to CO_2 occur faster as temperature increases. Therefore, for the overventilated conditions discussed above, the high temperatures associated with the hexane and PMMA compartment fires resulted in virtually all CO being oxidized to CO_2 for $\phi_p < 1$.

Overall, the compartment fire test results revealed that the production of CO is primarily dependent on the compartment flow dynamics (i.e., the equivalence ratio) and the upper layer temperature.

The National Institute of Standards and Technology, (NIST) Building and Fire Research Laboratory, has also performed reduced-scale compartment fire experiments using a natural gas burner for the heat source.[6] The compartment (0.98 m $\times$ 1.46 m $\times$ 0.98-m-high) had a single ventilation opening consisting of a 0.48-m wide by 0.81-m-high doorway. A large number of tests were conducted covering a range of heat release rates from 7 to 650 kW. Fires greater than 150 kW resulted in upper layer temperatures greater than 870 K and flames 0.5 to 1.5 m out of the door. This single ventilation opening and the large fires (up to 650 kW) produced non-uniform upper layer conditions. For fires with heat release rates greater than about 250 kW ($\phi > 1.5$), carbon monoxide concentrations in the front of the compartment were approximately 30 to 60 percent higher than in the rear. Temperature gradients of 200 to 300°C were observed from the back to the front of the compartment. Due to the nonuniform air entrainment at the base of the fire and possible mixing of additional air near the front, it is difficult to determine the local equivalence ratio for each region. The concentration gradient from front to rear of the compartment may have been due to differences in the local equivalence ratios. Nonetheless, plots of concentration measurements in the rear of the compartment versus equivalence ratio are quite similar to the data of Zukoski et al. and Toner et al. Yield data for these results have not yet been reported.

A second set of experiments was performed by NIST to investigate the generation of CO in wood-lined compartments.[18] Douglas fir plywood (6.4 mm thick) was lined on the ceiling and on the top 36 cm of the walls of the compartment described above. Natural gas fires ranging from 40 to 600 kW were burned in the compartment. The results showed that, for tests in which wood pyrolysis occurred, increased levels of CO were observed compared to burning the natural gas alone. Carbon monoxide concentrations (dry) reached levels of 7 percent in the front and 14 percent in the rear of the compartment. These are extremely high concentrations compared to the peak levels of 2 to 4 percent observed in the unlined compartment fire tests with the methane burner only. Typical peak CO concentrations observed for a range of fuels (including wood) in hood experiments[8–11] and the compartment fire experiments of Gottuk et al.[5] also ranged from 2 to 4 percent. However, concentrations greater than 5 percent have also been reported for cellulosic fuels burning in enclosures.[15,19]

Since wood is an oxygenated fuel, it does not require additional oxygen from entrained air to form CO. This enhances the ability of the wood to generate CO in a vitiated atmosphere. Therefore, there are two reasons that high CO concentrations can result in fires with oxygenated fuels in the upper layer. First, the fuel-bound oxygen allows the fuel to generate CO during pyrolysis. Second, due to preferential oxidation of hydrocarbons over CO, the limited oxygen in the upper layer reacts with the pyrolizing wood to form additional CO. Aspects of this chemistry are discussed in the next section.

These initial test results for fires with wood on the walls and ceiling emphasized the importance of adding additional fuel to the upper layer. The practical implications are significant, as many structures have cellulosic-based wall coverings and other combustible interior finishes. Because of the initial studies by NIST, Lattimer et al.[20] conducted a series of tests to evaluate the effect on species production from the addition of wood in the upper layer of a reduced-scale enclosure fire. The enclosure was the same as used by Gottuk et al.,[5] measuring 1.5 m wide, 1.2 m high and 1.2 m deep. Two primary sets of tests were conducted for cases with and without Douglas fir plywood suspended below the ceiling 1) with a 0.12 m^2 window vent opening and 2) with a 0.375 m^2 doorway opening, both leading to a hallway.

In the compartment with a window opening and wood burning in the upper layer, Lattimer et al. measured CO concentrations of 10 percent on average, which is nearly three times greater than the levels measured without the wood. Peak concentrations were as high as 14 percent, the same as measured by Pitts et al.[18] CO concentrations were similarly high when the doorway opening was used. In this case, the quasi-steady state average CO concentrations were 8 percent with peaks greater than 10.6 percent with wood compared to approximately 5.7 percent average levels with a doorway vent and no wood. Regardless of the vent opening, these tests

showed that wood in the upper layer resulted in CO concentrations increasing dramatically (10.1 percent, vs. 3.2 percent without wood) with only small increases in the CO_2 concentrations (11.6 percent, vs. 10.4 percent without wood). These trends are summarized in Table 2-5.3, which presents the average upper layer species concentrations for tests with and without wood for both window and doorway vent conditions. For comparison, the data from the NIST research has also been included.

The compartment equivalence ratio was calculated for both the tests with and without wood in the upper layer when the window vent was used. Figures 2-5.8 through 2-5.10 show the corresponding calculated yields of CO_2, O_2, and CO plotted as a function of equivalence ratio. Also included in these plots are the data from the compartment fires of Gottuk et al.[5] The results show that the global equivalence ratio concept is capable of predicting the CO_2, O_2, and CO yields, although somewhat fortuitous, in a compartment with wood pyrolyzing in the hot, vitiated upper layer. These tests also indicate that the correlations hold to fairly high equivalence ratios of about 5.5, as observed for the tests with wood. More work is needed to determine whether the global equivalence ratio concept can predict species levels when non-oxygenated fuels are in the upper layer. It is also unclear whether other oxygenated fuels will follow the correlations as well as the available wood fire data.

The data in Table 2-5.3 should provide an assessment of the effect of the ventilation opening on species generation. However, it is uncertain whether the differences are due more to differences in sampling locations relative to the flame regions. In the tests with a doorway vent, the larger opening resulted in larger air flow rates and, thus, larger fires in the compartment (approximately 500 kW vs. 220 kW with the window vent). The larger fires increased the flame zone within the compartment. Consequently, the sampling probe was probably within the flame zone at times, which would yield higher CO and lower CO_2 concentrations than measurements from the window vent tests in which the sampling probe was not

sampling from a flame zone. With the window vent, the fires were small enough such that there was no ceiling jets at the level of the sampling probe.

The research discussed thus far has concentrated on reduced-scale enclosures. Limited full-scale studies have been reported in the literature to date. One study by NIST systematically examined the production of species in light of the global equivalence ratio concept. NIST conducted a set of tests using a standard enclosure (as defined by ISO 9705) to compare the results from the NIST reduced-scale enclosure tests to fires conducted in a full-scale enclosure.[22–25] The enclosure measured 2.44 m wide, 3.67 m deep and 2.44 m tall, with a door (0.76 m by 2 m) centered at one end of the compartment. The fires consisted of a 35-cm-diameter natural gas burner centered in the enclosure. The burner was scaled to provide the same exit gas velocities as in the reduced-scale enclosure tests. Twelve tests were conducted, with fires ranging in size from 0.5 to 3.4 MW. In one test, the ceiling and upper portions of the walls were lined with 12.7 mm thick plywood.

In the full-scale enclosure, fires greater than 1250 kW created underventilated conditions. The NIST researchers concluded that although the reduced-scale and full-scale enclosures were geometrically similar, with good agreement between predicted mass flows, the differences in measured gas concentrations indicated that the generation of combustion products is not entirely controlled by the ventilation within the compartment. CO concentrations (upwards of 6 percent by volume) were as much as two times higher in the full-scale enclosure than in the reduced-scale tests. These results also coincided with higher upper layer temperatures, approaching 1400 to 1500 K. The variation in CO concentrations from front to back in the enclosure was reversed in the full-scale enclosure compared to the reduced-scale enclosure. In the full-scale enclosure, higher CO concentrations were observed in the back of the compartment. In the reduced-scale enclosure, higher concentrations were measured in the front. Pitts primarily associates the higher CO concentrations with the high layer temperatures that are in the range that strongly favor the formation of CO toward equilibrium concentrations (values can approach 16 percent at ϕ of 3).[25]

One full-scale enclosure test was conducted with wood in the upper layer. This test resulted in high CO concentrations of 8 percent in the front and 12 percent in the rear for a 2 MW fire. The temperatures were lower than those observed in the full-scale tests without wood. These results are similar to those observed in the NIST reduced-scale enclosure.

Chemical Kinetics

The field of chemical kinetics can be used to describe the changes in gas composition with time that result from chemical reactions. The kinetics of actual combusting flows are dependent on the initial species present, temperature, pressure, and the fluid dynamics of the gases. Due to the inability to adequately characterize the complex mixing processes and the significant temperature gradients in turbulent flames, the use of kinetic models is restricted to simplified combusting flow processes. Consequently, the fire plume in a compartment fire is beyond current chemical kinetics models. However, the reactivity of the upper layer gas composition can be reasonably modeled if one assumes that the layer can be characterized as a perfectly stirred reactor, or that the layer gases flow away from the fire plume in a plug-flow-type process.[13,14] Pitts has shown that no significant differences between results exist for either modeling approach when applied to these upper layers.[13]

Several kinetics studies have been performed to examine aspects of the reactivity of upper layer gases.[12,13,14] Comparisons between different hood experiments and between hood and compartment fire experiments have indicated that upper layer temperatures have an effect on CO production. The results of these chemical kinetics studies provide insights into CO generation in compartment fires, which also serve to explain the differences in CO yields between experiments with respect to temperature effects. These studies primarily focused on the question "What would the resulting composition be if the upper layer gases in the hood experiments existed at different isothermal conditions (constant temperature)?" A particular focus was to examine the resulting compositions for cases modeled under the high temperatures characteristic of compartment fires. Chemical kinetics models calculate the change in species concentrations with respect to time. Calculations are dependent on the reaction mechanism (i.e., the set of elementary reactions and associated kinetic data) and the thermodynamic data base used.

Thermodynamic data is fairly well known and introduces little uncertainty into the modeling. However, reaction mechanisms do vary, and this is an area of active research. Pitts presents a comparison of the use of various

mechanisms in the literature.[13] The comparison indicates that reaction kinetics for high temperatures (greater than 1100 K) are fairly well understood. However, the elementary reactions for the range of 800 to 1000 K are not as certain; therefore, quantitative modeling results in this range may be suspect. Nevertheless, the general trends presented below are valid despite any uncertainty associated with the mechanisms used.

Chemical kinetics modeling shows that significantly different trends occur for overventilated and underventilated burning conditions. This can be seen in Figures 2-5.11 and 2-5.12, which present major species concentrations with respect to time for an overventilated and underventilated condition, respectively. Figure 2-5.11 shows a modeled case for ϕ equal to 0.91 and a temperature of 900 K. The initial composition is taken from Beyler's data for a fire with a layer temperature of 587 K. The temperature of 900 K corresponds to the temperature observed by Gottuk et al. for a hexane compartment fire at the same global equivalence ratio. For overventilated conditions, increased temperatures cause CO concentrations to initially increase. As can be seen in Figure 2-5.11, this is due to the incomplete oxidation of hydrocarbons (modeled as C_2H_4). Once the hydrocarbons are consumed, available O_2 is used in the oxidation of CO to CO_2. Since overventilated conditions indicate excess oxygen, CO concentrations are reduced to zero given sufficient time. This is representative of the case of the overventilated hexane and PMMA compartment fires studied by Gottuk et al., in which the higher compartment temperatures, compared to the hood tests of Beyler, resulted in near-zero CO yields for $\phi < 1$.

Figure 2-5.12 shows an underventilated case for ϕ equal to 2.17 and a temperature of 1300 K. The initial composition is taken from Morehart et al. for a methane hood experiment.[12] Similar to the overventilated conditions, CO increases due to the oxidation of hydrocarbons (CH_4).

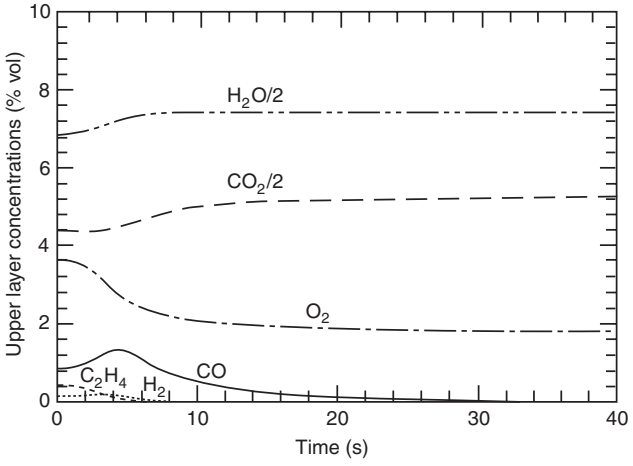

Figure 2-5.11. ***Chemical kinetics model calculated species concentrations versus time for an overventilated (ϕ = 0.91) burning condition with an upper layer temperature of 900 K. (Figure taken from Reference 14.)***

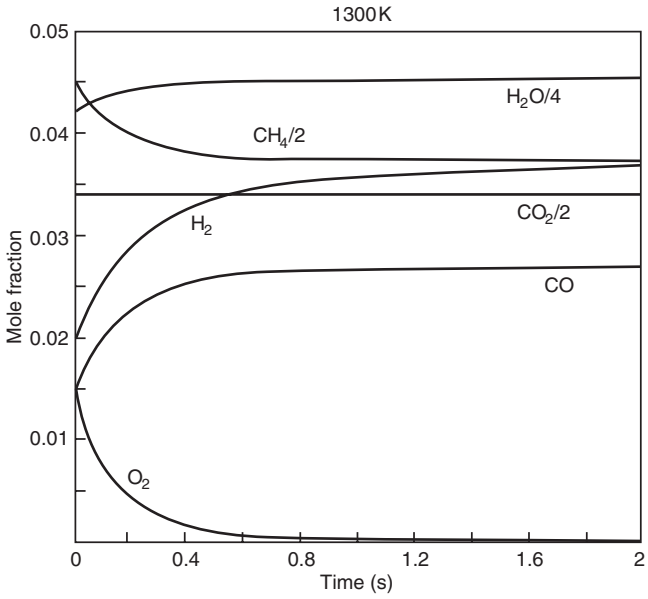

Figure 2-5.12. ***Chemical kinetics model calculated species concentrations versus time for an underventilated (ϕ = 2.17) burning condition with an upper layer temperature of 1300 K. (Figure taken from Reference 13.)***

However, the available oxygen is depleted before the hydrocarbons are fully oxidized. The resulting composition consists of higher levels of CO and H_2 and decreased levels of unburned fuel. Carbon dioxide levels remain virtually unchanged. The much higher temperature studied in this case results in much quicker reaction rates, as is reflected in the 2 s time scale for Figure 2-5.12 compared to 30 s for Figure 2-5.11.

It is clear from Figures 2-5.11 and 2-5.12 that hydrocarbon oxidation to CO and H_2 is much faster than CO and H_2 oxidation to CO_2 and H_2O, respectively. This is a result of the preferential combination of free radicals, such as OH, with hydrocarbons over CO. Carbon monoxide is oxidized almost exclusively by OH to CO_2.[26] Therefore, it is not until the hydrocarbons are consumed that free radicals are able to oxidize CO to CO_2.

The formation and consumption of CO in a reactive gas mixture is dependent on both the temperature of the mixture and the amount of time over which the mixture reacts. This point is illustrated in Figure 2-5.13 which shows the resulting CO concentrations at different isothermal conditions from an initial gas mixture taken from an underventilated fire (ϕ = 2.17). Pitts noted that there are three distinct temperature regimes. At temperatures under 800 K, the gas mixture is unreactive and the CO to CO_2 reactions are said to be "frozen out." As the temperature increases in the range of 800 to 1000 K, the mixture becomes more reactive and CO is formed at faster rates, due to the oxidation of unburned hydrocarbons. For the time period shown, it is interesting to note that the ultimate concentra-

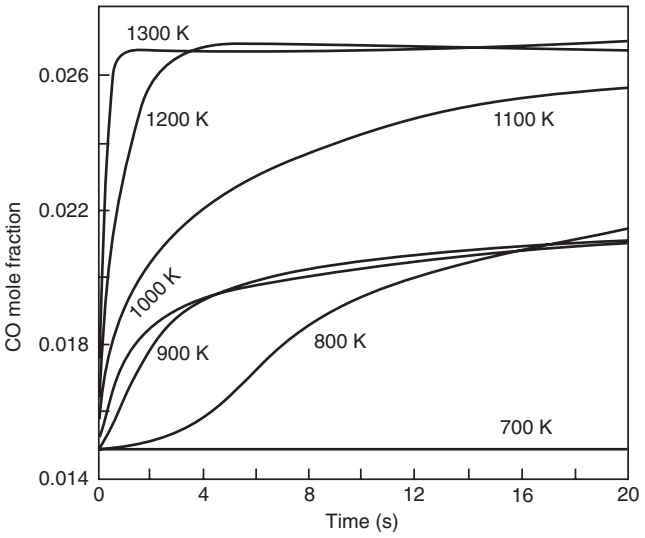

Figure 2-5.13. ***Carbon monoxide concentrations as a function of time for a range of isothermal conditions. Initial concentrations from a methane hood fire at ϕ = 2.17.[13]***

tion is approximately constant* for each case in this temperature range. The third regime of high temperatures above 1100 K is characterized by fast reaction rates and much higher CO production for the 20 s reaction time shown. With sufficient time, the ultimate CO concentration for the 800 to 1000 K conditions would approach the same value as that seen for the higher temperatures.

Results of Zukoski et al.[10] and Gottuk et al.[14] indicated that layer temperatures of 850 to 900 K or higher are needed for the layer gases to be reactive. Considering that the minimum (freeze out) temperature above which a gas mixture is reactive is dependent on the time scale evaluated. These values are consistent with the results shown in Figure 2-5.10. In terms of compartment fires, the time over which the gases react can be taken as the residence time of the gases in the upper layer, which is calculated according to Equation 11. In many practical cases of high-temperature compartment fires, it would be reasonable to assume that the residence time of layer gases would be longer than the time needed for the gas mixture to react fully.

Fire Plume Effects

Although a fire plume is too complex to adequately model the chemistry, the hood experiments discussed earlier provide significant insights with respect to the fire plume and species production in compartment fires. Results of Beyler's hood experiments suggest that the production of upper layer gases is independent of the structure and fluid dynamics of the flame.

Beyler modified a 19 cm propane burner by including a 2.8 cm lip to enhance turbulence and the large-scale structure of the flame.[8] Compared to the no-lip burner, the flame was markedly changed, and air entrainment was increased by 30 percent. Yet, the upper layer species-equivalence ratio correlations were the same for both burners. Additionally, as shown in Figure 2-5.3, correlations for different size burners are also identical.

The insensitivity of species yields to the details of the flame structure is also suggested by the compartment fire hexane results of Gottuk et al.[5] The correlations include data from fires utilizing various size burn pans and with a wide range of air entrainment rates. In several cases, nearly equal steady-state equivalence ratio fires were obtained with quite different burning rates and air entrainment rates. Although the conditions varied significantly, the positive correlation between yields and equivalence ratio suggests that the yields are not sensitive to the details of the flame structure.

The temperature of the fire plume has a significant effect on species production from the fire plume. It is reasonable to assume that differences in upper layer temperature are also reflective of a similar trend in the average temperature of the fire plume gases. An increase in the upper layer temperature can increase the fire plume temperature in two ways. For plumes that extend into the upper layer, entrainment of hotter upper layer gases will result in increased plume temperatures compared to plumes in layers with lower temperature gases. Secondly, an increase in the surrounding temperature (both gases and compartment surfaces) reduces the radiant heat loss from the plume, thus resulting in a higher plume temperature.

The effect of temperature on species generation in a fire plume can be found in the methane hood experiments of Morehart et al.[12] and Zukoski et al.[11] Morehart studied the effect of increasing temperature on layer composition by adding different levels of insulation to his hood. Except for the insulation, the test conditions (e.g., ϕ of 1.45 and layer interface height) were held constant. For the range of temperatures studied (500 to 675 K), substantial increases in products of complete combustion and decreases in fuel and oxygen occurred with increasing layer temperature. Upper layer oxygen mass fraction was reduced by approximately 70 percent and methane was reduced by 25 percent. Excluding one outlier data point, CO concentrations increased by 25 percent. The temperatures of the Morehart et al. upper layer were well below 700 K. Therefore, based on kinetics modeling, these layers were unreactive at these low temperatures. It follows that the change in layer composition must have been due to changes in the plume chemistry. The more complete combustion can be attributed to an extension of the flammability limits (or reaction zone) in the plume due to raising the flame temperature. The above discussion demonstrates that increasing the plume temperature substantially increases the consumption of O_2 and fuel, and primarily increases the levels of products of complete combustion.

*Note that although the ultimate CO concentration is roughly constant, the value of 2.1 percent for this illustration is not to be taken as a universal limit for this temperature range. In general, the resulting CO concentration will depend on the initial gas composition and the time to which the mixture is allowed to react.

The effect of changing temperature on a compartment fire upper layer composition is twofold (1) the generation of species in the fire plume is changed, and (2) oxidation of post-flame gases in the layer is affected. Elevated compartment temperatures correlate with increased fire plume temperatures and more complete oxidation of the fuel to CO_2 and H_2O within the fire plume. The layer temperature dictates post-flame oxidation in the upper layer.

Upper layer temperatures below about 800 K indicate chemically unreactive layers. As such, combustion within the fire plume controls the final CO levels that would be measured in the upper layer. At these low temperatures significant levels of CO can be generated even for some overventilated conditions ($0.5 < \phi < 1$). The yield of CO is inversely proportional to temperature for overventilated conditions and directly proportional to temperature for underventilated conditions.

Upper layer temperatures of about 900 K and higher indicate chemically reactive layer gases. As such, reactions in the layer dictate final CO production. Temperatures above 900 K allow nearly complete oxidation of CO to CO_2 for overventilated conditions. For underventilated fires, chemical kinetics modeling indicates that higher temperature environments may result in slightly higher CO yields due to preferentially accelerated hydrocarbon oxidation compared to CO oxidation.

During underventilated conditions, two mechanisms affecting net CO formation compete (i.e., CO and hydrocarbon oxidation). Increasing gas temperatures above 900 K depletes CO by accelerating the CO to CO_2 conversion. However, incomplete oxidation of unburned hydrocarbons increases the CO production. Since hydrocarbon oxidation is much faster than CO oxidation, net CO levels increase until all available oxygen is consumed.

Transient Conditions

Transient conditions cause the upper layer equivalence ratio to differ from the plume equivalence ratio. A fast-growing fire will tend to have a ϕ_{ul} that is less than ϕ_p. Conversely, a fire that is dying down quickly, such that ϕ_p is decreasing rapidly, will have a ϕ_{ul} that is higher than ϕ_p. These trends result due to the upper layer being a temporary collection reservoir for the gases from the fire plume.

In an effort to characterize transient conditions, Gottuk et al. defined a steady-state time ratio, τ_{SS}, as the ratio of the residence time, t_R, to a characteristic growth time of the fire. Since fire growth is directly related to the fuel volatilization rate, a representative growth time of the fire was defined as the ratio of the fuel mass loss rate, $\dot{m}_f$, to the derivative of the fuel volatilization rate, $\ddot{m}_f$. An increase in τ_{SS} is indicative of more transient conditions.

$$\tau_{SS} = \frac{t_R}{\dot{m}_f/\ddot{m}_f} \tag{18}$$

An analysis of the transient nature of the compartment fires studied by Gottuk et al. showed that values well below 1 indicated near steady-state conditions, such that the plume and upper layer equivalence ratios could be considered equal. Investigation of individual fires showed that the steady-state time ratio decreased below 1.0 at very early times in the fire. Typically, the ratio was 0.1 or less for the quasi-steady-state periods over which data was averaged. For some fires, during the highly transient transition from overventilated to underventilated conditions, the τ_{SS} increased quickly, approaching a value of 1.

The correlations presented in the engineering methodology represent data that have been averaged over steady-state (hood experiments) or quasi-steady-state (compartment fires) periods. For the purpose of modeling fires with respect to time it is of interest to know how the species yields correlate with the equivalence ratio during transient conditions (i.e., as the fire is growing). Determining this correlation was accomplished by plotting the yield to equivalence ratio data for individual fires from the time of ignition to the steady-state period. These transient correlations were compared to the steady-state correlations obtained from steady-state averaged data from all tests (e.g., the CO yield correlation shown in Figure 2-5.7). An example of one comparison is shown in Figure 2-5.14. Figure 2-5.14 shows the steady-state hexane CO yield correlation along with the transient yield vs. equivalence ratio data for a hexane compartment fire that obtained a steady-state average ϕ_p of 3. The solid dots in Figure 2-5.14 represent the steady-state time ratio data, τ_{SS}. For this example, τ_{SS} remained fairly constant at about 0.1 for the entire fire. And as can be seen, the agreement between the transient and steady-state correlations is quite good, even for the transition to underventilated conditions. Good agreement between transient and steady-state data was also observed for CO_2 and O_2 yield correlations.

Although more transient in nature than the hood experiments, the compartment fires are characterized as primarily quasi-steady and, therefore, do not differ significantly from Beyler's hood experiments in this respect. This analysis also shows that the species yield correla-

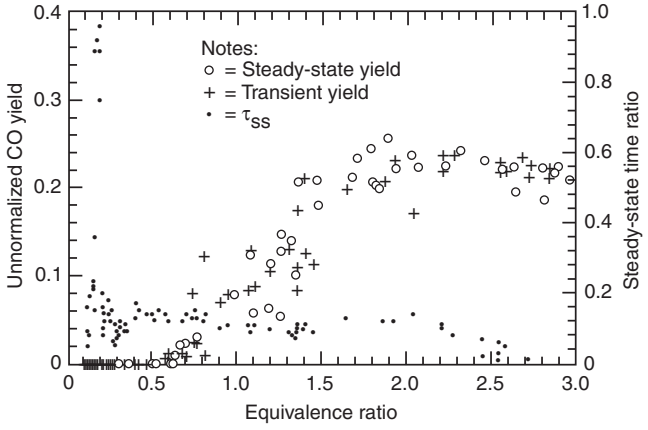

Figure 2-5.14. ***Comparison between a transient, unnormalized CO yield correlation for a hexane fire with an average steady-state ϕ_p of 3 and the steady-state correlation for all hexane fires studied by Gottuk et al. The steady-state time ratio, τ_{SS}, data are shown as solid dots. (Figure taken from Reference 16.)***

tions developed for steady-state conditions are representative of the transient growth periods of these fires.

In terms of full-scale application, these results suggest that ϕ_p and ϕ_{ul} are approximately equal for compartment fires characterized by relatively slow growth compared to the upper layer residence time (i.e., $\tau_{SS} \ll 1$). However, the low τ_{SS} values observed in the reduced-scale compartment fires may not always be representative of full-scale fires. The reduced-scale compartment fires had residence times typically between 4 and 20 s. These short residence times were a result of having relatively large fires compared to the compartment volume. Until flashover conditions are approached, a full-scale compartment fire will most likely have smaller fires compared to the volume of the space. As a result, the residence time of gases in the upper layer of a full-scale fire may be much longer. Times on the order of 5 to 10 min. may not be unrealistic in some cases. Therefore, in the case of a fast-growing full-scale fire, values of ϕ_p could increase relative to ϕ_{ul}. The application point is that the control volume used for the equivalence ratio must be considered with respect to the residence time of gases in the upper layer.

Species Transport to Adjacent Spaces

The species levels transported from a compartment depend on a variety of conditions produced during the course of the fire. As compartment fire gases exit the compartment, they entrain the gases present in the adjacent space. (See Figure 2-5.15.) If a fuel-rich mixture is produced in the compartment, the gases flowing out may ignite, causing burning in the adjacent space. This burning is an indication that oxidation reactions are taking place, which ultimately affects the species levels transported to remote areas. As the gases continue to flow through the adjacent space, they are cooled by mixing with surrounding gases and heat losses to the boundaries. Eventually, gases are cooled to a temperature below which oxidation reactions do not readily occur. At this point the reactions are said to be frozen. The amount of combustion products that exist at this point will continue to flow throughout the rest of the structure. As a result, combustion product levels in the overall structure will accumulate as the fire inside the compartment persists and/or additional items in the structure begin to burn.

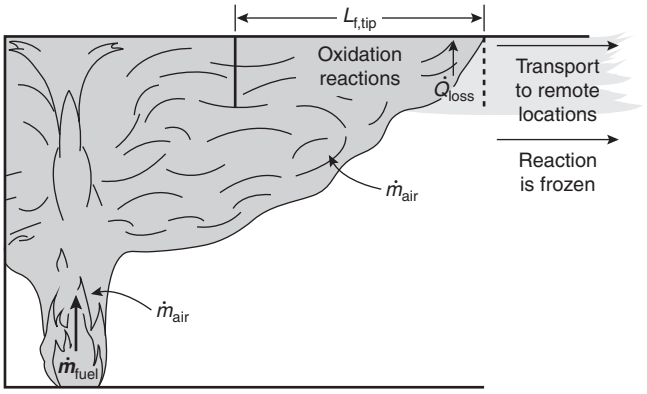

Figure 2-5.15. ***Phenomena controlling species transport to remote locations.***

Conditions inside the fire compartment and in the directly adjacent space will govern the species levels transported to remote locations. The primary consideration is the conditions that develop inside the compartment. If burning outside of the fire compartment occurs due to either flame extension or external burning, gases will continue to react outside of the compartment influencing the species levels transported to remote areas. The degree to which gases react outside the compartment depends on the mixing of oxygen with the fuel-rich gases flowing out the compartment, and the addition of fuel to the gases flowing along the adjacent space.

General Effects of Burning Outside the Compartment

Species levels transported to remote locations will be equivalent to those formed inside the compartment unless burning occurs outside. Chemical kinetics indicate that oxidation reactions cannot occur efficiently outside the compartment unless gas temperatures are near those produced at the onset of flashover (775–875 K). (See the section in this chapter on chemical kinetics.) In the presence of oxygen, hydrocarbons begin to react efficiently when temperatures are above 700 K.[13] Perhaps more importantly, the oxidation of CO to CO_2 does not readily occur until temperatures rise above 800 K. The occurrence of burning outside the compartment, either from flame extension or the onset of flashover, will result in local temperatures in excess of 1300 K.[4] At these temperatures, oxidation reactions for both hydrocarbons and CO occur in the presence of available oxygen.

The occurrence of burning outside the compartment has been shown, in most situations, to reduce the incomplete combustion products (including smoke and CO levels) transported to remote locations.[5,27–29] The burning in unconfined adjacent areas (e.g., surroundings) has been measured to decrease incomplete combustion products more efficiently than burning in confined adjacent areas (e.g., a corridor). In addition, the consumption of incomplete combustion products during burning in confined areas was found to be sensitive to the air entrainment into the plume/ceiling jet flow. This entrainment is a function of the mass flow from the compartment, the geometry of the opening between the compartment of fire origin and the adjacent space, and the geometry of the adjacent space itself. Smoke layers that develop in confined adjacent spaces can cause lower oxygen levels to be entrained into the plume/ceiling jet flow in the adjacent space, increasing the incomplete combustion product levels transported to remote areas.

Burning in Unconfined Adjacent Areas

Unconfined adjacent areas are those areas where the flame extending from the compartment of origin is not redirected by the boundaries of the adjacent area, and the

gases are allowed to burn as a buoyant plume. Examples of unconfined adjacent areas include surroundings, atriums, and corridors with high ceilings relative to the door height of the burning compartment. Gottuk et al.[14,30] investigated the impact of external burning on combustion products downstream of an unconfined jet. The compartment was connected to its surroundings through a window opening. Tests were performed with compartment fires with and without external burning. In these tests, a compartment equivalence ratio of 1.6 was the lowest ϕ_c where external burning was noted to occur. The effects of external burning on the CO levels downstream of the fire are shown in Figure 2-5.16. With a compartment equivalence ratio greater than 1.6, CO levels were measured to decrease below the fire compartment levels. The CO yield is shown to decrease to a minimum of 0.02 at ϕ greater than 2.0. The decrease in CO represents a 75 to 90 percent reduction of the CO generated in the fire compartment.

Burning in Confined Adjacent Areas

Burning in a confined adjacent area, such as a corridor or room, causes the external flame to impinge on a ceiling, and possibly on walls. Compared with flow in an unconfined area, the ceiling and walls in the confined area will reduce the amount of air entrainment into the gas jet exiting the fire compartment. The effects of burning in confined areas on species transport have been investigated by Ewens et al.[27,31] and Lattimer et al.[28,29] using the same fire compartment design in the unconfined external burning study (Figures 2-5.17a and b).[16,30] The transport of species to remote locations is geometry dependent and can be affected by smoke layers that develop in the confined area. However, species levels transported to remote areas can be predicted by defining an equivalence ratio for a control volume involving both the fire compartment and the burning in the adjacent space.

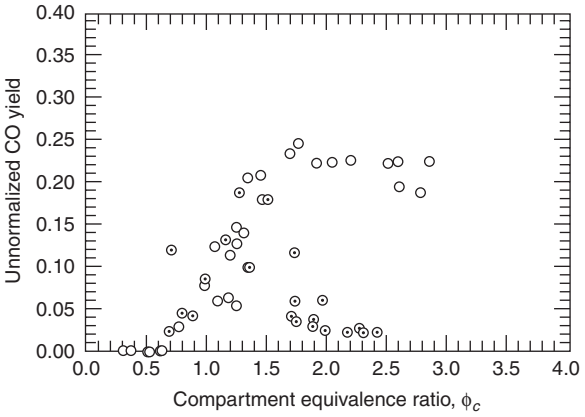

Figure 2-5.16. ***Effect of external burning on CO levels downstream of an unconfined adjacent area. CO yield versus compartment equivalence ratio for hexane compartment fires with an exhaust jet to the open atmosphere through a window opening; (○) compartment levels, (⊙) downstream levels. (Data taken from References 16 and 30.)***

Species transport has been evaluated for two common compartment-hallway configurations. Ewens[27] and Lattimer et al.[29] evaluated species transport in a configuration with the fire compartment on the end of a hallway. (See Figure 2-5.17a.) Lattimer et al.[28,29] performed a study with the fire compartment on the side of a hallway. (See Figure 2-5.17b.) In both studies, most tests were performed with a window connecting the compartment and hallway.

Using the apparatus shown in Figure 2-5.17a, Ewens[27] evaluated the effects of different geometric variables and compartment stoichiometry on CO levels (in addition to other species) downstream of the external burning where reactions were considered frozen. As shown in Figure 2-5.18, Ewens[27] demonstrated that burning in confined areas outside the compartment decreases incomplete combustion product levels, but not always to the same extent as when the fire gases spill into an unconfined space. The degree of oxidation was found to be dependent on both air entrainment into the gases exiting the compartment and the fuel flowing out of the compartment. The data of Ewens shows that both fire size and geometric parameters will impact species production. The two important results to understand are that geometries which increase air entrainment in the adjacent space (e.g., an inlet soffit vs. no soffit), or reduce the layer depth in the adjacent space, will enhance the oxidation reactions and result in lower levels of incomplete combustion products, such as CO.

Fire gases flowing into and through the adjacent space entrain surrounding gases as they flow away from the fire compartment. These gases can undergo chemical reactions, particularly as they are within the flaming region. A sample plot of the species variation along the flame length in the hallway is shown in Figure 2-5.19.[27] Results shown in Figure 2-5.19 are from post-flashover hexane fire tests with an average compartment equivalence ratio of $\phi = 2.0$, a 0.12 m^2 opening (0.50 m wide $\times$ 0.24 m high) connecting the compartment and adjacent space, and no inlet soffit above the opening in the hallway. These data represent time-averaged conditions 0.025 m below the ceiling along the hallway during the quasi-steady state period of the fire, when external burning was occurring.

Gases entered the adjacent space as a ceiling jet, but were allowed to expand horizontally until intersecting the walls of the hallway. For this geometry, the largest increase in the total mass flow rate was during the first half of the flame length, which was 2.7 m (on average) from the compartment. By $x/L_{f,\text{tip}} = 0.75$, the total mass flow rate had reached a maximum. This indicated that all of the entrainment into the ceiling jet flow occurred by $x/L_{f,\text{tip}} = 0.75$. The majority of the oxidation reactions had also occurred by $x/L_{f,\text{tip}} = 0.75$. The mass flow rates of CO, CO_2, and O_2 were essentially constant downstream of $x/L_{f,\text{tip}} = 0.75$. This indicates that the oxidation of CO to CO_2 was frozen by an $x/L_{f,\text{tip}} = 0.75$. Small amounts of total hydrocarbons (THC) continued to react from $0.75 < x/L_{f,\text{tip}} < 1.0$; however, this was not measured to significantly increase CO levels.

Analysis of data in Figure 2-5.19, as well as other data by Ewens et al.[27,31] and Lattimer et al.,[28,29] indicates that by the flame tip all of the oxidation reactions have oc-

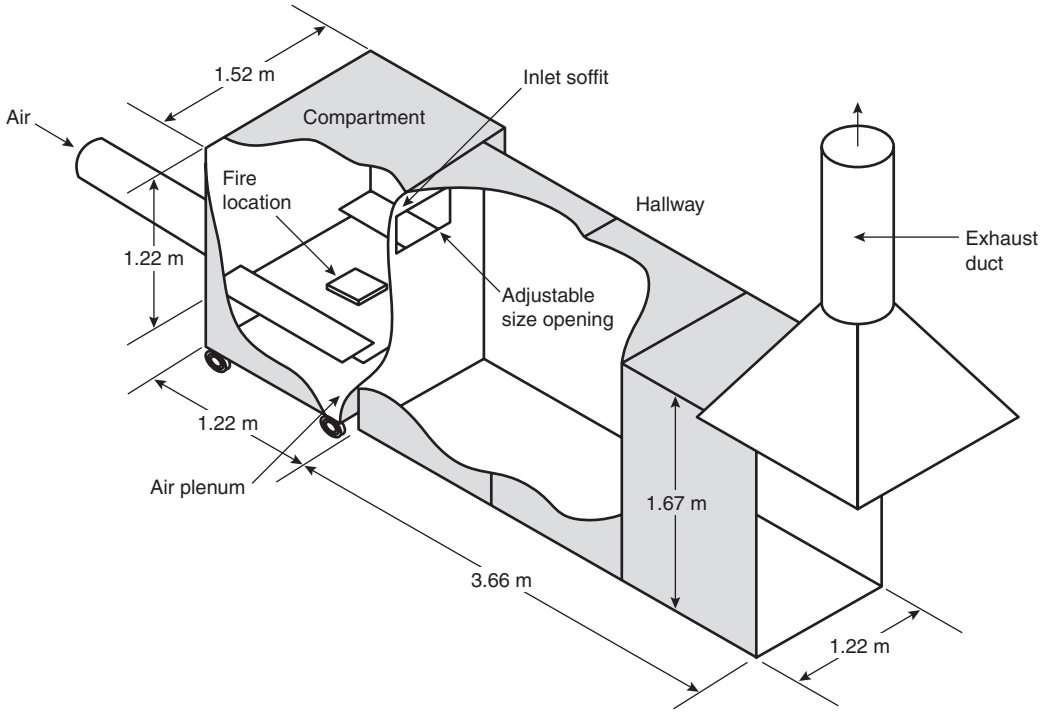

Figure 2-5.17a. ***Compartment on the end of a hallway.***[27,29,31]

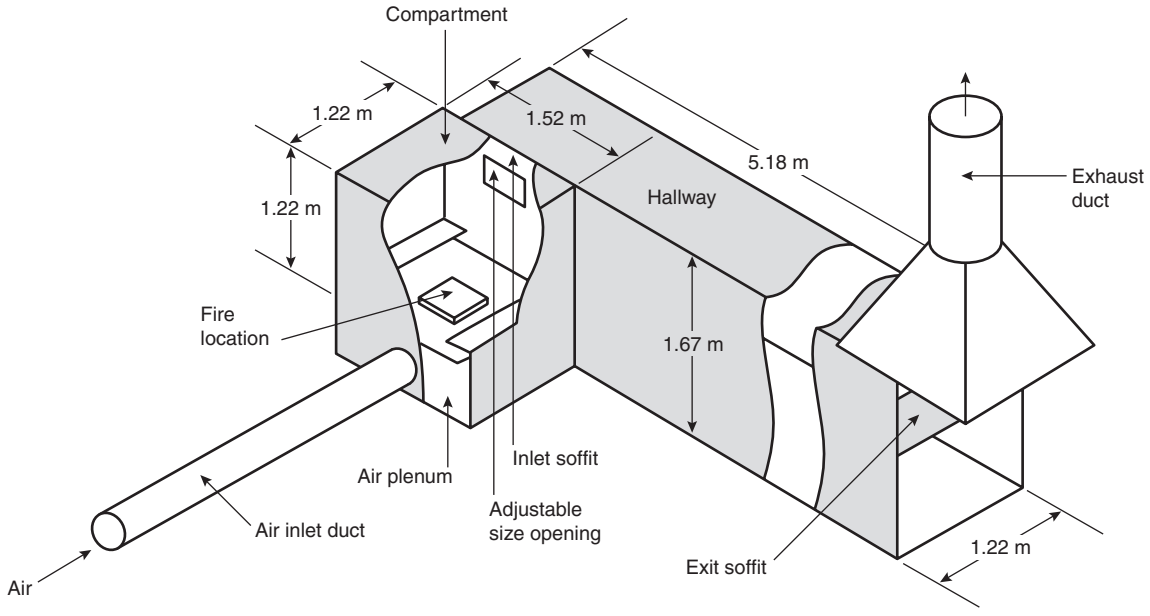

Figure 2-5.17b. ***Compartment on the side of a hallway.***[28,29]

curred. As a result, the mass flow rates of the major combustion products beyond the flame tip will be transported to remote locations. The mass flow rate levels will be influenced by the oxygen availability in the flaming region. Based on test results from Ewens et al.[27,31] and Lattimer et al.,[28,29] mixing near the compartment has been shown to have the most significant influence on the combustion products transported to remote areas.

Predicting Species Levels

Lattimer[32] performed additional analysis on Ewens' data to develop a correlation between species transported and ϕ for a control volume consisting of part of the area in the adjacent space where burning occurred. In this set of data, the mixing in the adjacent space (hallway) was varied by using windows with different areas and aspect ratios to connect the compartment to the adjacent space, and by adding a 0.20 m soffit above the window. The equivalence ratio in this analysis was calculated using a control volume that extended to the sampling point located in the adjacent space. Using this control volume, the mass flow rate of air for the ϕ_{cv} calculation in Equation 13 was the air flow rate into the compartment plus the air entrainment into the plume/ceiling jet flow in the adjacent space, up to the sampling location. In these experiments, gas sampling was always performed in or just downstream of the flame within the hallway.

The species yields are plotted in Figures 2-5.20 through 2-5.23 vs. the control volume equivalence ratio, ϕ_{cv}. Note that CO yields are not normalized because for various fuels unnormalized CO yields were found to correlate best with ϕ. The line in the normalized O_2 depletion, and CO_2 and THC yield plots, represents the results from the complete combustion model presented in Equation 14. Due to limited data near the compartment, there are few data points at high ϕ_{cv}.

The trends in the species data were similar to those observed in the hood experiments by Beyler[8,9] and in the compartment experiments by Gottuk et al.[5] The normalized O_2 depletion is approximately unity at ϕ_{cv} less than

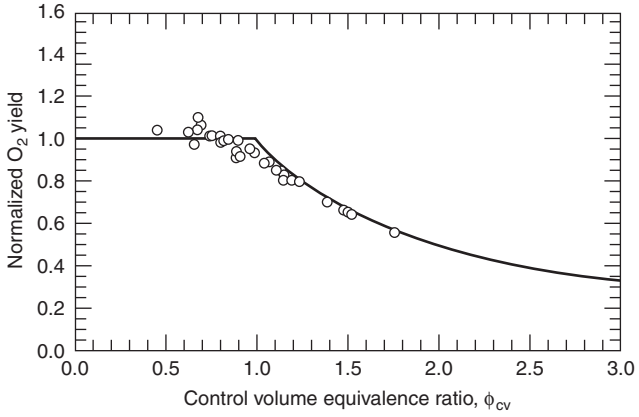

Figure 2-5.20. ***Normalized O_2 depletion of gases in a space adjacent to a post-flashover compartment fire. Control volume includes fire compartment and a portion of the adjacent space where burning occurs.***

1.0 and decays at the rate prescribed by the complete combustion model at higher ϕ_{cv}. CO_2 normalized yields are near unity up to a ϕ_{cv} of approximately 0.8. At $\phi_{cv} > 0.8$, the CO_2 levels begin to decay and are consistently less than the level predicted by the complete combustion model. This behavior is consistent with the rise in incomplete combustion products, such as CO and THC, at ϕ_{cv} ranging from 0.6–0.8. These results indicate that species levels in adjacent spaces can be adequately correlated by the same global equivalence ratio correlations obtained for species production in fire compartments as long as ϕ_{cv} is calculated using the appropriately defined control volume. ϕ_{cv} accounts for the effects of external burning on species levels and can be used with Equations 19–25 to estimate species transported to remote areas.

Effects of Oxygen Deficient Smoke Layers in Adjacent Spaces

The development of hot, oxygen deficient smoke layers in the adjacent space affects both the entrainment into the plume-ceiling jet and the amount of oxygen mixing with the fuel-rich gases flowing from the fire compartment.

Ewens et al.[27,31] demonstrated that layers as thin as 0.20 m may have an impact on incomplete combustion products being transported to adjacent areas. Lattimer et al.[28,29] performed a series of tests with different oxygen deficient layer depths in the space directly adjacent to a post-flashover fire. (See Figure 2-5.17b.) Tests were performed with three different opening sizes connecting the compartment to the adjacent space, but the compartment stoichiometry was approximately the same in all tests. In each test, the layer depth was kept at a constant level by the use of an exit soffit. In order to change the layer depth from test to test, the height of the exit soffit was adjusted for each test.

Except for cases with a deep smoke layer in the adjacent space, external burning occurred in all tests. Figure 2-5.24 contains a plot of time to ignition for tests with different layer depths. Layer depth is represented as a dimensionless depth, $\gamma = \delta/z$, which relates the distance between the ceiling and the bottom of the visible smoke layer, δ, to the distance between the ceiling and the bottom of the gases flowing out of the compartment, z. (For a window configuration, z is measured to the bottom of the window.) As shown in Figure 2-5.24, the smoke layer did not affect the time to ignition until the visible smoke layer was nearly deep enough to prevent ignition altogether (indicated by the infinite time to ignition). At layer depths greater than $\gamma = 1.7$, external burning did not occur since the exiting fire gases were not able to entrain sufficient fresh air to provide the necessary oxygen for combustion. Rather, the gases exiting the fire compartment entrained primarily vitiated gases in the upper layer of the adjacent space.

The CO, CO_2 and THC yields measured at a remote location (in the exhaust duct) for the different window opening sizes are shown plotted in Figures 2-5.25a to 2-5.25c with respect to the smoke layer depth. Each data point is the time-averaged yield during the quasi-steady

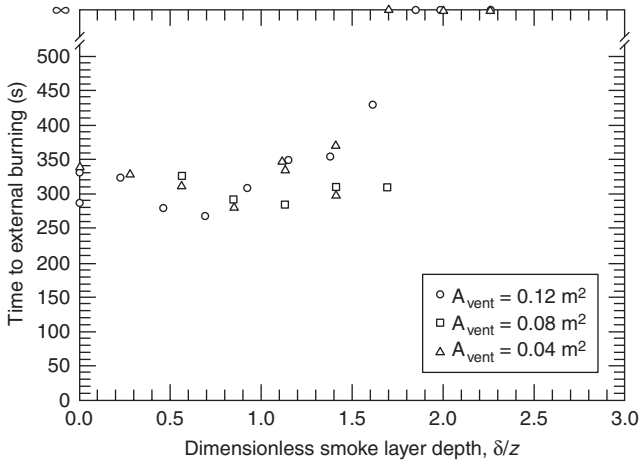

Figure 2-5.24. ***Time for external burning in tests with a range of layer depths in the adjacent space with a 6.32 m² floor plan area.[29]***

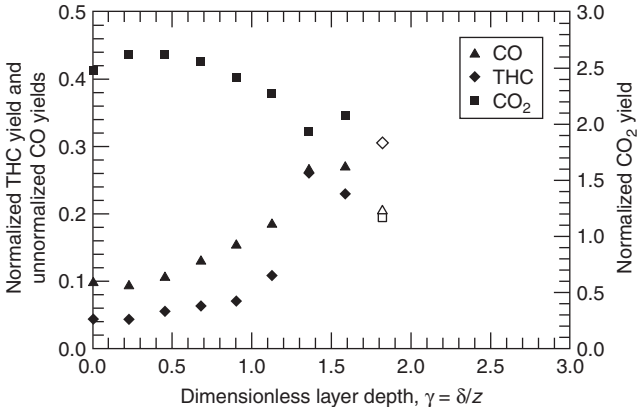

Figure 2-5.25a. ***The effect of an oxygen deficient upper-layer on downstream species yields from a post-flashover fire extending into a hallway. Opening of 0.12 m², 0.20 m soffit above the opening, and an average ϕ_c = 3.1. Open symbols are tests with no external burning. $\gamma > 1$ indicates layer is below the bottom of the vent.[28,29]***

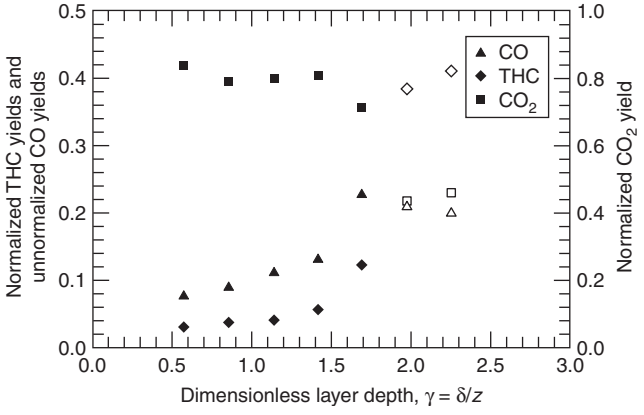

Figure 2-5.25b. ***The effect of an oxygen deficient upper-layer on downstream species yields from a post-flashover fire extending into a hallway. Opening of 0.08 m², 0.20 m soffit above the opening, and an average ϕ_c = 2.8. Open symbols are tests with no external burning.[29]***

state part of the fire. For this geometry, combustion product levels were not significantly affected by the smoke layer until it fell below the bottom of the opening ($\gamma > 1.0$). As the layer depth increased from $\gamma = 1.0$ to 1.8, the burning outside the compartment became increasingly less efficient. This resulted in an increase in CO and THC yields and a decrease in the CO_2 yield. The increase in CO and THC yields was attributed to reducing the oxygen available to oxidize the combustion products. When the smoke layer was increased to a dimensionless layer depth of $\gamma = 1.7$–1.8, external burning was not observed and downstream species yields were consistent with levels inside the fire compartment.

External burning in some tests with deep oxygen deficient upper-layers actually caused additional CO formation in the adjacent space. As shown in Figure 2-5.25a, in tests with the largest opening, 0.12 m², and a dimensionless layer depth of $\gamma = 1.3-1.5$, CO yields increased to approximately 0.27 kg/kg, which is approximately 0.05 kg/kg higher than compartment levels. In addition, corresponding normalized THC yields were on average 0.06 kg/kg lower than compartment levels. These results indicate that available oxygen is being used to preferentially oxidize THC instead of CO. This oxidation of THC forms additional CO, causing an increase in CO levels transported to remote locations. The exact conditions in the adjacent space necessary to produce these results have not been fully established.

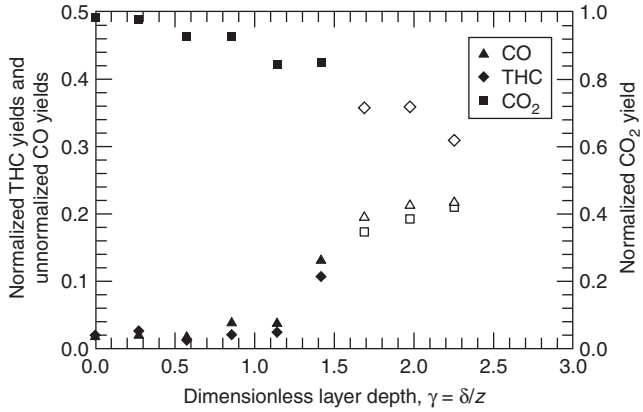

Figure 2-5.25c. ***The effect of an oxygen deficient upper-layer on downstream species from a post-flashover fire extending into a hallway. Opening of 0.04 m², 0.20 m soffit above the opening, and an average ϕ_c = 2.8. Open symbols are tests with no external burning.[28,29]***

Other Considerations

There are other variables that may influence the combustion product levels being transported to remote locations that have not been fully explored. These variables include the effects of air addition through forced ventilation, additional fuel decomposition in the adjacent space, and heat losses to the ceiling and walls.

The addition of air to the system through forced ventilation may have an influence on species levels, depending on where the air is added relative to the external burning. Forced ventilation in the region where external burning is occurring will introduce additional oxygen into the flow, and possibly induce additional mixing. This may result in better oxidation of incomplete combustion products, such as CO. Addition of air to the system downstream of the external burning will dilute the gases, but will not reduce the amount (in terms of mass) of incomplete combustion products being transported to remote location.

Decomposition of fuel in the adjacent space may affect species levels transported to remote locations. This effect may be sensitive to the location of the decomposing fuel, the type of fuel, whether it is flaming or smoldering, and the conditions surrounding the fuel.

Heat losses to the ceiling and walls can cause gas temperatures in the adjacent space to decrease more readily for some materials, compared to well insulated boundaries. An example of this may be steel decks and bulkheads on ships. A decrease in gas temperature may cause temperatures to reach levels where no reactions can occur sooner than those observed in well-insulated cases. As a result, higher heat loss to the boundaries may result in higher incomplete combustion products, including CO, to be transported to remote areas.

Species concentrations may not always be transported away from the compartment in a uniform manner. In experiments performed by Lattimer et al.,[28,29] with the compartment located on the side of a hallway, the bulk flow from the compartment was measured to flow across the hallway and down the side of the hallway opposite the fire compartment. This resulted in higher CO, CO_2, and THC levels (and lower O_2) flowing along the side of the hallway opposite the fire compartment. For example, CO levels were measured to be as high as 1.9 percent along the side of the hallway opposite the fire compartment, while on the side of the hallway with the fire compartment the maximum CO level was measured to be 1.0 percent. As these gases flow further from the compartment, they are expected to become more uniform across the hallway. However, the distance away from the compartment where mostly uniform flow occurs was not quantified.

Engineering Methodology

In light of the experimental work and chemical kinetics considerations discussed previously, several correlations can be used as guidelines for fire protection engineering. The production of chemical species in compartment fires has been shown to be correlated with the control volume equivalence ratio, ϕ_{cv}. For most purposes, the equivalence ratio can be calculated using instantaneous fuel burning rates and air mass flow rates assuming quasi-steady state conditions. The following methodology presents a guide to determining bounds on species production as well as comments on the limits of this approach.

The methodology for estimating species transported to remote locations is provided in Figure 2-5.26. This approach considers the occurrence of external burning outside the compartment. In general, the primary steps in the analysis are

1. Determine the compartment equivalence ratio, ϕ_c.
2. If $\phi_c < 1$, estimate species levels using the global equivalence ratio-yield correlations presented in Equations 19–25 with the ϕ_c.
3. If $\phi_c > 1$, determine whether external burning will occur outside of the compartment. External burning can be assumed to occur at a ϕ_c (plume or compartment) of 1.6, or by calculating the ignition index using Equation 1.
4. If there is no external burning, use the ϕ_c and Equations 19–25 to calculate the species transported.
5. If external burning is occurring, determine the effect of the smoke layer using the dimensionless smoke depth, $\gamma = \delta/z$, where δ is the depth of the layer below the ceiling and z is the lowest elevation of gases exiting the compartment.
6. If $\gamma > 1.0$, and external burning is predicted, the smoke layer can be assumed to inhibit oxidation in the adjacent space. CO and other incomplete-combustion products are not reduced. The ϕ_c and Equations 19–25 can be used to estimate the species transported to remote locations.
7. If $\gamma < 1.0$, and external burning is predicted, the smoke layer does not inhibit the oxidation in the adjacent space and incomplete-combustion products, such as CO will be reduced. The species transported can be estimated using Equations 19–22 and the equivalence ratio for a control volume, ϕ_{cv}, that incorporates the compartment and the adjacent space out to the flame tip. (See Figure 2-5.15.)

It should be noted that this methodology may not provide the maximum levels of incomplete combustion products that can be produced in a fire. Equations presented in this methodology for species yields as a function of equivalence ratio have been shown to provide good correlations even for wood as a secondary fuel pyrolyzing in the hot upper layer. However, it is not clear whether these correlations will hold for non-oxygenated fuels in the upper layer or how well they will represent other oxygenated fuels.

Several empirical correlations have been developed to predict species levels at a range of equivalence ratios. Different correlations are given in the following paragraphs to accommodate analyses of various levels of complexity.

Due to its toxicity, CO production is of primary importance. Four correlations (see Equations 19–22) are presented, representing varying degrees of complexity. In each case, the correlations basically represent a lower bound for the yield of CO. Equation 19 (parts a and b) represents a "zeroth order" correlation between CO yield and equivalence ratio. For overventilated burning conditions, there is no CO production and for underventilated conditions CO is produced at a yield of 0.2 grams per gram of fuel burned. This correlation applies best to fires with average upper layer temperatures greater than 900 K.

$$f_{CO} = 0 \qquad \text{for } \phi < 1 \tag{19a}$$

$$f_{CO} = 0.2 \qquad \text{for } \phi > 1 \tag{19b}$$

Equation 20 (parts a, b, and c) accounts for some of the temperature effect by including a linear rise in CO yield over the transition region from ϕ of 0.5 to 1.5.

$$f_{CO} = 0 \qquad \text{for } \phi < 0.5 \tag{20a}$$

$$f_{CO} = 0.2\phi - 0.1 \qquad \text{for } 0.5 < \phi < 1.5 \tag{20b}$$

$$f_{CO} = 0.2 \qquad \text{for } \phi > 1.5 \tag{20c}$$

The temperature effect on CO production is best represented in the following two correlations. Equation 21, which represents a fit to the hexane data of Beyler's hood experiments, is suggested for compartment fires with

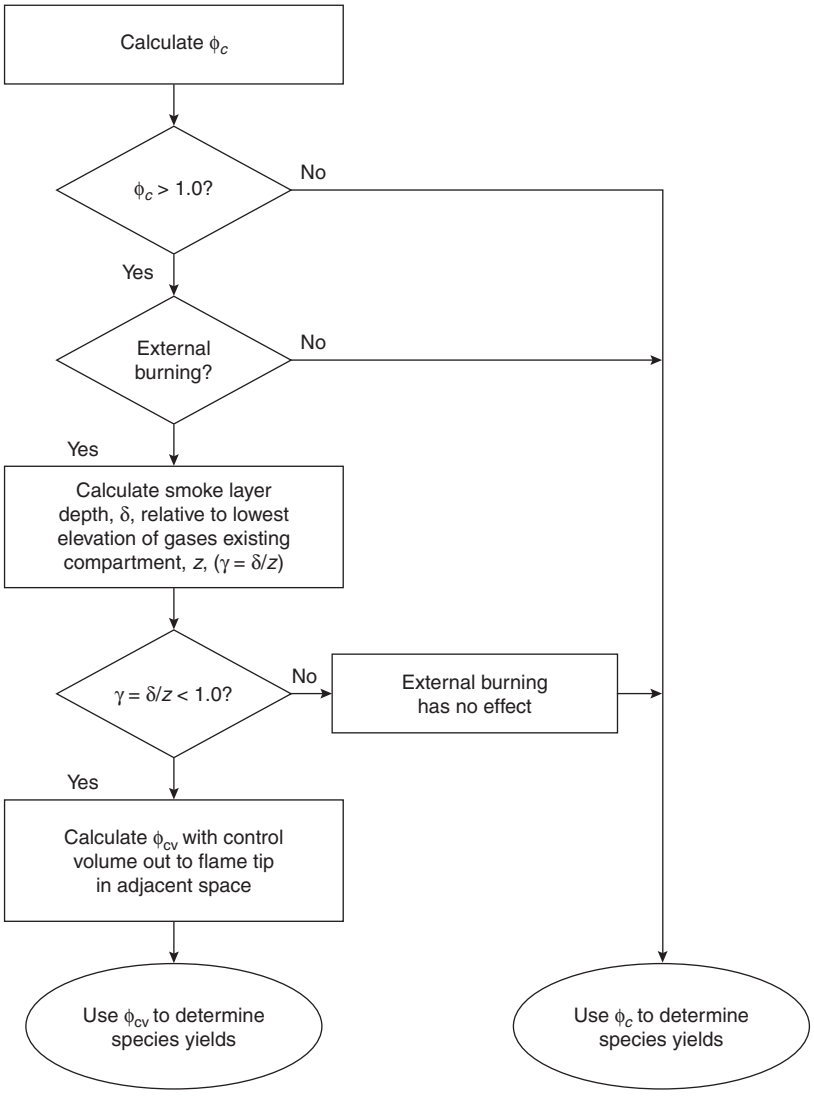

Figure 2-5.26. ***General methodology for predicting species levels transported to remote locations from a fire compartment.***

average upper layer temperatures below 800 K. Equation 22 is used for fires with upper layer temperatures above 900 K. Equation 15 is an approximate fit to the compartment fire hexane data of Gottuk et al. For the most part, CO yields from hexane fires represent lower limits observed for the fuels studied to date.[5,8] Therefore, these equations provide a *minimum* CO production that can be used for hazard analysis.

$$Y_{CO} = (0.19/180)\ \tan^{-1}(X) + 0.095 \qquad \text{for } T < 800\ \text{K} \quad (21)$$

where $X = 10(\phi - 0.8)$ in degrees

$$Y_{CO} = (0.22/180)\ \tan^{-1}(X) + 0.11 \qquad \text{for } T > 900\ \text{K} \quad (22)$$

where $X = 10\ (\phi - 1.25)$ in degrees

The figures presented earlier of CO yield versus equivalence ratio also show plots of Equations 21 and 22. Figure 2-5.5 shows the CO yield data for methane hood experiment fires in which upper layer temperatures ranged from 490 to 870 K. The CO yield data of Zukoski et al. and Toner et al. lies between the curves of Equation 21 and 22, particularly for slightly overventilated and stoichiometric conditions. This is consistent with the fact that these fires had temperatures that were higher than those represented by Equation 14 and some were within the transition range of 800 to 900 K.

The simple model presented as Equation 14 (parts a through e) with the inclusion of the empirically determined yield coefficients, is fairly adequate for predicting CO_2, O_2, and H_2O normalized yields. (See Equations 23–25.) Suggested average yield coefficients for compartment fires of elevated temperatures ($T > 900$ K) are 0.88

for B_{CO_2} and 0.97 for B_{O_2}.[5] Suggested values for low upper layer temperatures ($T < 800$ K) are 0.77 for B_{CO_2}, 0.92 for B_{O_2}, and 0.95 for B_{H_2O}. Average yield coefficients for underventilated fires are shown in Table 2-5.2.

$$f_{CO_2} = 1 \quad \text{for } \phi < 1 \tag{23a}$$
$$f_{CO_2} = B_{CO_2}/\phi \quad \text{for } \phi > 1 \tag{23b}$$
$$f_{O_2} = 1 \quad \text{for } \phi < 1 \tag{24a}$$
$$f_{O_2} = B_{O_2}/\phi \quad \text{for } \phi > 1 \tag{24b}$$
$$f_{H_2O} = 1 \quad \text{for } \phi < 1 \tag{25a}$$
$$f_{H_2O} = B_{H_2O}/\phi \quad \text{for } \phi > 1 \tag{25b}$$

As presented in Equations 23–25, normalized chemical species yields, f, can be correlated quite well by the global equivalence ratio. This is true for a wide range of fuel types. However, it is worthwhile to point out that for different fuels, the CO_2, O_2, and H_2O yields to equivalence ratio correlations only collapse down to a single curve when the yields are normalized by the maximum possible yield for a given fuel (i.e., presented as f rather than Y). Although complete combustion does not occur, combustion efficiencies with respect to equivalence ratio are similar enough between fuels that the stoichiometry of a particular fuel will dictate the generation of CO_2 and the depletion of O_2. Therefore, the species associated with complete combustion (CO_2, O_2, and H_2O) are not expected to have equal yields for different fuels, since varying fuel compositions will dictate different limits of CO_2 and H_2O that can be generated and O_2 that can be consumed for a gram of fuel burned. By normalizing the yields, the variability of fuel composition is removed.

On the other hand, carbon monoxide production is best correlated by the equivalence ratio when represented as a simple yield, Y_{CO}, rather than a normalized yield, f_{CO}. This is one indicator that CO production is not strongly dependent on fuel type, as is production of CO_2 and O_2. The reason for this is believed to be due to the fact that CO is effectively an intermediate product that depends more on the elementary chemistry than on fuel composition which determines products of complete combustion.

Once yields are determined using the above correlations, species gas concentrations can be calculated. Equation 26 can be used to calculate the concentration of species i for all species except oxygen. Oxygen concentrations can be calculated from the depletion of oxygen using Equation 27.

$$X_{i_{wet}} = \frac{Y_i \dot{m}_f M_{mix}}{(\dot{m}_f + \dot{m}_a) M_i} \tag{26}$$

$$X_{O_{2\,wet}} = \frac{0.21 \dot{m}_a M_{O_2}/M_a - D_{O_2} \dot{m}_f}{(\dot{m}_f + \dot{m}_a) M_{O_2}/M_a} \tag{27}$$

The yield-equivalence ratio correlations shown in Figure 2-5.7, which are also represented by Equations 21 and 15, have been replotted as CO concentration vs. equivalence ratio in Figure 2-5.27a. As indicated previously, the yield correlations in Figure 2-5.7 (and thus, the concentrations in Figure 2-5.27a) represent a reasonable lower bound for a range of typical fuels. Higher concentrations of CO can be created, particularly when additional fuel is added to a vitiated upper layer. Corresponding to 2-5.27a, CO_2 and O_2 concentrations for hexane compartment fires are shown in Figures 2-5.27b and c, respectively. Even though the peak concentrations of CO_2 will be dependent on the fuel type, the oxygen concentration as a function of ϕ will be similar for most hydrocarbons.[5]

The ratio of CO to CO_2 concentrations can be used as an indicator of the combustion mode. Higher combustion efficiency is obtained as more fuel is burned completely to CO_2 and H_2O and is indicated by a ratio of CO to CO_2 near zero. Since CO is a product of incomplete combustion, the ratio of CO to CO_2 concentrations will increase as fires burn less efficiently. The ratio increases with equivalence ratio even for underventilated conditions, as evidenced by experimental data [e.g., Reference 5] and the engineering correlations presented above.

EXAMPLE 4:

Consider that the piece of furniture described in Example 1 is burning in a room such that a two-layer system develops. The only ventilation to the room is an open doorway through which 217 g/s of air is being entrained. The material is burning at a rate of 37 g/s, and the average temperature of the upper layer is 700°C. Calculate the plume equivalence ratio and determine the yield of CO and depletion of O_2.

SOLUTION:

The plume equivalence ratio is calculated using Equation 10b. The stoichiometric fuel-to-air ratio, r, has already been calculated in Example 1.

$$\phi_p = \frac{\dot{m}_f/\dot{m}_a}{r} = \frac{37/217}{0.1139} = 1.5$$

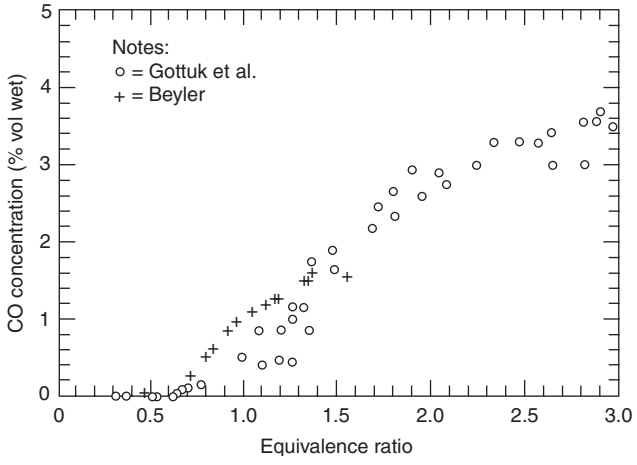

Figure 2-5.27a. ***Carbon monoxide concentrations as a function of equivalence ratio for hexane fires in a compartment (•) and under a hood (+). Data represent the same tests shown in Figure 2-5.7 as unnormalized yields.***

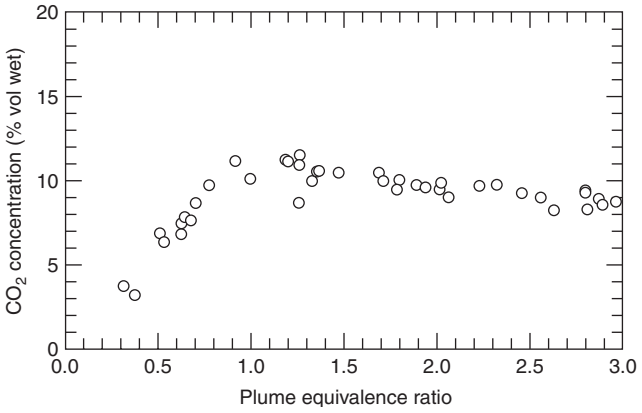

Figure 2-5.27b. ***CO_2 concentrations as a function of equivalence ratio for hexane compartment fires. (Data taken from Reference 5.)***

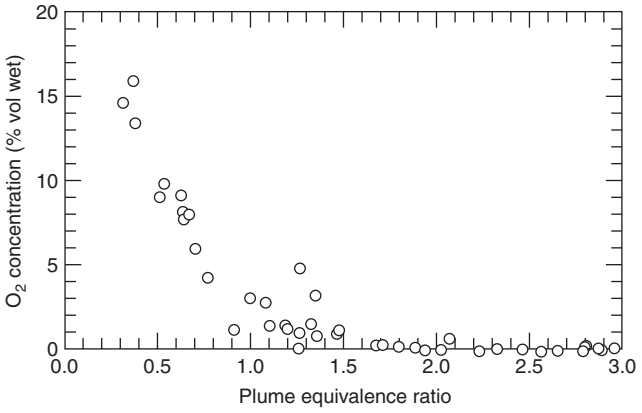

Figure 2-5.27c. ***O_2 concentrations as a function of equivalence ratio for hexane compartment fires. (Data taken from Reference 5.)***

Since the average upper layer temperature (700°C + 273 = 973 K) is above 900 K, Equation 22 is used to calculate the yield of CO. The argument, X, of the inverse tangent is

$$X = 10(\phi_p - 1.25) = 10(1.5 - 1.25) = 2.5$$

$$Y_{CO} = \left(\frac{0.22}{180}\right)\tan^{-1}(X) + 0.11$$

$$Y_{CO} = \left(\frac{0.22}{180}\right)\tan^{-1}(13.75) + 0.11$$

$$Y_{CO} = 0.19$$

Therefore, 0.19 grams of CO are produced for every gram of polyurethane foam that burns. The production rate of CO is equal to that yield, Y_{CO}, multiplied by the fuel burning rate (0.19 × 37 g/s = 7.0 g/s).

The normalized yield of oxygen is determined using Equation 24, and the recommended yield coefficient, B_{O_2}, of 0.97.

$$f_{O_2} = \frac{B_{O_2}}{\phi} = \frac{0.97}{1.5} = 0.65$$

From Example 1, we obtain the maximum theoretical depletion of oxygen, k_{O_2}, and calculate the depletion of oxygen as

$$D_{O_2} = f_{O_2} k_{O_2} = 0.65 \quad (2.05)$$
$$= 1.33\text{g of } O_2 \text{ per gram of fuel burned}$$

The depletion rate of oxygen is 49.2 g/s (1.33 × 37 g/s).

EXAMPLE 5:

For the piece of furniture burning in Example 4, calculate the CO and O_2 concentrations in the upper layer.

Gas concentrations can be calculated from the yields determined in Example 4 using Equation 26 for CO and Equation 27 for O_2.

$$X_{CO_{wet}} = \frac{Y_{CO}\dot{m}_f M_{mix}}{(\dot{m}_f + \dot{m}_a)M_{CO}} = \frac{0.19(37)(28.8)}{(37 + 217)(28)} = 0.028$$

$$X_{O_2} = \frac{0.21\dot{m}_a M_{O_2}/M_a - D_{O_2}\dot{m}_f}{(\dot{m}_a + \dot{m}_f)M_{O_2}/M_a}$$

$$= \frac{0.21(217)32/28.8 - 1.33(37)}{(32 + 217)32/28.8}$$

$$X_{O_2} = 0.005$$

The resulting concentrations of CO and O_2 are 2.8 and 0.5 percent by volume, respectively.

EXAMPLE 6:

A fire is burning in a room that has one door open and no other ventilation. The room is 7 m wide and 4 m deep with a 2.43 m high ceiling. The door measures 0.76 m wide and 2.05 m high (area = 1.56 m²). The peak heat release rate of the fire has been estimated to be 4.5 MW. Determine how much CO can be transported to other rooms in the building.

SOLUTION:

The first step is to calculate the compartment equivalence ratio, ϕ_c. Since details of the fire are not provided, the mass burning rate of the fuel is not known. Therefore, ϕ_c is estimated via Equation 13c using the heat release rate, Q, of 4.5 MW

$$\phi_c = \frac{Q}{\dot{m}_a} \cdot \frac{1}{3030} = \frac{4500\text{ kW}}{\dot{m}_a \cdot 3030}$$

The mass flow rate of air, $\dot{m}_a$, into the room is estimated using the ventilation parameter[33] as follows:

$$\dot{m}_a = 0.5A\sqrt{h} = 0.5 \cdot 1.56\sqrt{2.05} = 1.12\text{ kg/s}$$

Substituting $\dot{m}_a$ into the equation above for the compartment equivalence ratio yields a ϕ_c of 1.3. Since $\phi_c > 1$, the occurrence of external burning must be considered. However, using the criteria that $\phi_c < 1.6$, it is assumed that no external burning will occur. Species levels inside the room are calculated by Equations 19–25 using ϕ_c. The yield of

CO is calculated using Equation 21 or 22, depending on the temperature of the upper layer. The upper layer temperature can be estimated using the McCaffrey, Quintiere, and Harkleroad (MQH) correlation[34] that is presented in Section 3, Chapter 6 of this book. According to the MQH correlation, the upper layer gas temperatures exceed 900 K for fires above 1100 kW. For temperatures above 900 K, Equation 22 is used to calculate the CO yield as

$$Y_{CO} = (0.22/180) \cdot \tan^{-1}(10(\phi - 1.25)) + 0.11 = 0.14$$

Since there is no external burning, the CO generated in the compartment (0.14 kg of CO per kg of fuel burned) will flow to other parts of the building. Before dilution occurs away from the fire compartment, the initial concentration of CO in the gases from the fire compartment can be calculated using Equation 26

$$X_{CO_{wet}} = \frac{Y_{CO}\dot{m}_f M_{mix}}{(\dot{m}_f + \dot{m}_a)M_{CO}} = \frac{0.14(\dot{m}_f)28.8}{(\dot{m}_f + 1.12)28}$$

Since there is no information on the contents burning in the room, an accurate assessment of the fuel mass burning rate, $\dot{m}_f$, cannot be obtained. An estimate of $\dot{m}_f$ can be made using Equation 13a, with an assumed value of r, the stoichiometric fuel-to-air ratio. Values of r are presented in Table 2-5.1 for various fuels as $1/r$. In order to bound the possible CO concentrations, values of $1/r$ of 4 to 15 are chosen to represent a reasonable range of hydrocarbon fuels that may be burning in the room. The following shows an example of the $\dot{m}_f$ calculation using Equation 13a and $1/r = 4$:

$$\dot{m}_f = \frac{\phi \cdot \dot{m}_a}{1/r} = \frac{1.3(1.12 \text{ kg/s})}{4} = 0.36 \text{ kg/s}$$

The corresponding calculation for $1/r$ of 15 yields a $\dot{m}_f$ of 0.097 kg/s. Substituting the values for $\dot{m}_f$ into the above equation for $X_{CO_{wet}}$ results in CO concentrations of 3.5 and 1.1 percent, respectively.

Nomenclature

B_i	yield coefficients of species i
C	stoichiometric molar ratio of water to carbon dioxide
C_j	volume concentration of fuel j when fuel stream is stoichiometrically mixed with oxidant stream
C_p	heat capacity of products of complete combustion, (kJ/g·mol K)
D_{O_2}	mass depletion of oxygen per gram of fuel burned (g/g)
E	energy released per kg of oxygen consumed
f	normalized yield or generation efficiency
$\Delta H_{c,j}$	heat of combustion of the species j, (kJ/g·mol)
j	fuel species of interest
k	maximum theoretical yield
$L_{f,tip}$	Length of flame tip for flame extending down a corridor ceiling
M	molecular weight
m_a	mass of air
$\dot{m}_a$	mass flow rate of air
m_f	mass of fuel
$\dot{m}_f$	mass loss rate of fuel
$\ddot{m}_f$	the derivative of the fuel mass loss rate
$\dot{m}_{exhaust}$	mass flow rate out of the layer
n	molar quantity
n_{prod}	number of moles of products of complete combustion per mole of reactants (stoichiometric mixture of fuel and oxidant streams)
Q	ideal heat release rate
r	stoichiometric fuel-to-air ratio
r_a	stoichiometric air-to-fuel ratio
r_{O_2}	stoichiometric fuel-to-oxygen ratio
T	temperature
$T_{SL,j}$	adiabatic flame temperature at the stoichiometric limit for fuel species j, (K)
T_o	temperature of the gas mixture prior to reaction, (K)
t	time
t_r	residence time of gases in the upper layer
τ_{SS}	steady-state time ratio
V_{ul}	volume of the upper layer
X	mole fraction
$X_{i_{dry}}$	dry mole fraction of species i (H_2O removed from sample)
$X_{i_{wet}}$	wet mole fraction of species i
Y	yield (g/g) also refers to D_{O_2}
$Y_{O_2,air}$	mass fraction of oxygen in air
z	distance between the bottom of the compartment outflow and the ceiling in the adjacent space
γ	dimensionless layer depth in adjacent space ($\gamma = \delta/z$)
δ	layer depth in the adjacent space
ϕ	equivalence ratio
ϕ_c	compartment equivalence ratio
ϕ_{cv}	equivalence ratio defined per a specified control volume
ϕ_p	plume equivalence ratio
ϕ_{ul}	upper layer equivalence ratio
ρ_{ul}	density of the upper layer

Subscripts

a	air
f	fuel
CO	carbon monoxide
O_2	oxygen
CO_2	carbon dioxide
H_2O	water
H_2	hydrogen
THC	total unburned hydrocarbons
resid,C	residual carbon

wet gas concentration including with water in the mixture

dry gas concentration with no water in the mixture

CHAPTER 6

Toxicity Assessment of Combustion Products

David A. Purser

Introduction

It has long been recognized that exposure to toxic smoke products is one of the hazards confronting people in fires. There was a considerable increase in concern in this area during the 1970s and 1980s. In the United States, attention has been focused on the toxicity problem by a number of large fire disasters where victims have died from exposure to toxic smoke products.[1] Although this is also true to some extent for the United Kingdom, a major impetus for work in this area followed statistical surveys of fire casualties carried out in the mid-1970s. These surveys of casualties from all fires, and particularly from fires in domestic dwellings, revealed that not only were a large proportion of fatal and nonfatal fire casualties being reported in the category "overcome by smoke and toxic gases" rather than "heat and burns," but also that there was a fourfold increase in the former category between 1955 and 1971[2] (Figures 2-6.1 and 2-6.2). This increasing trend has continued into the 1980s, so that now approximately half of all fatal casualties and a third of all nonfatal casualties of dwelling fires (the majority caused by fires in furniture and bedding) were reported as being "overcome by smoke and toxic gases."[3] This has occurred despite the fact that the total numbers of fires have remained approximately constant. During the 1990s there was some reduction in total annual numbers of fire deaths in the United Kingdom (and in the United States), but smoke deaths in the United Kingdom are still running at

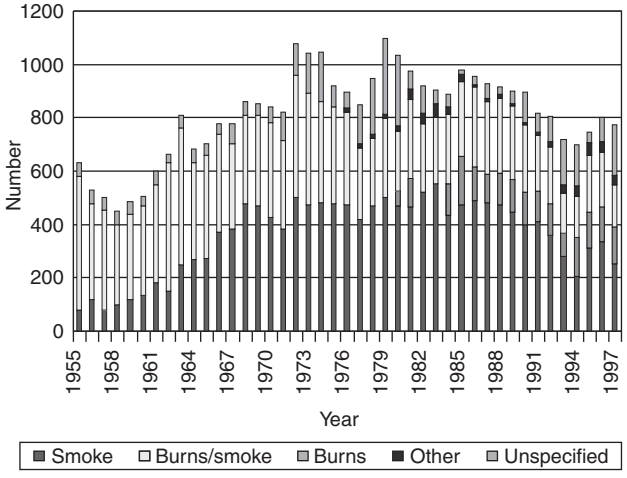

Figure 2-6.1. ***U.K. fire deaths.[3]***

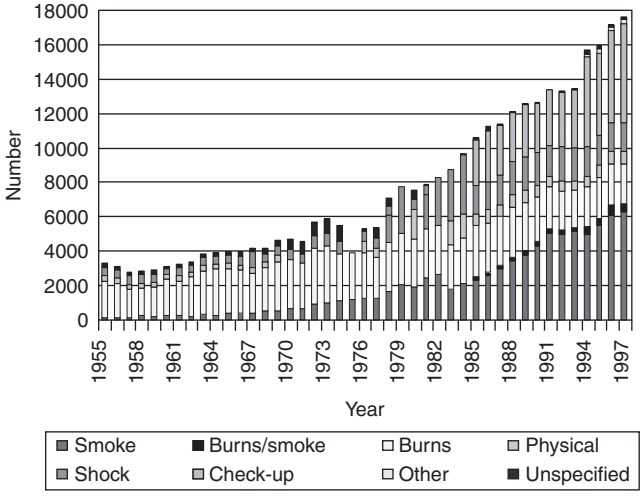

Figure 2-6.2. ***U.K. nonfatal fire injuries.[3]***

Professor David A. Purser has a Ph.D. in neurophysiology, and a diploma in toxicology from the Royal College of Pathologists. As former director of combustion toxicology research at Huntingdon Research Centre, England, and, currently, as associate director of the Fire Safety Engineering Centre in the Fire and Risk Sciences Division at BRE Ltd., Watford, England, he has worked on fire toxicology and life assessment for 30 years, and serves as an expert for the International Organization for Standardization (ISO) fire hazard and fire safety engineering working groups.

approximately four times the levels during the 1950s. Injuries from smoke and toxic fumes have increased continuously from an annual rate of approximately 1000 to more than 6000 during the late 1990s.

A number of possible reasons have been suggested for this increase in smoke-related casualties. They have been linked with the increased use of modern synthetic materials in furnishings. Another view is that the increase may not be directly related to modern materials but to changes in living styles over the period which have led to more furnishing and upholstery material being used in the average British home, and, therefore, a greater fire load. It has also been suggested that the increase is not real, but a statistical anomaly resulting from an increased awareness by the emergency services of toxic effects on victims. Epidemiological data are often difficult to interpret, but many of those working in this area are convinced that the increase in smoke-related casualties is real. The situation in the United States is difficult to interpret since it contains a larger and more diverse population, and statistics may not have been collected to reveal such a trend. The U.S. fire death rates were around twice those in the United Kingdom, western Europe in general and Japan 20 years ago, but have improved steadily up to the 1990s so that they are currently close to the U.K. and European death rates of approximately 14 per million inhabitants.[4–5] However in the United States and the United Kingdom, toxic smoke products are recognized as being the major cause of death in fires.[6] A possible difference between the pattern of fire deaths in the United Kingdom and United States is that in the United Kingdom the majority of fatalities occur in the room of fire origin (mainly in domestic dwellings) for fires that have not spread beyond the room of fire origin (65 percent of deaths). For 50 percent of deaths the fire spread is restricted to less than one third of the room area.[3] In the United States more than 50 percent of deaths are reported to occur remote from the room of origin, from fires that have spread beyond the room of origin (mostly post-flashover fires).[7] Although deaths remote from the room of origin involving spreading fires are also common in the United Kingdom, these differences indicate that cultural differences and differences in building styles can be important.

Materials-Based and Combustion Product-Based Approaches to Toxicity Assessment

There are two main views as to why smoke toxicity appears to be an increasing problem, which in turn have led to two rather different approaches to the evaluation of toxicity.

1. One view held that smoke from modern synthetic materials contained new toxic products that were not present previously, and that in some cases these products (the so-called "supertoxicants") might be very potent, exerting novel toxic effects at very low doses. Such effects could therefore be detected by means of simple, small-scale toxicity tests which could be used for regulatory purposes.[8–10] To some extent this approach followed the discovery that two materials, a flexible polyurethane foam containing a phosphorus-based fire retardant, and polytetrafluoroethylene (PTFE), could under certain laboratory conditions evolve products with a very high toxic potency.[8,9] This led to the use of rather simplistic materials-based toxicity tests, where the toxicity of materials is ranked in terms of the rodent LC_{50} (the concentration of combustion products expressed in terms of mg of material per liter of air causing the deaths of 50 percent of animals exposed).[10,11] This approach implies that the engineer should design by using those materials with the better performance in toxicity tests and that are consistent with good performance in other types of small-scale fire tests.
2. The other main view was that the basic toxic products of fires were much the same as always, but that in many modern fires the rate of fire growth and the rate of evolution of the common toxic products were much greater than they had been previously. Therefore, the best way to mitigate toxic hazard in fires was to control such factors as ignition, flame spread, and rate of smoke evolution rather than the qualitative nature of toxic products. For this approach, which is favored in the United Kingdom, there is more interest in estimating toxicity by making a chemical determination of the main toxic products given off by materials. This can be achieved by carrying out large-scale fire tests. Alternatively data on the yields of the main toxic products can be obtained from suitable small-scale tests and used as input to calculation of full-scale fire behavior using engineering calculation models such as those described in Chapters 2-5[12] and 3-4.[13] These data are then used to estimate time to incapacitation and death. In this context the main function of small-scale toxic potency tests (other than to provide data on yields of the main toxic gases) would be to confirm that the toxicity associated with particular burning materials was indeed due to the common toxic fire products via chemical atmosphere analysis in conjunction with animal exposures, and to identify those cases where unusual toxic effects occurred. This approach enables a firesafety engineer to design to a set of fire scenarios in a system (for example, a hotel bedroom or an aircraft cabin) and, by a simple chemical analysis of atmospheres produced during small- and large-scale fire tests, predict likely toxic hazard. The difficulty with these models is that they are often based on simplistic and erroneous assumptions concerning the effects and interaction of toxic products.

In practice there is a need for both small-scale materials-based toxicity tests and for profile modeling based on a few major toxic fire products. Existing information is often inadequate and misleading, and a better standard of research and testing is needed if data are to be produced for practical use. This chapter will give the reader an understanding of what is known about combustion product toxicity, the extent to which effects can be predicted from a knowledge of common fire products, and how small-scale tests should be performed and the results interpreted and used.

The Significance of Toxicity as Part of Total Fire Hazard

For scenarios involving the escape of occupants from a fire, survival depends upon the outcome of two parallel processes.

1. *The developing hazard from the fire.* This process incorporates ignition, fire growth, and the spread of fire and fire effluent. These depend upon a range of variables, such as the nature and disposition of the fire load, potential ignition sources, the reaction to fire properties of the lining materials and contents, the height and ventilation of the compartment, and the nature of the fire effluent. The actions of occupants and the provision of passive containment and active smoke extraction or suppression systems also affect the rate of development and extent of the hazard from a fire.

   Assessment of these processes for any particular scenario is aimed at calculating the time when an occupant would receive an incapacitating exposure to fire effluent.
2. *The process by which occupants escape.* This depends upon detection, the provision of warnings, response to warnings (premovement time), occupant profile (such as age and physical and mental ability, sleeping or waking, and population density) subsequent preegress behavior (such as seeking information, collecting belongings, choosing an exit, and other activities), egress (including wayfinding, movement towards an exit, crowd flow, and other factors), design of escape routes, exit numbers and widths, and the psychological and physiological influence of exposure to heat and smoke on escape behavior.

   Assessment of these processes for any particular fire scenario is aimed at calculating the time required for escape.

Once a fire has started, the outcome of the situation depends upon the outcome of these two processes. If the occupants have escaped before the fire becomes hazardous, with a reasonable margin of safety, then the design can be considered to have succeeded, but if the fire growth processes result in the fire becoming hazardous before the occupants have escaped, or within a narrow margin of safety, the design may be considered to have failed.

It is evident from this list of parameters that when all the needs of building occupants are considered, there is no single answer to fire safety or fire hazard, and that any practical system involves some compromise between all of these parameters. Fire safety can be improved or compromised in a number of different ways, while the occupants are involved in a number of ways, both in terms of their physiology and their behavior.

It is possible to consider the effects of fires on victims in three phases.

1. The first phase consists of the period when the fire is growing, but before the victim is affected by heat or smoke. During this phase the important factors influencing escape and ultimate survival are largely psychobehavioral or logistical factors, such as how the victim is alerted to the fire and reacts to that knowledge, whether he/she responds to alarms, attempts to leave or stays to fight the fire, interacts with other individuals, and how the person responds to the geography of the fire environment in effecting an escape.
2. The middle phase is the period when the victim is exposed to smoke, heat and toxic products, and where physiological factors such as irritancy and asphyxiation affect the victim's escape capability. During this phase such factors as the toxic nature of fire products and the dynamics of their production become critically important to escape.
3. The third phase is death in the fire, which may be caused by the major factors of toxicity and burns or a number of other factors.

The toxic effects of fire products are therefore most important during the second and third phases of fire growth. Most studies of fire toxicity have been confined to aspects of lethality. The ultimate causes of death in fires have been studied through pathological investigations of fire fatalities such as the Strathclyde study in the United Kingdom.[14] Also, the majority of combustion toxicity studies on laboratory animals have been used to measure lethality, principally in terms of the LC_{50} for individual fire products such as carbon monoxide (CO) or hydrogen chloride (HCl), or mixtures of thermal decomposition products from individual materials.[15]

The middle phase, of incapacitation in fires, can be studied either by animal experimentation or by investigations of the circumstances surrounding real fire casualties, particularly survivors of serious smoke exposure. However, this crucial area of toxicity has been largely neglected.

One particular series of studies has been carried out on the sublethal effects of combustion atmospheres on animals, mainly primates, to examine the mechanisms whereby people become incapacitated in fires.[16] Incapacitation rather than death has been studied because most fires are potentially lethal due to heat or CO if the victim is exposed to these for sufficient time. The two major determinants of whether a potential victim escapes are (1) the point at which incapacitation by toxic products is reached, and (2) how these products affect escape capability during the window of time available for escape between ignition and the development of lethal conditions.

The physiological effects of exposure to toxic smoke and heat in fires result in varying degrees of incapacitation which may also lead to death or permanent injury. Incapacitating effects include

1. Impaired vision resulting from the optical opacity of smoke and from the painful effects of irritant smoke products and heat on the eyes
2. Respiratory tract pain and breathing difficulties or even respiratory tract injury resulting from the inhalation of irritant smoke which may be very hot. In extreme cases this can lead to collapse within a few minutes from asphyxia due to laryngeal spasm and/or bronchoconstriction. Lung inflammation may also occur, usually after some hours, which can also lead to varying degrees of respiratory distress

3. Asphyxia from the inhalation of toxic gases, resulting in confusion and loss of consciousness
4. Pain to exposed skin and the upper respiratory tract followed by burns, or hyperthermia, due to the effects of heat preventing escape; this can lead to collapse

All of these effects can lead to permanent injury, and all except item 1 can be fatal if the degree of exposure is sufficient.

With regard to hazard assessment the major considerations are

1. The time when partially incapacitating effects are likely to occur which might delay escape
2. The time when incapacitating effects are likely to occur which might prevent escape, compared with the time required for escape
3. Whether exposure is likely to result in permanent injury or death

Up to a certain level of severity, the hazards listed in items 1 through 4 under physiological effects cause a partial incapacitation, by reducing the efficiency and speed of escape. These effects lie on a continuum from little or no effect at low levels to relatively severe incapacitation at high levels, with a variable response from different individuals. It is important to make some estimate of effects that are likely to delay escape, which may result in fewer occupants being able to escape during the short time before conditions become so bad that escape is no longer possible. Most important in this context is exposure to optically dense and irritant smoke, which tends to be the first hazard confronting fire victims. For more severe exposures a moment may be reached when incapacitation is predicted to be sufficiently bad as to prevent escape. For some forms of incapacitation, such as when asphyxia leads to a rapid change from near normality to loss of consciousness, this moment is relatively easy to define. For other effects a defining moment is less easily characterized; for example, when smoke becomes so irritant that pain and breathing difficulties lead to the cessation of effective escape attempts, or when pain and burns prevent movement. Nevertheless it is considered important to attempt some estimate of the moment when conditions become so severe in terms of these hazards that effective escape attempts are likely to cease, and when occupants are likely to suffer severe incapacitation or injuries. In the following text the mechanisms whereby these various factors cause incapacitation and death, and how they are likely to produce partial incapacitation and affect escape capability, are examined in detail. Toxicological and physiological data and models are presented to enable calculations to be made of time (or exposure dose) to incapacitation and death.

Basic Toxicity Patterns of Fire Products

As a result of chemical studies of large- and small-scale experimental fires[17] and animal exposures to the thermal decomposition products from a wide range of materials,[16] two important basic points have emerged concerning the nature of fire product toxicity.

1. Atmospheres of thermal decomposition products, even from single materials, contained large numbers of potentially toxic products. The chemical composition of the products could vary considerably depending upon the different conditions of temperature and oxygen supply under which they were decomposed.[16] When animals were exposed to these atmospheres, similar variations in toxicity were observed. In many cases, however, similar basic ranges of products were evolved from quite different materials.[17]
2. Despite the great complexity in chemical composition of smoke atmospheres, the basic toxic effects were relatively simple. For each individual smoke atmosphere the toxicity was dominated either by an asphyxiant gas (CO or HCN) or by irritants. Also, interactions between individual asphyxiant gases or, between asphyxiants and irritants, were found to be approximately additive, so that a reasonably good predictive model for incapacitation could be developed by summing the effects of each individual toxic component as acting separately.[16]

This work and that done by others using rodents[15] seems to indicate that the theory that smoke casualties have increased because new, highly toxic products are formed from modern materials is unlikely to be correct. Also, the finding that a small number of basic products are particularly important leads to the possibility of predicting toxic effects from a relatively simple chemical analysis of fire products. (This is not to say that unusual highly toxic products cannot occur, as at least two examples have been discovered in the laboratory;[8,9] and this is one important reason that the toxicity of thermal decomposition products from materials should be submitted to an animal screen.)

Dose/Response Relationships and Dose Estimation in the Evaluation of Toxicity

Before considering the particular effects of individual toxic fire products it is necessary to determine the basic parameters required to quantify exposure. Ultimately, the degree of toxicity is determined by such factors as the concentration of toxic product in the target organ of the body, and the time period for which a toxic concentration is maintained. For an asphyxiant product, the most important criterion is the concentration in the cerebral blood supply or inside the brain cells, while for an irritant product the most important factor is the concentration in the lining of the nose, throat, or lung. In some cases it is important and feasible to measure such parameters directly. For CO it is not the concentration in the smoke that directly determines how someone will be affected, but the concentration that has accumulated in the blood in the form of carboxyhemoglobin, and this can be determined relatively simply from a drop of blood.[18,19]

In practice, however, it is often not feasible to measure the amount of toxic product directly accumulated in the subject. Also, relating observed toxic effects to measurements of toxic products in the smoke itself is preferable, since it enables predictions of toxicity to be made based on chemical measurements of fire atmospheres without necessarily exposing animals. A series of useful

secondary measurements can, therefore, be made that can be related to toxic effects in animals, but it must be remembered that these indirect measurements of exposure always involve some degree of error or uncertainty.

The Relationships between Concentration Inhaled, Duration of Exposure, and Toxicity

In inhalation toxicology two parameters that are always measured and reported are the actual analyzed concentration of the test material per unit volume of air in the animals' exposure chamber, and the duration of exposure. For droplet aerosols or dusts the particle size range in the atmosphere is also measured so the respirable fraction (the part capable of entering the body) can be calculated. Where toxic effects can occur rapidly, as with the asphyxiant gases, it is also important to measure the rate of uptake of the toxicant. This can be estimated by measuring the volume of air breathed by the animal per minute (the respiratory minute volume, or RMV), although for accurate calculation of uptake and dose, further measurements, such as of blood levels, must be made. Variations in RMV can have dramatic effects on toxicity as will be described in the following section.

Although such parameters as respiration and particle size of aerosols are important, the most basic parameters reported are the concentration of the toxicant and the duration of exposure, which enables a rudimentary estimation of the dose. Thus the product of concentration and time (*Ct* product) gives an estimate of the dose available to the animal. In general safety evaluation of novel chemicals for an acute exposure, a standard single 4-hr exposure time is used and toxicity is expressed in terms of the concentration of test material causing the death of 50 percent of the animals during exposure or within 14 days after exposure. This is known as the 4-hr LC_{50} concentration.

In practice, however, it may be necessary to predict what will happen to a subject exposed to a higher concentration for a shorter period of time, or a lower concentration for longer time. Although this can be done by carrying out more LC_{50} experiments using different exposure durations, as an approximation toxicologists often resort to Haber's rule, which states that the toxicity depends upon the dose accumulated, and that the product of time and concentration is a constant,[20] so that

$$W = C \times t \tag{1}$$

where W is a constant dose, specific for any given effect. In practice, dose in inhalation toxicology is often expressed in terms of Ct product. In the case of the LC_{50}, the effect is death of 50 percent of the animals and

$$W = LC \cdot t_{50} \tag{2}$$

expressed in mg·min/liter (i.e., the product of the concentration and the duration of exposure causing lethality). This relationship implies a linear uptake of the toxic substance with time. (See Figure 2-6.3.) It holds true for many substances where the primary target organ is the lung; in the context of combustion toxicology this relationship can be applied to estimates of the dose of a lung irritant likely

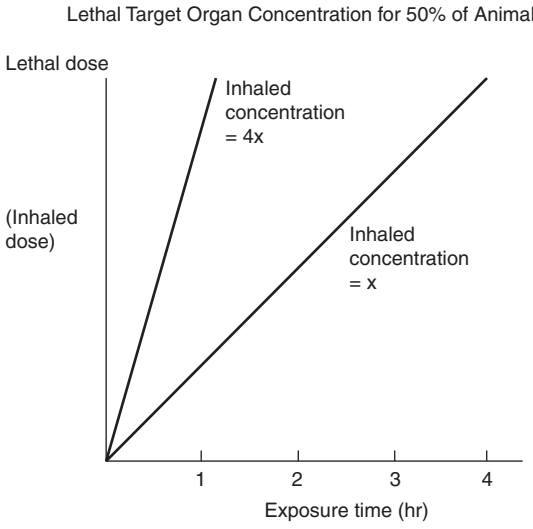

Figure 2-6.3. ***Uptake of a substance obeying Haber's rule (i.e., with a long halflife of detoxification or excretion), where the rate of uptake is directly proportional to the inhaled concentration, so that 1-hour LC_{50} is four times the 4-hour LC_{50}. The lethal represents a lethal target organ concentration for 50 percent of the animals.***

to cause postexposure fire deaths from lung inflammatory responses. An example of such an irritant is carbonyl fluoride, a highly toxic lung irritant produced during the thermal decomposition of PTFE, which has a 1-hr LC_{50} of 0.990 mg/L, which is exactly four times the 4-hr LC_{50} of 0.248 mg/L.[21]

Unfortunately, this simple principle does not always hold true. In particular, some volatile substances (such as CO) are both taken up and excreted via the lungs. In this case the rate of uptake depends upon the difference between the concentration inhaled and that in the body, giving an exponential uptake so that

$$W = C(1 - e^{-tk}) \tag{3}$$

which is the basis for the Coburn-Forster-Kane (CFK) equation[22,23] describing the uptake of CO in humans. This relationship approaches the linear Haber's rule (Equation 1) when the concentration, C, in the atmosphere is high with respect to the concentration in the body required to cause incapacitation or death (Figure 2-6.4), and for short exposures to high CO concentrations, uptake is approximately linear. This is illustrated by the results from CO exposure experiments in primates. At a constant level of activity, and thus respiration, the animals became unconscious when exposed to approximately 27,000 ppm·min of CO at concentrations between 1000 and 8000 ppm (Figure 2-6.5). For such situations it is therefore possible to use linear models for CO uptake without serious error.

Some toxic effects, however, are not dependent upon a dose acquired over a period of time, but are concentration related. Thus the irritant effects of smoke products on the eyes and upper respiratory tract (sensory irritation) occur immediately upon exposure, with the severity depending upon the exposure concentration. In fact, far

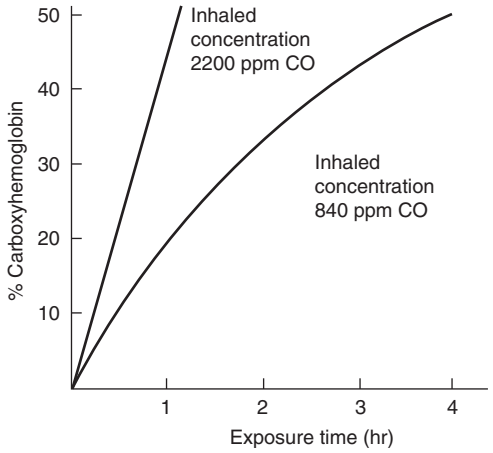

Figure 2-6.4. ***Uptake of a substance (carbon monoxide) which is both absorbed and excreted via the lungs, and where the rate of uptake depends upon the difference between the concentration inhaled and that in the body. For short exposures at high concentrations, uptake to a lethal dose is almost linear, obeying Haber's rule. For longer exposure times, uptake follows a curve so that the inhaled concentration necessary to achieve a lethal dose (50 percent carboxyhemoglobin) at four hr (840 ppm), is 0.38 times that required for deaths at one hr, as opposed to 0.25 times (550 ppm) as predicted by Haber's rule. Uptake was calculated for a 70 kg human at rest (RMV 8.5 L/min) using the CFK equation.***

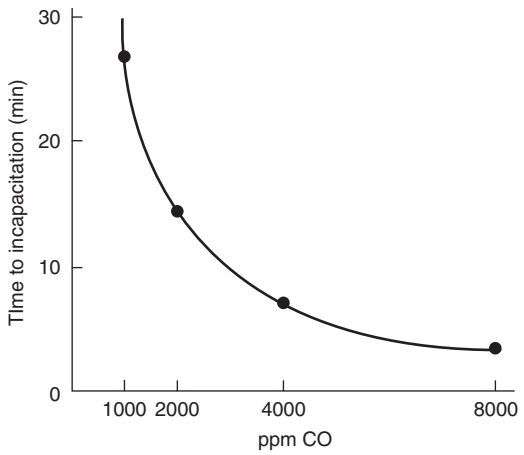

Figure 2-6.5. ***Relationship between time to incapacitation and carbon monoxide concentration in active monkeys. 1000 ppm Ct = 26,600 ppm·min; 2000 ppm Ct = 28,097 ppm·min; 4000 ppm Ct = 26,868 ppm·min; 8000 ppm Ct = 26,086 ppm·min.***

from increasing as exposure continues, the effects usually lessen, as the subject adapts to the painful stimulus even though the dose is increasing.[24]

Other cases where concentration is an important determinant of toxicity as well as duration of exposure are the asphyxiant effects of hypoxic hypoxia (oxygen lack) and hypercapnia (high CO_2 concentrations). If a subject is exposed suddenly to a low oxygen concentration, a finite time is required for the air in the lungs and gases in the blood to equilibrate to the new conditions, so to some extent a "dose" of hypoxia is acquired over a period of time. Once equilibrium is established, usually within a few minutes, the severity of the effects depend upon the oxygen concentration and do not then change appreciably with time.[25,26] This also applies to high CO_2 concentrations. Equilibrium is established within a few minutes and concentration related effects then determine the pattern of toxicity.[25]

For the other main asphyxiant gas in smoke, hydrogen cyanide (HCN), although accumulation of a dose is one factor, the most important determinant of toxicity appears to be the rate of uptake, which in turn depends upon the concentration. Thus as shown in Figure 2-6.6 incapacitation occurs rapidly (after 2 min) at the high concentration of 180 ppm (*Ct* product 400 ppm·min), but at the lower concentration of 100 ppm, incapacitation occurs only after approximately 20 min, requiring a much higher *Ct* product dose (2000 ppm·min). This effect leads to the unusual kinked HCN time/concentration curve shown in Figure 2-6.6 compared to the smooth curve for CO.

In attempting to predict what will happen to a subject exposed to a smoke atmosphere containing all these products it is therefore important to allow for these different concentration/time/effect relationships.

Ct Product and Fractional Effective Dose

The basic concept established in the previous section is that for the majority of toxic products in a fire atmosphere a given toxic endpoint such as incapacitation or death occurs when the victim has inhaled a particular *Ct* product dose of toxicant. In order to make some estimate of the likely toxic hazard in a particular fire it is therefore necessary to determine at what point in time during the course of the fire exposure the victim will have inhaled a toxic dose. This can be achieved by integrating the area under the fire profile curve for the toxicant under consideration. When the integral is equal to the toxic dose the victim can be assumed to have received a dose capable of producing that toxic effect.

A practical method for making this calculation is the concept of *fractional effective dose* (FED).[27] The *Ct* product doses for small periods of time during the fire are divided by the *Ct* product dose causing the toxic effect. These fractional effective doses are then summed during the exposure until the fraction reaches unity, when the toxic effect is predicted to occur. Thus

$$\text{FED} = \frac{\text{dose received at time } t(Ct)}{\text{effective } Ct \text{ dose to cause incapacitation or death}} \qquad (4)$$

For substances obeying Haber's rule the denominator of the equation is a constant for any particular toxic effect. For substances deviating from Haber's rule the denominator for each time segment during the fire is the *Ct* product dose at which incapacitation or death would occur at the concentration during that time segment. For

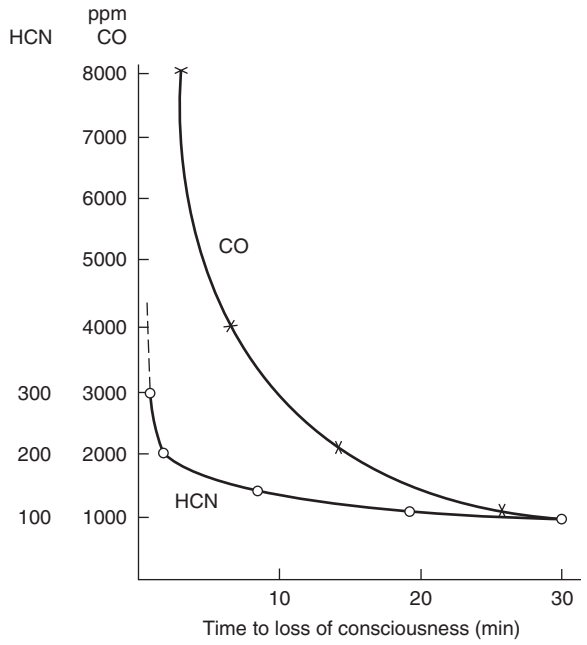

Figure 2-6.6. ***Comparison of the relationship between time to incapacitation and concentration for HCN and CO exposures in primates. Time and concentration are equivalent for CO; for HCN, a small increase in concentration causes a large decrease in time to incapacitation.***

the hazard model presented in this chapter the denominator is presented in the form of equations giving the required *Ct* product doses predicted for man, which have been derived for each toxic gas and are presented in the following sections. Special cases of the fractional effective dose are referred to as the *fractional incapacitating dose* (FID) and the *fractional lethal dose* (FLD).

For sensory irritation—a toxic effect which depends upon the immediate concentration of an irritant to which a subject is exposed, rather than the dose—a concept of *fractional irritant concentration* (FIC) has been developed, where

$$\text{FIC} = \frac{\text{concentration of irritant to which subject is exposed at time } (t)}{\text{concentration of irritant required to cause impairment of escape efficiency}} \quad (5)$$

The Nominal Atmosphere Concentration

There are occasions in combustion toxicology when it may be desirable to relate the toxic effects of an exposure to the material being decomposed rather than to its individual toxic products. This applies particularly to small-scale test results, where, for example, the LC_{50} of wood when decomposed in a particular way might be considered. This is a somewhat unsatisfactory approach, since it cannot be predicted that any material will evolve the same products with the same yields in a large-scale fire as in a small-scale test, and therefore exhibit the same degree of toxicity. However, this parameter does have some value when calculated in conjunction with measurements of the actual toxic products. This approach is related to another concept used in inhalation toxicology, that of the nominal atmosphere concentration, NAC. This theoretical concentration of test material in the test atmosphere is calculated from the amount of material produced from the atmosphere generation system each minute, divided by the diluent airflow rate. This concept is not strictly applicable in combustion toxicology since the test material is decomposed in the fire or furnace system, but two analagous concepts are very useful with regard to small-scale test methods since they enable some relationship to be established between the test material and the degree of toxicity. These are the nominal atmosphere concentration in terms of mass charged into the furnace, and the nominal atmosphere concentration in terms of mass decomposed, as follows:

1. Nominal atmosphere concentration (mass charge) equals mass of material placed in the furnace system divided by volume of air into which it is dispersed.
2. Nominal atmosphere concentration (mass loss) equals mass lost by material during decomposition divided by volume of air into which it is dispersed.

In practice the calculation of these parameters depends upon the particular decomposition system used (see the section of this chapter on small-scale test methods) and a shortcoming of some systems is that these parameters cannot easily be estimated.

If predictions of toxicity are to be made from large-scale fire test atmospheres, or if toxicity data from animals are to be interpreted, the following data should be available:

1. The nominal atmosphere concentration(s) of the test material(s) mass charge ($g \cdot m^{-3}$) (NAC mass charge)
2. The nominal atmosphere concentration of the test material mass loss ($g \cdot m^{-3}$) (NAC mass loss)
3. The concentration of each major toxic product in the atmosphere and the anticipated duration of exposure, that is, the concentration/time profile
4. The rate of uptake of the atmosphere, or RMV
5. Measurement of the blood concentration of certain toxicants
6. Particle size range. This is also important in determining the respirability and site of deposition of atmospheric products. However, smoke from nonflaming decomposition in small-scale tests is usually highly respirable
7. The nature of the effects of toxic products and the time/concentration relationships of these effects

Allowance for Margins of Safety and Variations in Susceptibility of Human Populations

The methods for assessing the effects of toxic gases were originally developed to predict the exposure concentrations or exposure doses that would be expected to cause serious effects such as impairment of escape capability, incapacitation, or death in a building occupant.

When they are used for design purposes, the main consideration is to predict not a serious effect level, but a maximum safe level. When used in this context, it is necessary to use some degree of conservatism in applying tenability endpoints for two reasons. One reason is to allow for uncertainties in the predictability of the endpoints. This is mainly because the endpoints cannot be fully quantified within narrow limits without performing experimental human exposures to a variety of complex and dangerous toxic effluent mixtures. This obviously cannot be done for ethical reasons. Another reason is the wide range of sensitivities to toxic effects in a heterogeneous human population.

The physiological algorithms are based partly upon experimental data and reported effects in humans, and partly upon animal studies. These methods involve either the exposure dose or concentration predicted to produce a given effect on humans exposed to fire effluent. However, the effects are based upon data for healthy young adult animals or humans. The exposure dose or concentration therefore represents the maximum in a statistical distribution of subjects' responses surrounding that exposure dose or concentration, that is, the mode, or most frequently expected exposure dose for an exposed population. Individual exposure doses or concentrations for the response would, in practice, be statistically distributed around the mode in a probability curve. The overall human population contains a number of subpopulations, which exhibit greater sensitivity to various fire effluent toxicants, principally due to compromised cardiovascular and pulmonary systems.

Two of the largest such subpopulations are the elderly and the approximately 15 percent of children and 5 percent of adults who are asthmatic.[28] The elderly, and particularly those with impaired cardiac perfusion, are particularly susceptible to asphyxiant gases. Thus the average lethal carboxyhaemoglobin (COHb) concentration in adults dying in fires or from accidental CO exposure is lower in the elderly.[29] Figure 2-6.7 shows the distribution of postmortem carboxyhaemoglobin concentrations in human fire and non-fire CO fatalities in the United States.[29] The results show that some individuals died at COHb concentrations below 30 percent while other survived long enough to obtain blood concentrations above 90 percent COHb. Many fire fatalities occur at lower COHb concentrations than for cases of CO poisoning alone. This may partly reflect the influence of other toxic gases in addition to CO in fire atmospheres. Also it has been shown in experimental studies that as little as 2 percent COHb significantly reduces the time to the onset of pain in an exercise test of angina sufferers.[30] This could be very important when attempting to escape from a fire. Asthmatics, and sufferers of other lung conditions such as chronic bronchitis and reactive airways dysfunction syndrome, are particularly susceptible to bronchoconstriction upon even brief exposure to very low concentrations of irritants, with distress, severely reduced aerobic work capacity, collapse and death resulting, depending upon the sensitivity of the individual and the severity of the exposure.

It is the objective of fire safety engineering to ensure that essentially all occupants, including the sensitive subpopulations, should be able to escape safely without experiencing or developing serious health effects. Thus, safe levels for exposure of the human population to fire effluent toxicants must be significantly lower than those determined from experiments with uniformly healthy animal or even human surrogates.

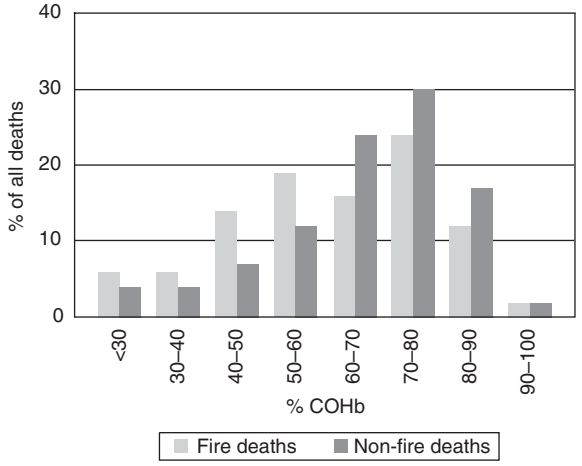

Figure 2-6.7. ***Range of lethal sensitivity to carbon monoxide in humans (after Nelson[29]).***

Fractional Effective Dose Hazard Assessments and Toxic Potency

In the context of fire safety, toxicity information is useful only to the extent that it can be used to assess toxic hazard in a full-scale fire scenario. There are a number of reasons for carrying out such an assessment. It may be needed in order to carry out a fire safety engineering assessment of a building design. In this context a particular set of fire scenarios may be run in order to assess probable outcomes in terms of the relationship between time available for escape compared to time required for escape. Time available for escape depends on the fire dynamics and time to incapacitation for building occupants exposed to toxic smoke. Time required for escape may also depend partly on the effect of toxic smoke on escape behavior. Another reason for modeling time to incapacitation may be the investigation of fire incidents in order to evaluate effects on fire victims. Another reason may be for a manufacturer to evaluate and compare potential toxic fire hazards from different materials of products, or for specifiers to determine the applicability of particular materials or products to particular design applications. In this situation a range of full-scale fire scenarios can be considered in order to evaluate product performance.

A difficulty with carrying out toxic-hazard assessments is that toxic products exert a range of different effects on building occupants, and toxicity information may be presented in a number of different forms. Confusion also often arises in relation to toxic potency data and its application to toxic-hazard assessment.

The toxic potency of a substance depends upon how much is required for a given toxic effect. The smaller the

amount needed, the more potent the toxic substance. For example, in fires, hydrogen cyanide is about 20 to 40 times more potent than carbon monoxide, because the amount needed to be inhaled to cause collapse is a much smaller exposure dose for hydrogen cyanide than for carbon monoxide.

Toxic hazard in a fire depends upon the extent to which toxic products in that fire scenario present a danger to building occupants. Put simply it depends upon how quickly and how much toxic products are produced, and how potent the products are.

Toxic Potency

Toxic potency can be considered in terms of

- An individual toxic gas such as carbon monoxide or hydrogen chloride
- A mixture of toxic products occurring in a fire (for example, the asphyxiant toxic potency of a CO and HCN mixture, or the irritant potency of a mixture, of acid gases)
- The mixture of toxic products evolved from the thermal decomposition under defined conditions of a particular material or product (such as wood, polyethylene, or a length of electrical cable)

The Toxic Potency of Individual Fire Gases and Gas Mixtures

In fires three major toxic effects are important.

1. The concentrations of irritant gases likely to impair escape efficiency or cause incapacitation (sensory irritation)
2. The exposure doses (*Ct* product doses) of asphyxiant gases likely to cause incapacitation through confusion and loss of consciousness (or to cause death)
3. The exposure doses of irritants likely to cause death through lung edema and inflammation after the fire

For sensory irritants the main criteria are the time during the course of a fire when the concentrations of irritants are sufficient to impair escape efficiency, and the time when they are likely to cause incapacitation through pain and respiratory distress. This is evaluated using the concept of fractional irritant concentration (FIC), by which the fractions of an irritant concentration for each irritant present are summed. When FIC = 1 a tenability endpoint (escape impairment) is predicted. Incapacitation is predicted at higher concentrations (FIC ~ 3–5). The sensory irritant potencies of different individual irritants occurring in fire atmospheres cover an enormous range spanning six orders of magnitude. More than 20 irritant compounds are considered to contribute to the overall sensory irritancy of fire atmospheres. The most important irritants identified are acid gases (hydrogen fluoride, hydrogen chloride, hydrogen bromide, nitrogen oxides, phosphoric acid, and sulphur dioxide) and organic irritants (such as acrolein, formaldehyde, and crotonaldehyde). Detailed guidance on the assessment of sensory irritancy of fire effluent is presented in the section on irritant fire products.

For asphyxiant gases the main criterion is the time during the course of a fire when a sufficient exposure dose (*Ct* product dose) of asphyxiants has been inhaled to cause incapacitation through confusion and loss of consciousness. This is evaluated using the FED concept, incapacitation being predicted at FED = 1. The gases important in causing asphyxiation are carbon monoxide, hydrogen cyanide, and reduced oxygen concentration. Carbon dioxide is important mainly because it increases the rate of uptake of CO and HCN. The toxic potencies of asphyxiant gases are less simple to define, because for cyanide (and reduced oxygen concentration) the incapacitating exposure dose is not a constant. However, the exposure doses lethal to rats over a 30-min exposure period are approximately 5700 ppm for CO and 164 ppm for HCN. The evaluation of asphyxiants is described in detail in the section on asphyxiants.

Another aspect of irritants that needs to be considered is the time during the course of a fire when a sufficient exposure dose of mixed irritants had been inhaled to cause potentially lethal lung inflammation. The toxic potencies of different lung irritants occurring in fire effluent cover a very wide range of approximately five orders of magnitude (see Table 2-6.1). Detailed guidance on the evaluation of lethal lung irritation is given in the section on irritants.

Toxic Potencies of Individual Materials

When individual materials are decomposed in full-scale fires or small-scale combustion toxicity tests, they produce a range of individual irritant and asphyxiant toxic products. The overall toxic potency of the resultant effluent mixture will depend on the yields of individual toxic products and their toxic potencies. For any particular material the yields of individual toxic products depend upon the thermal decomposition conditions (non-flaming oxidative, well-ventilated flaming, or vitiated flaming). In general, materials produce high yields of toxic products under nonflaming oxidative and vitiated flaming conditions, and lower yields under well-ventilated flaming conditions. This is described in detail in the sections on chemical composition and toxicity of combustion product atmospheres and the section on fire scenarios and victim incapacitation.

For any individual material decomposed under a particular decomposition condition in a small-scale test, it is possible to evaluate the toxic potency of the effluent mixture in terms of sensory irritation, asphyxiation or potential for lung inflammation. The toxic potency is then expressed in terms of the nominal concentration of the decomposed material rather than in terms of individual toxic products. Table 2-6.2 shows examples of the sensory irritant potency of fire effluent from materials, expressed in terms of the mouse RD_{50} concentration of the material decomposed (expressed as the mass loss concentration). The RD_{50} is the concentration causing a 50 percent decrease in respiration rate in mice during a short exposure. A reasonably good relationship has been found between the mouse RD_{50} concentrations for a range of irritant vapors and the concentrations reported as being painfully irritant to humans[93] (see section on

Table 2-6.1 ***Sensory and Pulmonary Irritancy of Combustion Products***

Irritant	RD_{50} (ppm) Mouse[b]	Severe Sensory Irritancy in Humans (ppm)	30-Min LC_{50} (ppm) Mammal[c]	LC_{50}/RD_{50}

The potential for causing sensory irritation spans six orders of magnitude, while that for causing death spans approximately three orders of magnitude. For substances down to NO_2 death is likely to be due to lung irritation, while for the remainder from styrene to acetone death is likely to be due to asphyxiation.

[a]Substances not detected in combustion atmospheres

[b]RD_{50} from Alarie,[93] where no data exist substances have been ranked according to their reported irritancy in man

[c]LC_{50} concentrations have been normalized to a 30-min exposure time according to Haber's rule.

irritancy). The table shows the mouse RD_{50} for a number of materials, some of which occur in aircraft, when decomposed under the thermal decomposition conditions indicated, using the BRE tube furnace method.[32] The majority of experiments were conducted under nonflaming oxidative decomposition conditions, but a small number of experiments were conducted under flaming decomposition conditions. The results show that the majority of materials have RD_{50} values lying between 0.05 and 0.5 g/m^3 under nonflaming oxidative decomposition conditions. This means that if the products of decomposition of between 0.05 and 0.5 g of material are dispersed into each cubic meter of air, then the resultant atmosphere is predicted to be painfully irritant to the eyes and respiratory tract. However, under flaming decomposition conditions the smoke irritancy decreases by a factor of 10 or more. For use in a hazard analysis for humans the RD_{50} mass loss concentration should be regarded as producing a total FIC_{irr} of approximately 0.5 for the effluent from the material in question.

Although it is therefore possible to measure or calculate the sensory irritant toxic potency of the fire effluent from materials decomposed under specific decomposition conditions, traditionally, toxic potencies for materials have been expressed in terms of overall lethal toxic potency to rats. This information was originally obtained by exposing groups of rats to thermal decomposition atmospheres from materials in small-scale tests and establishing the exposure concentrations causing the deaths of half the exposed animals (LC_{50} concentrations) during or within 14 days after a 30-minute exposure period. These data can also be expressed in terms of an exposure dose (*Ct* product dose) by multiplying the LC_{50} concentration by 30 to give an LCt_{50} exposure dose. Animal experiments of this kind have now largely been replaced by chemical measurements used in conjunction with appropriate calculation models as a method for estimating the rat LC_{50}. For this method the same small-scale tests may be used and the composition of the fire effluent is measured in terms of the major toxic fire gases. The data are then used as input to a

special type of FED calculation designed to predict lethal toxic potency in rats. (This should not be confused with the FED calculation methods used to predict incapacitation and death of humans exposed to full-scale fire atmospheres). Details of these FED calculations for rat lethality are presented in the section on the relationship between toxic potencies of materials in small-scale tests and full-scale fires. Standard methods have been published in British[33] and International[34] standards.

The lethal exposure concentrations or exposure doses expressed in this way represent the overall lethal toxic potency of the effluent from both asphyxia and lung irritation. Sensory irritation is not considered. The lethal toxic potency to rats is considered to be similar to that expected to occur in humans. It can therefore be used to represent an exposure dose of effluent from a material under defined fire conditions predicted to be lethal to humans. Incapacitation would be predicted at around a third of this exposure dose. In this context the toxic potency is expressed in terms of the nominal atmosphere concentration of the material (e.g., $g \cdot m^{-3} \cdot min$ mass loss of wood). This obviously provides a very crude estimate of the toxic potency of effluent to humans, since it does not take into account different toxic endpoints such as sensory irritancy and asphyxiation, it does not allow for deviations from Haber's rule known to be important with asphyxiant gases, it does not differentiate between effects occurring during exposure and afterwards, and it does not allow for differences between rodents and humans or the range of different sensitivities occurring within the human population.

The lethal toxic potencies of materials tend to be dominated by toxic gases evolved at high yields such as carbon monoxide, hydrogen cyanide, and acid gases when the relevant anions are present as a significant part of the elemental composition of the material. Under some conditions organic irritants or other compounds, including irritant ultrafine particulates, can be important. Figure 2-6.8 illustrates the range of lethal toxic potencies from individual compounds occurring in fire atmospheres and for individual materials decomposed under different combustion conditions.[35,36] The acute lethal toxic potencies of individual toxic products occurring in fire atmospheres range over more than five orders of magnitude. The most acutely toxic substance so far identified in the thermal decomposition product atmosphere is the ultrafine fluoropolymer particulate evolved when perfluorinated polymers such as polytetrafluoroethylene (PTFE) are decomposed under nonflaming conditions at temperatures of 400–650°C.[36] The LC_{50} of this particulate is $< 0.017\ g \cdot m^{-3}$. This toxic particulate has a short half life and is unlikely to present a hazard in most fire scenarios. It is not formed at high temperatures or when the fluoropolymer is flaming. Other compounds with a high acute lethal toxic potency evolved during fires are perfluoroisobutylene, carbonyl fluoride, and carbonyl chloride. Hydrogen cyanide and nitrogen dioxide, and some low molecular weight carbonyl compounds are also highly toxic in the 0.1–~1 g/m^3 range. Carbon monoxide and common acid gases such as hydrogen chloride lie in the 1.0–10 g/m^3 range, while a range of organic products with varying toxic potencies occupy higher ranges up to some with very low acute toxic potencies such as methane and other aliphatic compounds.

When the range of toxic potencies of these individual toxic products is compared with the acute lethal toxic potencies of effluent mixtures from particular materials or classes of materials expressed in terms of NAC mass loss (g/m^3), then a similar range of approximately four to five orders of magnitude occurs, ranging from fluoropolymers decomposed in such a way as to evolve ultrafine particulate (~0.017 g/m^3) to cellulosic materials decomposed under well-ventilated conditions in such a way that very low yields of toxic products are formed (>100 g/m^3). In practice, the lethal toxic potency of perfluorinated polymers covers a very wide range from

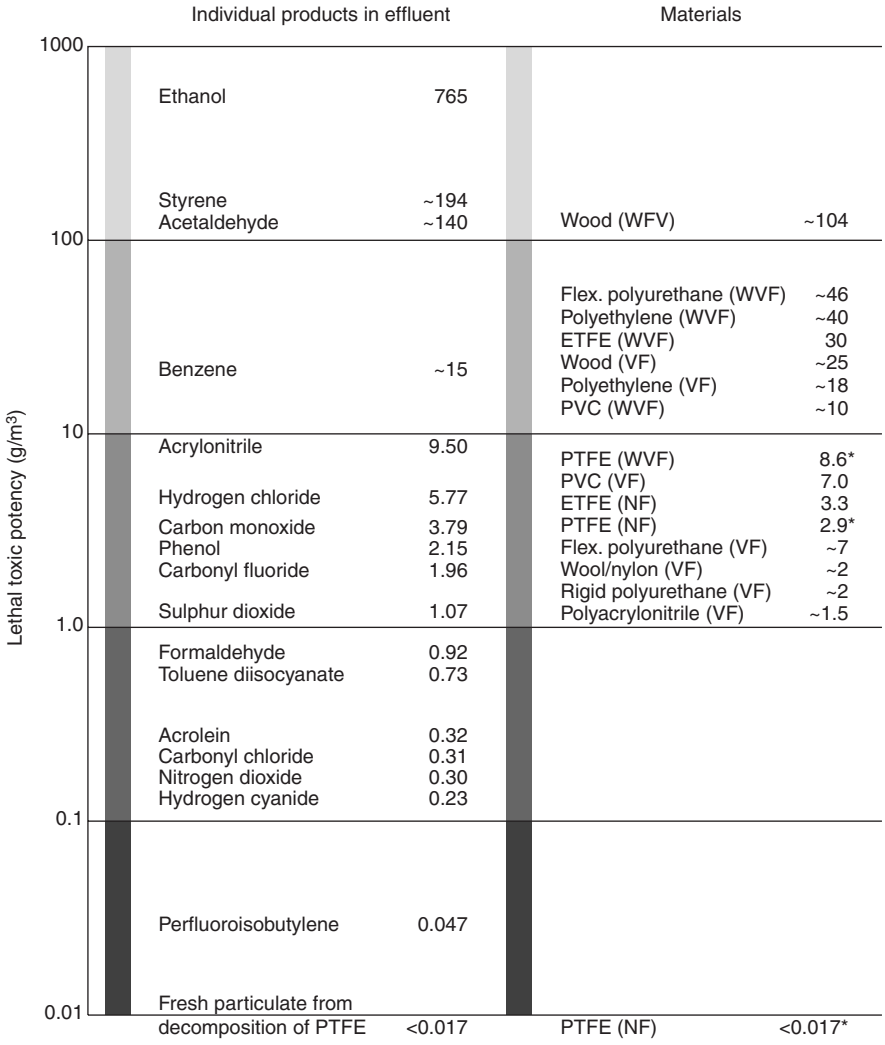

Figure 2-6.8. ***Lethal toxic potencies (g/m³) of individual compounds and the combustion products from various materials.***

NF = Nonflaming, WVF = well-ventilated flaming, VF = vitiated flaming

*The toxic potency of particulates evolved from fluoropolymers (and therefore the toxic potency of fluoropolymers themselves) varies considerably with the decomposition conditions and the age of the particulates. Extreme toxic potencies have not been observed for fluoropolymers under full-scale fire conditions.

approximately 0.017–8.6 g/m³, depending upon the decomposition conditions.[36] For most materials, the worst case conditions for producing high toxic potencies are nonflaming or vitiated flaming conditions, particularly for materials containing nitrogen or halogens. Many materials show toxic potencies in the range 1–10 g/m³ under these conditions. Well-ventilated flaming tends to destroy toxic products such as CO, HCN, and organic irritants, so that for polymers containing carbon, hydrogen, and oxygen the toxic potencies are low, with LC_{50} in the 10–100 g/m³ range. These aspects are discussed in more detail in later sections (see Tables 2-6.3 and 2-6.4), but the figure illustrates that for most materials under most fire conditions (including fluoropolymers) the lethal toxic potencies (30-min LC_{50}) fall within a range of approximately two orders of magnitude.

Despite the limitations of lethal toxic potency data for individual materials, they can be used for simple estimations of toxic hazard in full-scale fires. This represents one of a number of different approaches that can be used for the assessment of toxic hazard in full-scale fires, with varying degrees of sophistication and validity. The different methods are summarized in the next section.

Basic Requirements for Toxic Hazard Assessments of Full-Scale Fires

A key step in the process of toxic hazard assessment is to describe the growth of the fire, the production of toxic effluent, and its spread. A number of methods can be used to achieve this, but the main elements are as follows:

Table 2-6.3 ***Lethal Toxicity Data for Combustion Products from a Range of Materials***

Author	*n*	Test Method	30-Min LC_{50} (mg/l mass loss) Mean	Range	Wood	$L(Ct_{50})$ (mg·min/l mass loss) Mean	Range

NF = nonflaming
F = flaming

1. Obtain the mass loss curve for the fire and the dispersal volume of the effluent, either by conducting a simple large-scale test (measuring mass loss or heat release), by using a design fire, or by modeling
2. Determine the time-concentration curves for the main toxic fire gases, smoke optical density, and temperature of the fire either by
   a. direct measurement in a full-scale fire test
   b. calculation from the yields of toxic products, smoke and heat from the materials involved in item (1), measured in small-scale tests performed under appropriate fire conditions
   c. calculation from a knowledge of the composition of the materials involved in item (1) and fire decomposition chemistry
3. As an alternative to item (2), calculate the mass loss concentrations and mass loss exposure doses for materials involved in the fire

Once the growth of the fire and the spread of the fire and effluent has been described it is possible to proceed to quantify hazardous effects and estimate time to incapacitation and death. This can be done in two main ways.

Table 2-6.4 ***Approximate Lethal Exposure Doses (LCt_{50} g·m^{-3}·min), LC_{50} (g·m^{-3}), and Toxic Potency Factors for Common Materials under Different Fire Conditions***

Material	Nonflaming			Early Flaming			Post-Flashover		
Cellulosics	730	24	(0.7)	3120	104	(0.2)	750	25	(0.7)
C, H, O plastics	500	17	(1.0)	1200	40	(0.4)	530	18	(0.9)
PVC	500	17	(1.0)	300	10	(1.6)	200	7	(2.5)

Modacrylic/PAN	160	5	(3)	140	5	(3.6)	45	1.5	(11)

Toxic potency factors are calculated from the LCt_{50} based upon a "normal" potency of 500 g·m^{-3}·min. LC_{50} is for a 30-min exposure time with 14 days observation period.

1. Time to incapacitation and death can be estimated using physiological FIC and FED calculation models for smoke, irritant, and asphyxiant fire gases in conjunction with time-concentration curves for toxic fire gases as input data. This method calculates
   a. Time at which concentrations of smoke and sensory irritants are likely to impair or reduce the efficiency of egress due to psychological or physiological effects
   b. Time at which exposure concentrations or doses are likely to cause incapacitation or prevent egress due to psychological or physiological effects
   c. Time at which a lethal exposure dose has been inhaled
2. Alternatively, lethal toxic potency data for the materials involved in the fire can be obtained from small-scale combustion toxicity test atmospheres using animal exposures or using chemical analysis of the key toxic gases measured in such tests in conjunction with rat lethality FED calculations. These data can then be used with mass loss exposure dose curves (from method (3) to estimate time to incapacitation or death.

The Application of Small-Scale Tests for the Determination of Toxic Product Yields, and Time Concentration Curves, to Toxic Hazard Assessment

Where time concentration curve data are obtained from full-scale fire tests it is possible to proceed directly to an assessment of time to incapacitation using physiological FED algorithms. This method is described in the section on the prediction of time to incapacitation. Where full-scale fire data are unavailable, it is necessary to use modeling and small-scale test data obtained from performance-based tests to estimate the full-scale fire and the time-concentration curves of the main fire gases. In order to do this, it is necessary to use some form of fire growth curves (such as a t^2 fire growth curve or curves derived from heat release rate data) and a zone or computational fluid dynamics model to calculate the distribution and concentration of fire effluent (expressed in terms of fuel mass loss concentration) with time within the building enclosures. It is then necessary to obtain data for the yield of toxic fire products per unit mass of fuel decomposed, from which the concentrations of smoke and

toxic gases in the fire can be calculated. As described in Section 2, Chapter 5 and Section 3, Chapter 4, for particular fuels, the yields of CO and other toxic gases are dependent upon the equivalence ratio (ϕ) and particular characteristics of the fuels (such as the organic structure and the presence of oxygen or fire retardant additives [such as nitrogen, halogens, or phosphorus]).

As with all fire parameters the yields of toxic gases in full-scale fires can be variable and difficult to measure, while the equivalence ratio can be expressed in several different ways on a global or local basis within a fire enclosure. In practice, it is not practical to carry out full-scale tests to evaluate most hazard scenarios, so it is necessary to rely on modeling using reaction to fire data from small-scale tests or standardized fire curves, although these represent a further abstraction from the full-scale scenario, and need to be used with caution. One way of obtaining data on the relationship between ϕ and the yields of toxic products is to decompose the material in a small-scale toxicity test designed to combust materials under defined equivalence ratios. If the mass loss and product dispersal curve for the full-scale fire and the full-scale equivalence ratios are calculated, it is then possible to estimate the concentrations of toxic products by reference to the small-scale data. One example of such a small-scale test is the Factory Mutual apparatus, data from which are shown in Section 3, Chapter 4.[13] Another is the tube furnace method developed at the U.K. BRE Fire and Risk Sciences.[37–39] These methods have been used to examine the relationship between ϕ and toxic products yields, and the results obtained appear to be reasonably similar to those obtained in full-scale tests.[12,40] The apparatus is described in the section on second generation test methods. The following section gives a simple theoretical example of the application of this method.

Using small-scale toxic product yield data in toxic hazard assessments: Figure 2-6.9 shows the relationship between ϕ and CO yield for two fuels comprised of carbon and hydrogen only. Large-scale data using hexane and fuel are reproduced from Gottuk.[12,40] The small-scale data are taken from Hull et al.[39] and Purser[38] for polyethylene and PVC using the FRS Tube furnace. As the figure shows, CO yield is very low for these fuels at ϕ values > 1 and peaks at ϕ values of around 2 at approximately 0.2 g/g. Similar relationships occur for other toxic products and an inverse relationship for CO_2 (see Tewarson Chapter 3.4[13]). As a simple example, a full-scale fire is estimated as a medium growth rate t^2 fire, with a theoretical fuel decomposing with the same CO and CO_2 yields as were obtained from the tube furnace tests at ϕ values of 0.5 (well ventilated) and 1.5 (vitiated). The fire is in an enclosed room ($2.44 \times 3 \times 2.44$ m) with a 1 m $\times$ 0.3 m vent at floor level. The fire growth rate, heat release rate, and upper zone filling rate are modeled using CFAST. The mass loss rate is calculated from the heat release rate. The CO yield and CO_2 yields are taken from the tube furnace experiments as

well-ventilated:	0.007 CO	2.54 CO_2	g/g fuel mass loss
vitiated:	0.149 CO	1.57 CO_2	g/g fuel mass loss

The FED for human incapacitation from CO and CO_2 is calculated, using Equations 7 and 18. (Figure 2-6.10) Three cases were calculated. For one it was assumed that the CO and CO_2 yields remained fixed at the well-ventilated levels. For the second it was assumed that the yields changed linearly with time from the start to the peak of the fire, and for the third it was assumed that the yields remained constant throughout at those obtained under vitiated conditions. In reality, the yields would be expected to change with ϕ, which could be calculated for the full-scale fire case. The results of the exercise for the variable yields illustrate that the yields of CO and CO_2 during the early, well-ventilated phase of the fire produce only a small increase in FED for asphyxiation. This is partly because the smoke layer is above the occupant's head for some of the time, but mainly because the fire is small and producing only small amounts of effluent. During the later parts of the simulation the fire is larger, producing effluent at a much greater rate. It is also becoming vitiated so that both the mass and yield of CO are increasing. After 200 seconds the FED is predicted to reach 1 and incapacitation is predicted to occur. If the CO and CO_2 yields are assumed to remain constant at the well-ventilated levels throughout, then the increasing toxic hazard is seriously underestimated, reaching only an FED value of only 0.1 after 200 seconds. When the CO and CO_2 yields are assumed to remain constant at the vitiated yield values, then the increasing FED is slightly earlier than, but very similar to, that obtained when continuously varying yields were assumed. This illustrates the importance of obtaining toxic product yield data under the correct fire conditions and the extent to which the toxic hazard is driven by the later stages when the fire is larger and the CO yields greater. In this example the error obtained by assuming a constant high yield of CO throughout is small.

It is then possible to consider what outcome might have occurred if the polyethylene was substituted by a polymer treated with a fire retardant such as phosphorus or halogen additives. When these materials burn they tend

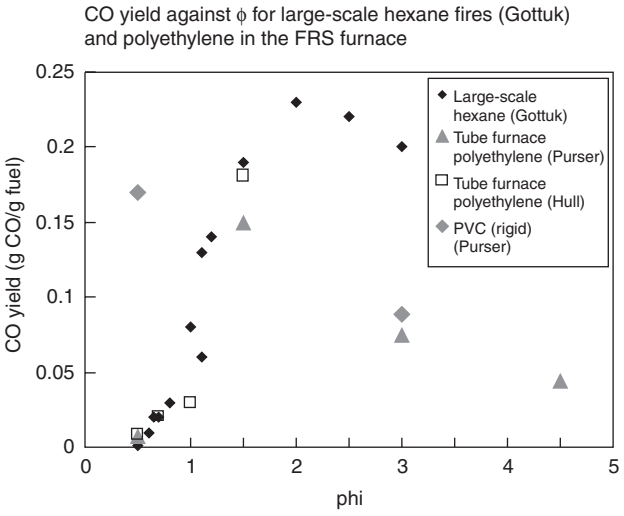

Figure 2-6.9. ***CO yield against ϕ.***

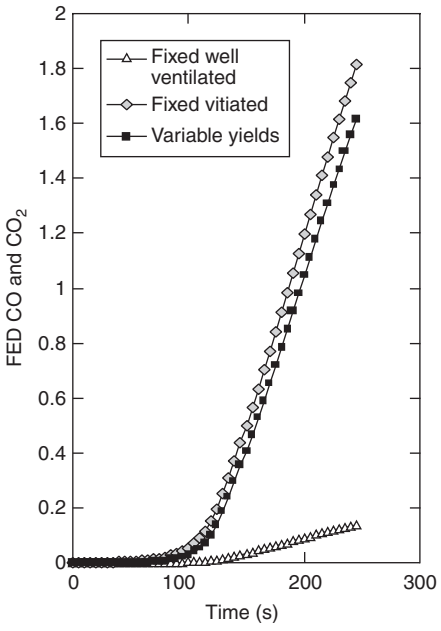

Figure 2-6.10. ***FED for human incapacitation due to CO and CO_2 during a theoretical enclosed room fire involving a polymeric material such as polyethylene. CO and CO_2 yields obtained using the FRS tube furnace, fire modeled using CFAST.[38]***

to produce high yields of CO even under well-ventilated conditions, and so might be considered to present a toxic hazard in some fires. For the example shown here, it is possible to examine the potential toxic hazard from CO and CO_2 if a halogenated polymer such as PVC was burned and the yields were as obtained in the tube furnace. Assuming that initially the fire growth rate of PVC was the same as for polyethylene (while in practice it is likely to be much slower) and the yields of CO were as obtained in the tube furnace, then it is possible to consider the effects on FED development for asphyxiant gases. As Figure 2-6.9 shows, the yield of CO from PVC under both well-ventilated and vitiated conditions was very similar to that obtained from polyethylene under vitiated combustion conditions. It can therefore be estimated that the FED for PVC would follow the case calculated for a constant high CO yield. If the toxic potency of PVC (in terms of asphyxiants) under well-ventilated combustion conditions was the only item considered, then it might be estimated that PVC was a much more hazardous material than polyethylene, because the CO yield under these conditions is more than 20 times greater than for polyethylene. However, as the hazard modeling shows, the differences in CO yield during the well-ventilated phase of the fire have very little influence on the hazard development, so that, at least for this example, very little difference in time to incapacitation from asphyxiation would be expected between either fuel. In practice it would be expected that the fire growth curve for the PVC would be much slower than for polyethylene (assuming flaming ignition occurred) with a consequently slower growing FED curve. However an additional hazard from a PVC fire would be the evolution of hydrogen chloride and other irritants, which would also need to be considered in the model. For all such hazard analysis it must be remembered that it is the concentration of toxic products at the breathing zone of a building occupant that is important. Depending upon the positions of the occupants and the time during the fire development it is likely that concentrations of acid gases in particular will be diluted relative to those near the fire and further reduced by losses to building surfaces.

Using Mass Loss Lethal Toxic Potency Data for a Simple Toxic Hazard Assessment

Another method for making a simple hazard assessment is to make use of lethal toxic potency data for materials obtained from a small-scale toxicity test. One way of performing a preliminary simple hazard analysis for a fire is to consider what exposure in terms of a single criterion, the mass loss concentration profile of products in a fire, is likely to be lethal to a victim. For such a calculation use can be made of mass loss lethality data from small-scale rodent toxicity test data for the material or materials involved in the fire. This makes the assumption that the lethal concentration to a human would be similar to that in a rat, but this is standard practice in toxicology for making approximate classifications of hazard for the acute effects of industrial chemicals. It is also necessary to make the assumption that mass loss lethality data follow Haber's rule, but any inaccuracies introduced by deviations from ideal behavior should not be important in such an approximate analysis. The three items of data needed for such an assessment are

1. The basic fire condition (smoldering, early flaming, or post-flashover)
2. The mass loss/dispersal volume-time curve for the fire
3. The rodent LCt_{50} concentrations for the materials involved in the fire in terms of the mass loss concentration for a quoted exposure time, determined under the same conditions as those in the fire

LCt_{50} data for common materials have been derived using a number of small-scale test methods under a variety of decomposition conditions. Most published data relate to nonflaming oxidative decomposition conditions, well-ventilated flaming, or mixed flaming and nonflaming conditions. Very few data are available for post-flashover fire decomposition conditions. Table 2-6.3 shows examples of data sets obtained using three well-known test methods. The range of LC_{50} for the references quoted (shown in Table 2-6.3) was approximately 5 to 60 $g \cdot m^{-3}$ mass loss for a 30-minute exposure, which is equivalent to an LCt_{50} dose range of approximately 150 to 1800 $g \cdot m^{-3} \cdot min$, with an average value of 23 $g \cdot m^{-3}$ (690 $g \cdot m^{-3} \cdot min$). Allowing for a small margin of safety, it has been suggested within British standards that, for a simple hazard assessment, a single figure of 500 $g \cdot m^{-3} \cdot min$ might be considered as a single average figure for the approximate toxic potency of the thermal decomposition products from common materials. For the purpose of carrying out hazard calculations, the toxic potency of any individual material can then be expressed in terms of a potency factor relating the actual LCt_{50} to 500, as follows:

Toxic potency factor for a material under a defined fire condition = $500/LCt_{50}$ g·m^{-3}·min

General Pattern of Toxic Potency for Common Materials under Three Fire Conditions

Using a wider database than that for Table 2-6.3, a survey of the toxic potency data for common materials in nonflaming, early flaming, and post-flashover fire conditions revealed an inadequate database, but it was possible to derive approximate LCt_{50} for common materials.[35] The results for individual materials range over approximately two orders of magnitude from 20 to 3750 g·m^{-3}·min; but when the data are reduced to basic types of materials under each decomposition condition, a relatively simple pattern can be described, as presented in Table 2-6.4. The table shows the approximate average lethal exposure doses (LCt_{50}) for classes of materials, the LC_{50} for 30-minute exposures, and a potency factor (based upon a figure of 500 g·m^{-3}·min for the "normal" lethal potency for combustion products), respectively. The findings are as follows:

Under nonflaming oxidative decomposition conditions at >400°C, most materials have a similar potency close to 500 g·m^{-3}·min, that is, potency factor of approximately 1, due mainly to the effects of carbon monoxide and irritants. The main exceptions are nitrogen-containing materials releasing significant HCN at low temperatures (e.g., polyacrylonitrile, modacrylic, and rigid polyurethane foam), which have toxic potency factors of 3 to 8.

Under early well-ventilated flaming conditions most nonfire-retarded materials are substantially less toxic than under nonflaming conditions. Cellulosics (wood and cotton) are the least toxic with LCt_{50} of >3000 g·m^{-3}·min (potency factor 0.2). Plastics containing carbon, hydrogen, or oxygen are somewhat more toxic with a potency factor of 0.4 ($LCt_{50} \sim 1200$), and those containing low percentages of nitrogen (e.g., flexible polyurethanes, wool, and nylon) also fall into this area. PVC and fire-retarded materials have a similar toxic potency factor to that under nonflaming conditions of approximately 1. Rigid polyurethanes and nitrogen-containing acrylics have high potencies similar to those under nonflaming conditions.

Under post-flashover conditions (and pre-flashover vitiated combustion conditions), the potency of all materials increases due to the increased yields of HCN and CO. More smoke and irritants are also present than under early flaming conditions, which may add somewhat to the potency, particularly of the non-nitrogen-containing materials. For cellulosic materials and hydrocarbon plastics, the potency is similar to that under nonflaming conditions (potency factor close to 1). For all nitrogen-containing materials, the toxic potency is high, ranging from approximately 2.5 for flexible polyurethane foam to approximately 11 for modacrylic and polyacrylonitrile. It is suggested that PVC would have a potency factor of approximately 2.5 under these conditions.

It is suggested that the data in Table 2-6.4 provide a mechanism whereby small-scale toxicity test data, obtained under appropriate decomposition conditions, can be applied in fire engineering calculations. A simple, first estimate could be based upon a single lethal toxic potency figure of 500 g·m^{-3}·min for all materials, using total fire load or heat release as the source of the mass term. In order to assess an incapacitating exposure dose (and to allow for possible greater sensitivities between rats and average humans) this should be multiplied by 0.3 to give an incapacitating dose of 150 g·m^{-3}. A further factor of 0.3 could then be applied to allow for the range of sensitivities in the human population, giving a figure of 45 g·m^{-3}·min to allow for escape of the majority of the occupant population. When more detailed information on the nature of the materials likely to be involved in a fire is known, the calculations for particular fire scenarios can be based upon the predicted mass loss rate for each material, adjusted by the appropriate toxic potencies. The range of toxic potencies of common materials decomposed under conditions occurring in flaming fires is approximately two orders of magnitude. Data obtained so far that relate to nonflaming fires show a relatively narrow range of potencies around 500 g·m^{-3}·min. Early flaming, well-ventilated fires show toxic potency to be generally low where combustion is efficient, ranging from approximately 75 to 3750 g·m^{-3}·min, while data obtained so far that relate to vitiated, post-flashover fires show that potencies are generally higher, due to increased yields of CO and HCN, ranging from approximately 21 to 3000 g·m^{-3}·min.

Difficulties in making estimates of the specific toxicities and toxic potencies of common materials arise from the very poor database of both small- and large-scale tests conducted under appropriate conditions. This is particularly true of the vitiated post-flashover condition, which is not well simulated by existing test methods, except possibly the DIN and FRS methods, for which very few data are available.

Theoretical Example of the Application of the Mass Loss Lethal Toxic Potency Data for a Simple Toxic Hazard Assessment[33]

Consideration is being given to replacing the floor covering material in a hotel bedroom. There is a concern that if the material is ignited by a small ignition source the rate of development of a toxic hazard from the new material (material B) should not be worse than that from the old material (material A). It is considered that the most likely scenario would involve a closed room, so that rapid smoke filling would occur and the effluent can be considered as evenly mixed throughout the room volume (i.e. layering effects can be considered very transient, and can be ignored). A problem is that the toxic potency of material B is twice that of material A, although it burns more slowly once ignited.

Information available: The volume of the room is 40 m^3. The floor covering materials are 1 cm thick with an area density of 1 kg/m^2. Horizontal burning tests have shown that both materials burn through rapidly so that a front of complete combustion spreads from the point of ignition. For material A the rate of flame spread is 10 cm/min while for material B the rate of flame spread is only 5 cm/min. However, small-scale toxicity tests have shown that, under well-ventilated flaming conditions, the toxic potency of material B (LC_{50} 10 g·m^{-3}, lethal exposure dose 300 g·m^{-3}·min) is twice that of material A (LC_{50} 20 g·m^{-3}, lethal exposure dose 600 g·m^{-3}·min).

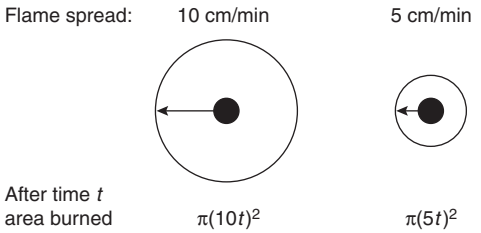

Figure 2-6.11. ***Flame spread rate for two materials.***

Hazard analysis: Assuming a small point ignition source, both materials will burn through, and a circle of burned area will spread out from the point of ignition (Figure 2-6.11). Since material A burns twice as quickly as material B, the area of material A consumed will be four times that of material B at any time during the early stages of the fire.

Table 2-6.5 shows how the FED calculations are made using material A as an example. The FED for each point in time is the exposure dose divided by the lethal exposure dose for that material. The FEDs for each time interval are them summed throughout the fire until the FED reaches unity, at which point the toxicological endpoint, in this case lethality, is predicted.

Figure 2-6.12 shows the results of the FED calculations for materials A and B in the 40-m^3 room. The analysis shows that lethal conditions are attained after approximately 6 min for material A, and approximately 1.5 min later for material B. It can therefore be concluded that material B presents less of a toxic hazard than material A in this scenario, despite the fact that material B has twice the toxic potency of material A.

Incapacitation

This rather crude method could be used to give an approximate indication of when conditions in a fire are likely to be lethal, but in practice the effects of fires on exposed victims are not so simple. In many cases death is not due to the immediate toxic effects of exposure, but results from the victim being trapped in the fire, either because irritant and optically-obscuring smoke prevents escape, or because asphyxiant gases cause incapacitation, so that the victim remains in the fire to die either from a fatal dose of toxic products acquired during the prolonged exposure, or from burns. One way of taking these factors into account would be to determine the *Ct* product dose at which effects such as incapacitation due to asphyxia occur in small-scale toxicity tests. These could then be applied to the fire hazard analysis to estimate the fractional incapacitating dose, rather than the fractional lethal dose. However, because of differences in generating small-scale fire test atmospheres similar to those occurring in large-scale fires, a potentially much more effective way of predicting toxic hazard would be to measure the concentration/time profiles of the important toxic products in the fire and to determine their effects from toxicity data derived from experiments in man and primates (and to a lesser extent also from rodents). In the following sections the characteristics of the major asphyxiant and irritant fire products are described, together with methods for calculating their uptake and predicting their toxic effects.

Table 2-6.5 ***Example FED Calculation Data for Materials A and B***

Time (min)	Area Burned (cm^2)	Mass Consumed (g)	Mass Loss Concentration (averaged for each time interval) (g•cm^{-3})	Exposure Dose (g•cm^{-3}• min)	FED

Asphyxiation by Fire Gases and Prediction of Time to Incapacitation

Asphyxiant gases cause incapacitation mainly by effects on the central nervous system and to some extent, the cardiovascular system.[25] In general, time to incapacitation and its severity are predictable in that usually a short period of intoxication is followed by a relatively sharp decline into severe incapacitation (i.e., loss of consciousness).[16,44] Most asphyxiant gases produce their effects by causing brain tissue hypoxia.[25,26] Since the body

possesses powerful adaptive mechanisms designed to maximize oxygen delivery to the brain, it is usually possible to maintain normal body function up to a certain dose of asphyxiant, and the victim is often unaware of the impending intoxication. Once a point is reached where normal function can no longer be maintained, however, deterioration is rapid and severe—beginning with signs similar to the effects of severe alcohol intoxication, consisting of lethargy or euphoria with poor physical coordination, and followed rapidly by unconsciousness and death if exposure continues.[26,44]

Asphyxiant Fire Products

The two major asphyxiant gases in fires are: (1) carbon monoxide (CO) and (2) hydrogen cyanide (HCN). Carbon monoxide is always present to some extent in all fires, irrespective of the materials involved or the stage (or type) of fire, so that there is almost always some degree of risk of asphyxia from CO exposure.[17] Hydrogen cyanide is always present to some extent when nitrogen-containing materials are involved in fires. These include materials such as acrylics, polyurethane foams, melamine, nylon and wool, which are likely to be involved to some extent in most fires in buildings. Hydrogen cyanide is likely to be present at high concentrations in large, post-flashover fires. Unlike carboxyhemoglobin, which is routinely measured in the blood of fire victims, blood cyanide is often not measured. However, it has been detected at high concentrations in the blood of some fire victims, particularly when blood samples have been taken immediately after exposure.[14] In addition, low concentrations of oxygen (less than 15 percent)[45] and very high concentrations of carbon dioxide, CO_2, (greater than 5 percent) can have asphyxiant effects.[46]

Carbon Monoxide

Carbon monoxide combines with hemoglobin in the blood to form carboxyhemoglobin (COHb), which results in a toxic asphyxia because it reduces the amount of oxygen supplied to the tissues of the body, particularly brain tissue. Tissue oxygen supply is reduced because the amount of hemoglobin available for the carriage of oxygen (in the form of oxyhemoglobin) is reduced, and also because the ability of the remaining oxyhemoglobin to release oxygen to the tissues is impaired (due to a leftward shift of the oxygen dissociation curve).

The affinity of hemoglobin for CO is extremely high, so that the proportion of hemoglobin in the form of carboxyhemoglobin increases steadily as CO is inhaled. The toxicity of CO therefore depends upon the accumulated dose of carboxyhemoglobin, which is expressed in terms of the percentage of total hemoglobin in the form of carboxyhemoglobin, (% COHb).[19]

There is little doubt that CO is the most important asphyxiant agent formed in fires. In the Strathclyde pathology study[10] lethal levels (>50 percent COHb) were found in 54 percent of all fatalities, while some 69 percent of fatalities had carboxyhemoglobin levels capable of causing incapacitation (>30 percent COHb). Incapacitating levels of carboxyhemoglobin are also common in victims surviving immediate fire exposure. Carbon monoxide is therefore particularly important because

1. It is always present in fires, often at high concentrations.
2. It causes confusion and loss of consciousness, thereby impairing or preventing escape.
3. It is the major ultimate cause of death in fires.

To understand the effects of CO exposure on fire victims and to predict the likely consequences of a particular exposure, it is essential to know a number of features of CO intoxication. (To some extent these apply to an evaluation of the toxicity of any fire product.) It is necessary to

1. Determine which types of toxic effects occur at different dose levels.
2. Determine the concentration/time relationships of these toxic effects, whether they occur immediately or some time after exposure, and whether the effects of a short high concentration exposure are the same as those of a longer, low concentration, exposure.
3. Quantify the parameters that determine the rate of uptake and removal of CO from the body.

Some information on these points is available from accidental exposures and low-level experimental exposures in humans,[19] and data are available on the symptoms experienced in humans at various carboxyhemoglobin concentrations at rest.[19,45,47] Loss of consciousness is predicted at approximately 40 percent COHb, but can occur at lower levels (~30 percent COHb), and lower levels can be dangerous for subjects with compromised cardiac function.[19] Death is predicted at COHb concentrations of 50 to 70 percent COHb,[45,48,49] but it has been suggested that death can occur at lower concentrations in susceptible subjects.[19,50] The severe incapacitation caused by high-level exposures, such as those encountered in fires, has been studied experimentally in animals.[25,44] The effects of experimental exposures on cynomolgus monkeys are shown in Figure 2-6.13 in terms of physiological parameters (respiration, cardiovascular parameters, and brain electroencephalogram or EEG) monitored in sedentary animals sitting in chairs, and in Figure 2-6.5, where free-moving animals were trained to perform a behavioral task designed to simulate some aspects of the escape maneuvers of human fire victims (i.e., tasks involving bodily movements with a certain amount of exercise, requiring the use of coordinated movements and the application of psychomotor skills).

The first important characteristic of CO poisoning illustrated by these experiments is that CO uptake and intoxication are extremely insidious. During the early stages as the carboxyhemoglobin concentration builds up gradually in the blood the effects are minimal. Thus Figure 2-6.13 shows no detectible changes in physiological parameters until the end of the exposure when the COHb concentration approached 40 percent. In active animals the first minor signs of behavioral performance deficits did not occur until concentrations of 15 to 20 percent COHb were achieved. Similar results have been obtained in humans, where O'Donnel et al.[51] could find no effects upon psychomotor performance at levels of up to 12 per-

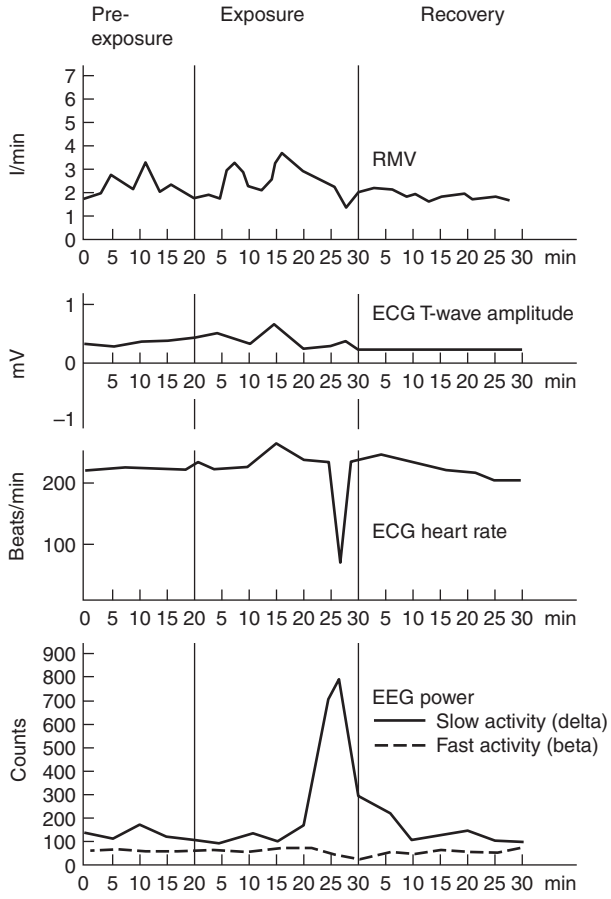

Figure 2-6.13. ***Physiological effects of an atmosphere containing CO (1850 ppm)—wood pyrolyzed at 900°C. From Purser and Woolley.[16]***

cent COHb, and Stewart et al.[47] reported the first symptoms (consisting of a headache) to occur at 15 to 20 percent COHb, while objective tests at these levels showed only minor deficits in behavioral performance.

Another major characteristic of asphyxia shown clearly by the animal experiments is that when significant effects do occur, their onset is sudden and the degree of incapacitation rapidly becomes severe, so that by the time a victim is aware that he or she is affected effective action is probably not possible. Thus Figure 2-6.13 shows the physiology of a monkey passing from a normal state to unconsciousness within a few minutes after 25 minutes of exposure, with decreased respiration, a severe decrease in heart rate, and greatly increased slow-wave EEG activity (indicative of cerebral depression). For active animals there was a sudden rapid decline in behavioral task performance accompanied briefly by signs similar to severe alcohol intoxication, which led rapidly to a state of deep coma.

These findings may explain why deaths from CO derived from defective heating appliances are so common. Survivors of such situations often report that they, or other victims that died, experienced headaches or nausea, but had no idea of the cause, so they did not attempt to leave the area until overcome by fumes.[52]

During the early stages of incapacitation the main effects appear to be on motivation and psychomotor ability, with a tendency for the victim to sleep if left undisturbed.[44] Under these conditions one might expect a subject, if alerted by a sudden noise such as of breaking glass (often reported by fire survivors), to "sober up" and awake sufficiently to make an escape attempt. However, such a victim is likely to fail for three reasons.

1. This stage is rapidly followed by unconsciousness and coma.
2. Active subjects are seriously affected by carboxyhemoglobin concentrations that have only minor effects on sedentary subjects. Thus, while sedentary primates were often unaffected at carboxyhemoglobin levels of up to 40 percent, those engaged in light activity were seriously affected at carboxyhemoglobin levels in the 25 to 35 percent range.[44] Similarly, in one study of humans, although a sedentary subject could perform such tasks as writing, even at the exceptionally high level of 55 percent carboxyhemoglobin, the subject collapsed and became unconscious immediately when attempting to rise and walk.[53] Therefore, a victim in a bed or chair attempting to escape not only would be in danger of a rapid collapse due to continued CO uptake, but even if no further uptake occurred the ability to perform even light work or exercise would be severely impaired. Even the simple act of rising from a horizontal to an upright position could precipitate loss of consciousness.
3. The rate of uptake of CO depends on the respiration (respiratory minute volume) and hence the activity of the subject. When the subject becomes active the blood carboxyhemoglobin is therefore likely to increase rapidly to an incapacitating level.

A Model for the Prediction of Time to Incapacitation by CO in Fires

Incapacitation by CO depends upon a dose accumulated over a period of time until a carboxyhemoglobin concentration is reached where compensatory mechanisms fail and collapse occurs. To predict time to incapacitation of fire victims due to CO it is necessary to know the carboxyhemoglobin concentrations at which incapacitation is likely to occur, and the rate of uptake of CO so that the time to achieve this concentration can be calculated. The carboxyhemoglobin concentrations likely to cause incapacitation depend upon the activity of the victim and should be similar to the concentrations causing incapacitation in primates at similar levels of activity.[44]

Since CO is both inhaled and excreted via the lungs, the rate of uptake depends upon the difference between the CO concentration in the blood, W, and that in the inhaled air, C, and is an exponential function described by the general equation (Equation 3):

$$W = C(1 - e^{-tk}) \tag{3}$$

where t is the time exposed and k is a constant determined by a number of factors, so that uptake is rapid initially, but gradually levels off as uptake and removal from the blood reach equilibrium. This relationship is described fully by the Coburn-Forster-Kane (CFK) equation,[22,23] which takes into account a whole range of variables, including RMV, body size, exposure duration, and parameters related to lung and blood physiology (see Appendix 2-6A). When all these various factors are known, this equation enables accurate predictions of CO uptake to be made that agree well with experimental data.[23,54] The uptake pattern for CO is illustrated in Figure 2-6.4, which predicts time to achieve a potentially lethal blood CO concentration (50 percent COHb) for a 70 kg human at rest (RMV 8.5 L/min) at two CO concentrations, 2200 and 840 ppm.

When the inhaled concentration is high compared to that in the blood as during short duration, high concentration exposures such as those that occur in flaming fires, the departure from linear uptake is not great as shown in Figure 2-6.4, and the deviation from Haber's rule ($W = C \times t$) is small. However, over long periods at lower concentrations, as equilibrium is approached, uptake deviates considerably from linearity. For short exposures at high concentrations when the blood concentration is well below saturation level, an approximate prediction of COHb concentration can therefore be made assuming a linear relationship. Such an equation is derived from experimental human exposures by Stewart et al.[48]

$$\%\text{COHb} = (3.317 \times 10^{-5})(\text{ppm CO})^{1.036}(\text{RMV})(t) \qquad (6)$$

where

ppm CO = CO concentration (ppm)
RMV = volume of air breathed (L/min)
t = exposure time (min)

Thus, for the examples shown in Figure 2-6.4, which were calculated using the CFK equation, a concentration of 50 percent COHb is predicted following a 1-hr exposure to 2200 ppm CO, while the Stewart equation predicts 49 percent COHb. However, for a 4-hr exposure the CFK equation predicts 50 percent COHb from 840 ppm, while the Stewart equation would predict 50 percent COHb from 550 ppm over 4 hr, or a concentration of 72 percent COHb from 840 ppm.

Justification of the linear uptake relationship under high concentration/short exposure duration circumstances is illustrated by a series of primate exposures carried out over a 1000 to 8000 ppm concentration range. These experiments were performed using an active behavioral model,[44] with the endpoint being loss of consciousness, which occurred at approximately 34 percent COHb. The results are illustrated in Figure 2-6.5, which shows time to incapacitation for different inhaled CO concentrations. At each concentration the inhaled dose (Ct product) required to produce incapacitation in ppm CO·minutes is constant, as predicted by the linear uptake model of Haber's rule.

As stated, it is possible to make accurate predictions of CO uptake for a range of situations by using the CFK equation, provided that a number of variables are taken into account. For a particular individual the most important variable is the RMV, which varies considerably depending upon the level of activity of the subject. Figures for this and other variables can be obtained from standard reference data.[55] Figure 2-6.14, generated from these data, shows the probable time to incapacitation (loss of consciousness) for a 70 kg human exposed to different CO concentrations at three levels of activity. The figure shows that the degree of activity can have a major effect on time to incapacitation. It must also be remembered that RMV per kilogram of body weight is greater for small subjects, which means that children will take up CO much more rapidly than adults and succumb much earlier, while uptake in small laboratory animals is even more rapid. An assumption made in these calculations is that the level of activity and hence the RMV remain constant during the exposure. In practice there is a tendency for the level of activity and ventilation to decrease slightly as the point of incapacitation is approached. It is considered that with a model for predicting time to incapacitation (unconsciousness), errors due to reduced ventilation will be minor, since the primate experiments demonstrate that there is little change in RMV until the point of incapacitation. Once the subject becomes unconscious, the RMV and hence the rate of CO uptake will be considerably reduced, particularly if the subject was previously engaged in heavy work. It is therefore possible that for calculating time to death allowance could be made for a low RMV (~6 L/min) once incapacitation has occurred. Not making this allowance does err slightly on the side of safety.

The Stewart[48] and CFK[22] equations enable reasonably good predictions of time to incapacitation or death for short (less than one hour) or long (greater than one hour)

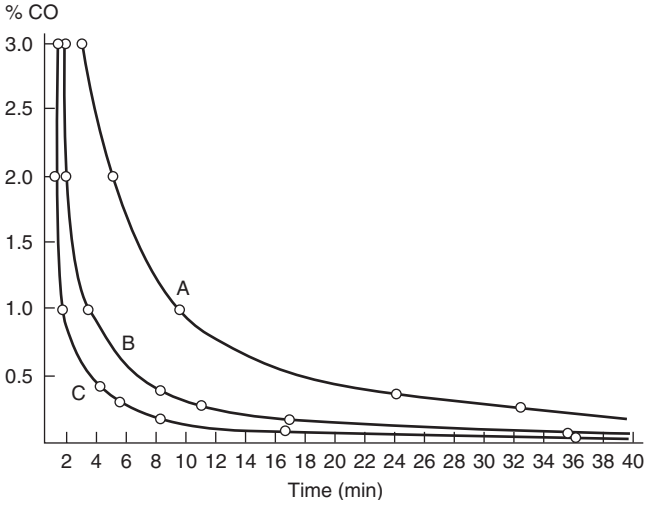

Figure 2-6.14. ***Time to incapacitation by carbon monoxide for a 70 kg human at different levels of activity. Curve A—40 percent carboxyhemoglobin RMV 8.5 L/min at rest sitting; Curve B—30 percent carboxyhemoglobin RMV 25 L/min, light work (e.g., walking 6.4 km/h); Curve C—20 percent carboxyhemoglobin RMV 50 L/min, heavy work (e.g., slow running 8.5 km/h) (or for walking 5.6 km/h up a 17 percent gradient).***

exposures, respectively, to constant concentrations of CO in air. In fires, however, victims are exposed to concentrations of CO which change during the course of the fire. For smoldering fires the CO concentration may grow slowly and remain fairly constant over long periods, but for early flaming fires and many fully developed fires where the victim is in a remote location, the CO concentration may increase rapidly over a short period of time as in Figure 2-6.15. It is therefore necessary to be able to apply the uptake models to situations where the CO concentration is not constant. For most situations, fluctuations in CO concentration do not present a problem since incapacitation depends upon the total dose of CO inhaled, in the form of COHb, and is not affected by the immediate CO concentration. The COHb concentration is thus dependent upon the average CO concentration over the period of exposure, and significant errors will not occur even if the CO concentration falls somewhat at certain stages of the exposure. Errors in predicting the COHb concentration are possible if the CO concentration drops dramatically toward the end of an exposure, or if it decreases moderately during a prolonged exposure of several hours duration, when COHb concentrations can approach equilibrium with the inhaled CO concentration. In this case a fall in CO may result in a decrease in COHb concentration. The basic rule to apply is that fluctuations are unlikely to cause the COHb concentration to deviate from that predicted by assuming the constant average concentration throughout, providing the CO concentration is on a rising trend, is stable, or is well above the equilibrium concentration with the blood COHb.

Ct Product and Fractional Incapacitating Dose

Although the average CO concentration during a fire exposure can be used to predict COHb concentration and time to incapacitation, another useful concept for predicting incapacitation or death is the relationship with concentration-time (*Ct*) product, which is a representation of CO "dose." In changing fire conditions the *Ct* product may be obtained by integrating the CO concentration/time curve. The dose inhaled may then be related to the dose required to cause incapacitation, and the fraction of an incapacitating dose at any time, *t*, may be calculated, incapacitation occurring when the fractional dose reaches 1.0. Since the *Ct* "dose" actually represents the COHb concentration, the fractional dose would be better represented by the ratio of the COHb concentration at time, *t*, with the COHb concentration known to cause incapacitation or death, rather than by simple *Ct* product ratios. The Stewart equation[48] can be rewritten in the form of COHb ratios, requiring only a knowledge of the CO concentration and the exposure time, as follows:

$$F_{I_{co}} = \frac{K(\text{ppm CO}^{1.036})(t)}{D} \tag{7}$$

where

$F_{I_{co}}$ = fraction of incapacitating dose
t = exposure time (min)
K = 8.2925×10^{-4} for 25 L/min RMV (light activity)
D = COHb concentration at incapacitation (30 percent for light activity)

This concept of *Ct* product fractional dose is also useful for predicting incapacitation and death from other fire products, and combinations of products, as will be discussed later in this chapter.

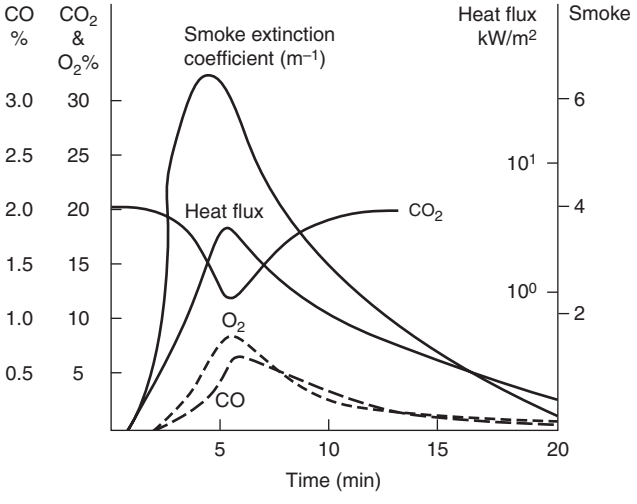

Figure 2-6.15. ***Smoke, heat, and gases during single armchair room burn. Armchair is polystyrene with polyurethane cushions and covers. Room is 39 m³ with open doorway. Gases measured in doorway at 2.1 m height.[56]***

Hydrogen Cyanide

Hydrogen cyanide (HCN) has been measured in the blood of both fatal[57] and nonfatal[58] fire victims. However, in the Strathclyde fire fatality study high concentrations of hydrogen cyanide in the blood of victims were usually associated with lethal levels of carboxyhemoglobin, so that the role of hydrogen cyanide as a cause of incapacitation was difficult to determine.[57] It is also difficult to relate blood cyanide levels from samples collected after a fire to likely HCN exposure, since the dynamics of HCN uptake and removal from the blood are poorly understood.[59,60]

Although the ultimate effects of HCN exposure (consisting of unconsciousness with cerebral depression) are similar to those produced by CO, the pattern of toxicity during the early stages is very different. While the onset of CO intoxication is slow and insidious, HCN intoxication tends to be rapid and dramatic. The physiological signs of incapacitation produced in monkeys by an atmosphere containing HCN are shown in Figure 2-6.16.[59] As with CO the immediate effects were relatively minor, consisting of a slightly raised ventilation, but at some time during a 30-minute exposure period there was a marked increase in respiration (hyperventilation), the RMV increasing up to four times. Within one to five minutes of the start of this episode of hyperventilation the animals lost consciousness. This was accompanied by EEG signs of severe cerebral depression; loss of muscle tone; and marked effects upon the heart and circulation, including a significant

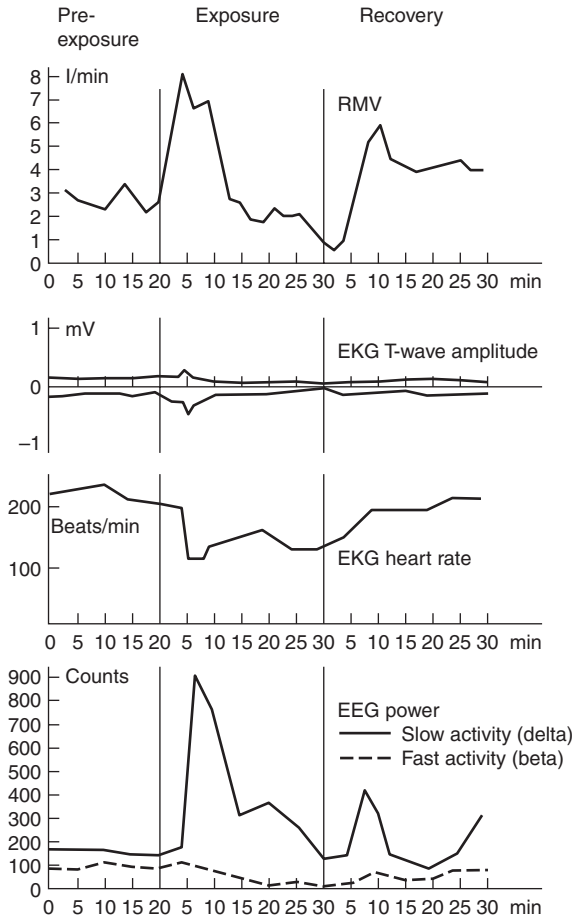

Figure 2-6.16. ***Physiological effects of an atmosphere of HCN gas (147 ppm) on monkeys.[59]***

decrease in heart rate, arrhythmias and changes in the EKG waveform indicative of cardiac hypoxia. This hyperventilatory episode was caused by the stimulatory effects of cyanide upon respiration. Since the cyanide was taken in via inhalation, a positive feedback situation resulted, and inhaled cyanide caused hyperventilation which increased the rate of HCN uptake and in turn provided a stronger hyperventilatory stimulus. Once the animals became unconscious the hyperventilation subsided and they went into a slow decline for the remainder of the exposure. This led eventually to a cessation of breathing in some cases, which would have proved fatal if exposure had not been terminated. It was therefore possible for an animal to survive a continuous HCN exposure for some time after the point of incapacitation. Once exposure was terminated the recovery was rapid and almost complete within five to ten minutes.

The pattern of incapacitation for HCN is somewhat different from that produced by CO in that the effects occur more rapidly, as unlike CO, HCN is not held almost exclusively in the blood, but is carried rapidly to the brain.[61] Although the accumulation of a dose is one factor, the most important determinant of incapacitation with HCN appears to be the rate of uptake, which in turn depends upon the HCN concentration in the smoke and the subjects' respiration. Thus in the animal experiments,[25,59] it was found that at HCN concentrations below approximately 80 ppm the effects were minor over periods of up to one hour, with mild background hyperventilation. At concentrations above 80 ppm up to approximately 180 ppm, an episode of hyperventilation with subsequent unconsciousness occurred at some time during a 30-minute period; there was a loose linear relationship between HCN concentration and time to incapacitation. Above 180 ppm the hyperventilatory episode began immediately with unconsciousness occurring within a few minutes. Data on human exposures to HCN are limited but Kimmerle[45] does quote some approximate data showing a similar effect in humans, with incapacitation occurring after 20 to 30 minutes at 100 ppm HCN and after 2 minutes at 200 ppm, death occurring rapidly at concentrations exceeding approximately 300 ppm.

Other data suggest that human victims might be able to survive higher concentrations of HCN for shorter periods. McNamara[62] suggests 539 ppm as the 10-minute LC_{50} for humans, and there is a report of a survival from an accidental exposure to 444 ppm.[63] An experimental human exposure to 530 ppm HCN was survived without immediate symptoms for 1.5 minutes, although a dog exposed at the same time suffered respiratory arrest.[64] Dogs are known to be particularly susceptible to cyanide poisoning,[62] but it does seem likely that, to some extent, with HCN (as with CO) body size influences time to incapacitation, and that a human would be able to tolerate exposure to a given concentration longer than a cynomolgus monkey. With HCN and CO, physical activity would be likely to cause more rapid uptake in adults, and uptake would be more rapid in children because of their smaller body size. The primate data therefore seem to provide a reasonable model for humans, possibly erring slightly on the side of safety.

The differences between CO and HCN in terms of the relationship between inhaled concentration and time to incapacitation are illustrated in Figure 2-6.6. While CO gives a smooth curve with incapacitation occurring at a constant *Ct* product of approximately 27,000 ppm·min for all CO concentrations, the almost linear portion of the HCN curve results in a *Ct* product of approximately 2000 ppm·min at 100 ppm HCN and 400 ppm·min at 200 ppm, with very rapid incapacitation at higher HCN concentrations. This deviation from Haber's rule (which predicts a constant *Ct* product) was recognized by Haber himself in 1924, when he stated that the *Ct* product for HCN depended upon the exposure concentration.[20] The exact reason for this is not known, but appears to be related to relationship between the rate of uptake of HCN and the dynamics of its distribution between different body fluid compartments.[60] The effect is to render concentrations in the range greater than 150 ppm more toxic than would be predicted from the effects of longer exposures to lower concentrations.

A Model for the Prediction of Time to Incapacitation by HCN in Fires

From these results it is possible to predict that HCN concentrations below a threshold concentration of ap-

proximately 80 ppm will have only minor effects over periods of up to 1 hour.

From 80 to 180 ppm the time to incapacitation (unconsciousness) t_{Icn} will be between 2 and 30 minutes approximately, according to the relationship

$$t_{I_{CN}}(\text{min}) = \frac{(185 - \text{ppm HCN})}{4.4} \quad (8)$$

For concentrations above approximately 180 ppm incapacitation will occur very rapidly (within two minutes). This linear expression gives a reasonably good fit with the primate data over the range 80–180 ppm, but it would be preferable to derive a more general expression to include the effects of higher and lower concentrations for making fractional dose estimations. An exponential expression has therefore been derived which also gives a reasonably good fit with the data (regression coefficient 0.984) as follows:

$$t_{I_{CN}}(\text{min}) = \exp(5.396 - 0.023 \times \text{ppm HCN}) \quad (9)$$

HCN could be particularly dangerous in fires due to its rapid "knockdown" effect, and low HCN levels in the 100 to 200 ppm range could cause fire victims to lose consciousness rapidly and consequently to die later as a result of accumulation of CO or some other factor. A small change in HCN concentration could also cause a large decrease in time to incapacitation; for example, doubling the concentration from 100 to 200 ppm could bring the incapacitation time down from approximately 20 min to approximately 2 min.[45,59]

Although this relationship should enable reasonable predictions to be made of time to unconsciousness for subjects exposed continuously to HCN, especially over the critical range between 180 ppm (above which incapacitation will be rapid) and 80 ppm (below which incapacitation is unlikely over periods of up to 1 hour), real fires will involve exposures to changing concentrations. One method of predicting time to incapacitation or death would be to take the average concentration over the period of exposure. Although approximate times to incapacitation can be estimated with this method it is prone to error because of the departure from Haber's rule. In practice, since short exposures to high concentrations are more likely to cause incapacitation than longer exposures to lower concentrations, and averaging the concentration tends to give longer estimates of time to incapacitation than would be expected. This method also does not include the concept of fractional dose. A better model would include some degree of weighting to allow for the enhanced effect of high concentration exposure, and also enable incapacitation to be estimated in terms of *Ct* product fractional dose.

A method for estimating fractional dose to incapacitation has been developed for the rat by Hartzell et al.,[27] based on this concept. In that model the *Ct* product over short periods of time is expressed as a fraction of the *Ct* product required to cause incapacitation or death at that concentration. The fractions for each short time interval are summed until the fraction reaches unity, which indicates incapacitation.[27] This approach should enable reasonable predictions of time and dose to incapacitation and death to be made, provided that the HCN concentration is stable or increasing (Hartzell et al. have found a good correspondence between calculated predictions and experimental data in rats). This approach can be used to derive a fractional dose model for humans based upon the time to incapacitation equation (Equation 9), derived from primate and human data, as follows:

For a constant HCN concentration

$$t_{I_{CN}} = \exp(5.396 - 0.023 \times \text{ppm HCN})$$

Dose to incapacitation = (ppm HCN)($t_{I_{CN}}$)
Therefore, for a short exposure time, t, to a given HCN concentration

$$F_{I_{CN}} = \frac{(\text{ppm HCN})(t)}{(\text{ppm HCN})(t_{I_{CN}})}$$

where $F'_{I_{CN}}$ = fraction of an incapacitating dose.
Taking t = 1 minute, this simplifies to

$$F_{I_{CN}} = \frac{1}{t_{I_{CN}}} \quad (10)$$

If the fractional doses per minute, $F'_{I_{CN}}$ are summed throughout the exposure, the dose and time to incapacitation can be predicted.

EXAMPLE:
A subject is exposed to 90 ppm HCN for 15 minutes, then to 180 ppm HCN for 2 minutes.

$$t_{I_{CN}} \text{ for 90 ppm} = \exp(5.396 - 0.023 \times 90) = 27.83$$
$$t_{I_{CN}} \text{ for 180 ppm} = 3.51 \text{ min}$$
$$F_{I_{CN}} = (1/27.83) \times 15 + (1/3.51) \times 2$$
$$= 1.111$$

Incapacitation is therefore predicted at between 17 and 18 minutes.

The $F_{I_{CN}}$ equation has since been simplified to

$$F_{I_{CN}} = \frac{\exp([\text{CN}]/43)}{220} \quad (11)$$

where [CN] represents the concentration of cyanide (ppm) corrected for the presence of other nitriles besides HCN and for the protective effect of NO_2. [CN] can be calculated as

$$[\text{CN}] = [\text{HCN}] + [\text{total organic nitriles}] - [\text{NO}_2]$$

Cyanide in Blood

The importance of HCN as a cause of incapacitation and death in fires can be underestimated, due to poor understanding of the dynamics of cyanide uptake, dispersal and metabolism in the body, and the inadequate database of blood cyanide measurements from both injured and dead fire victims. Carboxyhemoglobin is the only blood toxin routinely measured in fire victims, and when blood

cyanide is measured (usually post mortem), the sample and measurement are often taken a day or more after exposure.

Evidence from the primate experiments reported above, and from further experiments where measurements were made of arterial blood cyanide during and after exposure,[60] shows that when HCN is inhaled for short periods at air concentrations above approximately 150 to 200 ppm, loss of consciousness results from a transient high plasma cyanide concentration. HCN uptake rate is then greatly reduced when the subject loses consciousness (or dies) and the cyanide in the plasma disperses throughout the body fluids, leaving a low immediate post-exposure plasma concentration. Also, cyanide decomposes rapidly in cadavers,[65] by approximately 50 percent in 1 to 2 days, and may subsequently decrease further, or even increase slightly in stored blood. For these reasons, blood cyanide concentrations measured in fire victims are often relatively low, but when blood samples are obtained immediately after exposure,[66] higher, toxicologically significant or life-threatening levels are detected. It is suggested that, in freshly obtained whole blood samples, levels of 2.0 to 2.5 μg CN/ml should be considered capable of causing incapacitation and 3.0 μg CN/ml should be considered lethal, while for samples not taken and analyzed immediately after exposure, these concentrations/effect ranges should be at least halved, depending upon the time of storage.

Hypoxia

Apart from the tissue hypoxia caused by CO and HCN, hypoxia in fires can also be caused by exposure to low oxygen concentrations. To some extent, a lowered oxygen concentration in the inspired air or a lowered oxygen concentration in the lungs (during exercise for example) is a normal physiological occurrence, and there are compensatory mechanisms that tend to maximize the supply of oxygen to the brain. When a subject is placed in a hypoxic situation, there is a reflex increase in cerebral blood flow and also, up to a point, the unloading of oxygen from the blood is more efficient at lower arterial and venous blood oxygen concentrations.[67] These factors compensate to a large degree for any decrease in the oxygen concentration of the inspired air. When cynomolgus monkeys were exposed to atmospheres containing 15 percent oxygen no deleterious effects occurred beyond a slight increase in heart rate.[25]

However, a time is reached where these compensatory mechanisms fail; a 10 percent oxygen atmosphere produced a marked cerebral depression in monkeys.[25] In humans hypoxia due to lack of oxygen (hypoxic hypoxia) has been studied extensively, particularly hypoxia that occurs at high altitudes.[26,67] As in monkeys there is little effect down to 15 percent O_2, beyond a slightly reduced exercise tolerance, but at approximately 10 percent O_2 effects suddenly become severe. It is possible, however, to identify a number of degrees of physiological and behavioral decrement, and for low-oxygen hypoxia certain signs can be related to particular exposure concentrations. From experiments in humans the effects have been classified into four phases as follows,[26,45] the appropriate altitude ranges and equivalent sea-level oxygen concentrations being given for each phase:

1. Indifferent phase (sea level–3,000 m or 20.9–14.4 percent O_2): Minor effects on visual dark adaptation and beginnings of effects on exercise tolerance toward 15 percent O_2
2. Compensated phase (3,000–4,500 m or 11.8–14.4 percent O_2): Slightly increased ventilation and heart rate, slight loss of efficiency in performance of complex psychomotor tasks and short term memory, some effects on judgment. Maximal exercise work capacity is reduced
3. Manifest hypoxia (4,500–6000 m or 9.6–11.8 percent O_2): Degradation of higher mental processes and neuromuscular control, loss of critical judgment and volition, with dulling of the senses. Emotional behavior may vary from lethargy and indifference to excitation with euphoria and hallucinations. Marked increase in cardiovascular and respiratory activity. This is the region likely to be particularly dangerous during fire exposures, representing the catastrophe point as a victim passes from this stage into the fourth stage at approximately 10 percent O_2 (or COHb or blood cyanide concentrations producing an equivalent degree of brain hypoxia)
4. Critical hypoxia (6000–7,600 m or 7.8–9.6 percent O_2): Rapid deterioration of judgment and comprehension leading to unconsciousness followed by cessation of respiration and finally of circulation at death

If a subject is suddenly placed into a low-oxygen environment, a finite time elapses before the blood gas concentration equilibriates with the new conditions, and a certain degree of physiological effect then occurs, depending upon the equilibrium blood concentration attained. The time-to-effect functions described in the next section have been based on the concept of a certain "dose" of hypoxia being taken up over a period of time to reach equilibrium at the chosen endpoint of severe incapacitation (the catastrophe point). The concept of the catastrophe point relates to observations, mainly during exposures of primates to the asphyxiant gases CO, HCN and low-oxygen hypoxia,[25,44] that due to physiological compensatory mechanisms there is very little decrement in physiological status or behavioral task performance as the severity of an exposure increases, until a certain point is reached when tissue hypoxia becomes critical and deterioration becomes very marked and very rapid, usually leading to unconsciousness. This endpoint therefore marks the sudden change in a potential fire victim from a condition of near normality to a condition in which escape would not be possible.

A Model for the Prediction of Time to Incapacitation by Hypoxia in Fires

Incapacitation due to oxygen lack, consisting of loss of consciousness, occurs when the oxygen supply to cerebral tissue falls below a certain critical value, which in turn occurs when the partial pressure of oxygen in the cerebral venous blood falls below 20 mmHg.[26] Due to the effects of the compensatory mechanisms, to residual oxygen in the lungs, and to oxygen stores available from the

blood, a certain period of time elapses before the oxygen tension of venous blood declines to this critical level when a subject is suddenly faced with a reduced oxygen atmosphere after breathing normal air.[26] The time taken for this depletion depends upon the level to which the oxygen concentration falls, but also on the activity of the subject (which affects oxygen demand) and the RMV. It is therefore possible to plot time to loss of consciousness against oxygen concentration. Studies of this kind have been performed on human subjects, principally for hypoxia caused by exposure to reduced atmospheric pressures simulating the effects of high altitudes, which has similar effects to those of exposure to reduced oxygen concentrations at sea level. Figure 2-6.17 shows such a plot of time of useful consciousness for humans at rest following sudden decompression (less than one second transition time) to a range of simulated altitudes. The data are adapted from Luft,[26] and are expressed in terms of altitude. The equivalent sea-level oxygen concentrations have been added to the figure, and also the percentage oxygen vitiation (i.e., the equivalent decrease in percentage oxygen concentration at sea level below the normal concentration of 20.9 percent oxygen).

From this curve it is possible to derive an equation that should give a reasonable prediction of time to loss of consciousness (t_{I_O}) for a victim exposed to a hypoxic fire environment, as follows

$$(t_{I_O})\ \text{min} = \exp\,[8.13 - 0.54(20.9 - \%O_2)] \qquad (12)$$

where $(20.9 - \%\ O_2) = \%\ O_2\text{Vit}$ (percent oxygen vitiation)

As with exposure to HCN, time to incapacitation for exposure to low oxygen concentrations does not follow Haber's rule, since short exposures to severe hypoxia cause incapacitation very rapidly, and long exposures to modest hypoxia have little effect (e.g., at 17 percent O_2Vit, $Ct = 17 \times 0.33 = 5.61$ percent·min, while at 11.3 percent O_2Vit, $Ct = 11.3 \times 7.73 = 87.3$ percent·min). In attempting

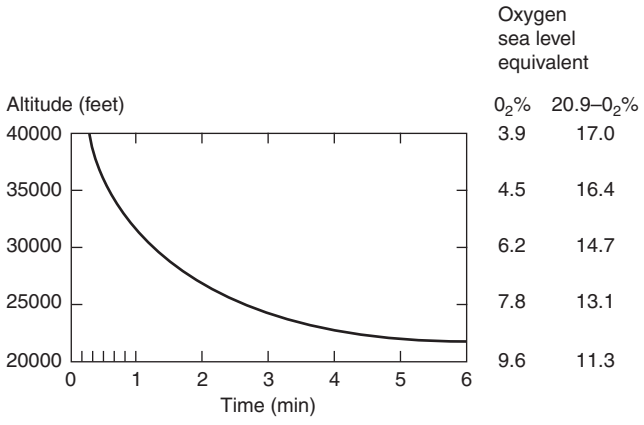

Figure 2-6.17. ***Time of useful consciousness on sudden exposure to high altitudes (less than 1 s transition time). Scales also show equivalent sea-level percent oxygen concentration and percent oxygen vitiation (decrease below 20.9 percent O_2).[26]***

to predict time or dose to incapacitation or death for a subject exposed to changing oxygen concentrations, it is therefore necessary to apply a weighting factor to allow for these deviations from ideal behavior. As with HCN this may be achieved by using the fractional effective dose concept as follows:

For a constant level of hypoxia, the time to incapacitation due to oxygen depletion is given by

$$t_{I_O} = \exp[8.13 - 0.54(20.9 - \%\ O_2)]$$

Dose to incapacitation $= (20.9 - \%\ O_2)(t_{I_O})$
Therefore, for a short exposure time, t, to a given level of oxygen vitiation

$$F_{I_O} = \frac{(20.9 - \%O_2)(t)}{(20.9 - \%O_2)(t_{I_O})}$$

Where F_{I_O} = fraction of an incapacitating dose of hypoxia, and where $t = 1$ min this simplifies to

$$F'_{I_O} = 1/t_{I_O} \qquad (13)$$

If the fractional doses per each minute are summed throughout the exposure, the dose and time to incapacitation can be predicted.

EXAMPLE:

A subject is exposed to a concentration of 10 percent oxygen for 5 min followed by 7.8 percent oxygen for 1.5 min. For 10 percent O_2 (10.9% O_2Vit)

$$t_{I_O} = \exp\,[8.13 - 0.54(20.9 - 10)]$$
$$1/t_{I_O} = 0.106$$

For 7.8% O_2 (13.1% O_2Vit)

$$t_{I_O} = 2.8748$$
$$1/t_{I_O} = 0.3478$$
$$F_{I_O} = 0.106 \times 5 + 0.3478 \times 1.5$$
$$= 1.05$$

Therefore loss of consciousness is predicted at 6.5 minutes.

A Model for the Prediction of Hyperventilation and Time to Incapacitation by Carbon Dioxide

Carbon dioxide (CO_2), like carbon monoxide, is universally present in fires. Although carbon dioxide is not toxic at concentrations of up to 5 percent it stimulates breathing, so that at 3 percent the RMV is approximately doubled, and at 5 percent tripled.[25] This hyperventilation, apart from being stressful, can increase the rate at which other toxic fire products (such as CO) are taken up.

For asphyxiant gases such as CO or HCN it is likely that the increased uptake resulting from carbon dioxide induced hyperventilation will significantly reduce time to incapacitation and death. The ventilatory response to carbon dioxide varies among individuals and reported data also vary. An average curve has been constructed from

data given in three sources[68–70] and is presented in Figure 2-6.18, giving the following regression equation

$$\text{RMV(L/min)} = \exp(0.2496 \times \%CO_2 + 1.9086) \quad (14)$$

From this expression a multiplication factor (VCO_2) can be calculated for the enhanced uptake of other asphyxiant gases as follows

$$VCO_2 = \frac{\exp(0.2496 \times \%CO_2 + 1.9086)}{6.8} \quad (15)$$

Where 6.8 L/min is a suggested figure for the resting RMV at the background CO_2 concentration. This has been simplified to

$$VCO_2 = \exp\left(\frac{[CO_2]}{4}\right) \quad (16)$$

Upon further examination of this relationship it is considered that, although it provides a reasonable estimate of the change in VCO_2, it gives an exaggerated value for the increase in uptake rate for other gases. This is primarily because the efficiency of uptake decreases as ventilation increases. A modified expression has therefore been derived, based upon that used in the CFK equation,[22] which gives a somewhat lower prediction for the increase in uptake rate of other gases. A slightly higher figure has also been used for the resting RMV. The modified equation is as follows:

$$VCO_2 = \frac{\exp(0.1903 \times \%CO_2 + 2.0004)}{7.1} \quad (17)$$

This has been simplified to

$$VCO_2 = \exp\left(\frac{[CO_2]}{5}\right) \quad (18)$$

At concentrations of approximately 5 percent and above carbon dioxide is itself an asphyxiant, but for elevated CO_2 concentrations (hypercapnia) the change in degree of incapacitation with exposure concentration is more gradual than with hypoxia. From approximately 3 percent up to 6 percent there is a gradually increasing degree of respiratory distress. This becomes severe at approximately 5 to 6 percent, with clinical comments from subjects such as "breathing fails to satisfy intense longing for air" or "much discomfort, severe symptoms impending," with headache and vomiting also occurring.[71] Although due to the gradual equilibration process these signs tend to worsen during exposure, it seems unlikely that they would proceed as far as loss of consciousness over the course of a 30- or even a 60-min exposure period. However, once the concentration of carbon dioxide is in the 7 to 10 percent plus range, a new set of signs consisting of dizziness, drowsiness, and unconsciousness is superimposed on the severe respiratory effects. A time factor does enter here due to gradual uptake, with loss of consciousness being more certain, and occurring earlier (over a period of a few minutes) as the exposure concentration approaches and exceeds 10 percent.[45,46,71,72] Approximate tolerance times for the distressing effects on breathing and the onset of asphyxia for humans are shown in Figure 2-6.18. The effects are perceptible to subjects from 3 percent as increasingly rapid breathing, and at approximately 6 percent become intolerable within 20 minutes. Symptoms of dizziness, headache, and fatigue start to occur at concentrations above 7 percent, with danger of unconsciousness occurring within a few minutes increasing from 7 to 10 percent. Loss of consciousness is likely within 2 minutes at 10 percent CO_2 in humans.[71]

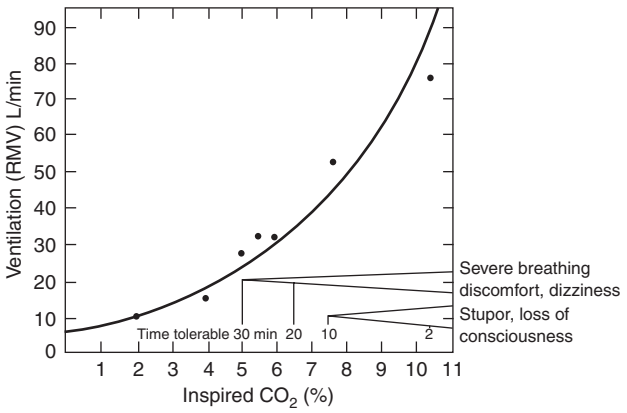

Figure 2-6.18. ***Ventilating response to carbon dioxide.[68–71]***

As with HCN and low-oxygen hypoxia, intoxication by carbon dioxide does not follow Haber's rule (Ct for 10 percent CO_2 = 20 percent·min, Ct for 5 percent CO_2 = 175 percent·min). From the approximate data in Figure 2-6.18 an expression predicting approximate time to incapacitation $t_{I_{CO_2}}$ has been derived as follows:

$$t_{I_{CO_2}} = \exp(6.1623 - 0.5189 \times \%CO_2) \quad (19)$$

Using the fractional-dose concept previously described for HCN and hypoxia, it is possible to predict approximate dose to incapacitation, provided that the CO_2 concentration is stable or increasing, as follows:

For a constant CO_2 concentration

$$t_{I_{CO_2}} = \exp(6.1623 - 0.5189 \times \%CO_2)$$

Dose to incapacitation = $(\%CO_2)(t_{I_{CO_2}})$

Therefore, for a short exposure time, t, to a given CO_2 concentration

$$F_{I_{CO_2}} = \frac{(\%CO_2)(t)}{(\%CO_2)(t_{I_{CO_2}})}$$

Where $F_{I_{CO_2}}$ = fraction of an incapacitating dose, and where t = 1 min. This simplifies to

$$F_{I_{CO_2}} = \frac{1}{t_{I_{CO_2}}} \quad (20)$$

If the fractional doses per minute are summed throughout the exposure, the dose and time to incapacitation can be predicted.

EXAMPLE:

A subject is exposed to a concentration of 5 percent CO_2 for 20 minutes, followed by 9 percent CO_2 for 2 min.

For 5% CO_2, $t_{l_{CO_2}} = 35.44$; $1/t_{l_{CO_2}} = 0.0282$

For 9% CO_2, $t_{l_{CO_2}} = 4.45$; $1/t_{l_{CO_2}} = 0.2247$

$$F_{l_{CO_2}} = 0.0282 \times 20 + 0.2247 \times 2 = 1.01$$

Severe incapacitation with probable loss of consciousness is therefore predicted at approximately 22 minutes.

Interactions between Toxic Fire Gases

Although data on the concentration/time/dose relationships of the dangerous and lethal asphyxiant effects in humans of individual fire gases are necessarily limited, they are adequate for the construction of a usable incapacitation model. However, the effect of interactions between combinations of these gases on time to incapacitation in fires is an area that requires further investigation, as very little information is currently available. The best that can be done currently is to suggest likely degrees of interaction based on physiological data from individual gases and on such experimental data for gas combinations as do exist.

Effect of Carbon Dioxide on Effects of CO, HCN, and Low-Oxygen Hypoxia

The interaction likely to be most important is that hyperventilation due to carbon dioxide exposure will increase the rate of uptake of other toxic gases and thus decrease the time to incapacitation (or the time taken to inhale a lethal dose), in proportion to the increase in ventilation. This is likely to be most important with respect to CO intoxication, particularly for a subject at rest, and also to some extent for active subjects. An expression for calculating the increase in RMV resulting from exposure to different carbon dioxide concentrations is given in the section on CO_2, but as an approximation it should be assumed that there would be little effect below 3 percent CO_2, while at 3 percent CO_2, RMV would be doubled, so time to incapacitation by CO should be halved. At 5 percent CO_2, RMV would be approximately tripled and time to incapacitation would be approximately one-third of that in the absence of carbon dioxide. There is a possibility that the effects on time to incapacitation would not be as dramatic as this, since there is evidence that the presence of carbon dioxide may counteract the leftward shift in the oxygen dissociation curve caused by carbon monoxide, somewhat counteracting its deleterious effects.[73] However, in the absence of experimental data on combination exposures it is best to ignore this possible beneficial effect, since the effect on uptake rate is likely to be dominant. A similar effect on uptake may also occur with HCN. With regard to low oxygen, carbon dioxide has been shown to have a marked beneficial effect on resistance to incapacitation. This is partly due to the hyperventilatory effect that increases the rate of oxygen uptake, and partly due to the rightward shift in the oxygen dissociation curve caused by carbon dioxide. This improves the delivery of oxygen to the tissues, counteracting the respiratory alkalosis that otherwise occurs.[74,75] New evidence is currently being obtained from experiments on the effects of combinations of asphyxiant gases with CO_2 in rodents, that with severe exposures, postexposure lethality is increased by the presence of CO_2. When animals are severely affected and suffering from a hypoxia-induced metabolic acidosis, this appears to be enhanced by the further acidotic effect of CO_2 inhalation, and the animals then fail to recover after exposure under conditions when they would otherwise be expected to do so. It is also to be expected that hyperventilation induced by CO_2 would increase the uptake of substances that irritate the lung, which also tend to cause toxic effects some time after exposure, and recent experiments in rodents are providing evidence that this is so, with increased deaths possibly caused by postexposure acidosis and increased lung damage. Exercise also causes a CO_2-driven hyperventilation, and there is new evidence that this may also cause deaths when rodents are exposed to irritants at normally sub-lethal concentrations.[76]

Interactions between CO and HCN

Some studies have been made of interactions between CO and HCN, with varying results.[77] On theoretical grounds little interaction is to be expected, since CO diminishes the carriage of oxygen in the blood and its delivery to the tissues, while HCN diminishes the ability to use oxygen once delivered to the tissues. It is therefore to be expected that either one or the other gas would constitute the rate-limiting step in oxygen supply and utilization. However the consensus view is that there is at least some additive effect between these two gases. Experiments in primates have shown that time to incapacitation by HCN is slightly reduced by the presence of near-toxic concentrations of CO;[77] also, the rate of uptake of CO may be increased by the hyperventilatory effect of HCN. In these circumstances it is probably safest to assume that these gases are additive in terms of time to incapacitation and dose to death, and that incapacitation or death will occur when the fraction of the toxic dose of each one adds up to unity.

Interactions between CO and Low-Oxygen Hypoxia

The most likely interaction between CO and low-oxygen hypoxia would be some degree of addition, since both reduce the percentage oxygen saturation of arterial blood, and CO also impairs the delivery of oxygen to the tissue by causing a leftward shift of the oxygen dissociation curve.[73] It is possible that during the early stages of CO exposure in hypoxic subjects the CO occupies the upper, oxygen-free part of the oxygen dissociation curve, and therefore has little effect. Von Leggenhager[53] reports that subjects at rest at altitude remain symptom free at low levels of CO saturation. However, it is likely that the effect of more severe exposure to CO in a hypoxic subject would be additive to some extent, as reported by Heim[78] and McFarland et al.[79]

An important point is the possible interaction between irritant smoke products and asphyxiant gases. This effect is particularly strong when rats and mice are exposed to smoke, since the rodent response to irritation of the upper respiratory tract is a marked decrease in respiratory rate and RMV. Thus if CO is present in the smoke, the rate of uptake will be considerably reduced if the smoke is irritant. This sometimes leads to misleading results in combustion product toxicity tests, where a material producing irritant smoke will have an apparently low LC_{50}, although high CO concentrations are present in the atmosphere.

This marked, prolonged decrease in respiratory rate does not occur in humans or nonhuman primates; indeed, in primate smoke experiments, irritant products tend to increase rather than decrease ventilation (although not sufficiently to increase CO toxicity).[16,25]

In summary, data on interactions between the asphyxiant gases CO, HCN, low oxygen, and CO_2 are limited, but where deleterious interactions are likely it would be prudent to include them in the incapacitation model, if only to err on the side of safety. For this reason it is proposed that the interactions should be quantified in the incapacitation model as follows:

1. Assume that CO and HCN are directly additive (1:1) on a fractional dose basis (the evidence suggests that they are additive, but that the additive interaction may actually be less than unity).
2. Assume that the rates of uptake of CO and HCN and their fractional doses are increased in proportion to any increase in ventilation (RMV) caused by carbon dioxide.
3. Assume that the fractional doses of CO and HCN, adapted for carbon dioxide, are additive with the fractional dose of low-oxygen hypoxia.
4. Assume that asphyxia by carbon dioxide is independent of that induced by CO, HCN, and hypoxia.
5. Assume that irritancy is independent of asphyxia, but that uptake of irritants is increased by carbon dioxide (see next section of this chapter).

Implications of Interactions for Predicting Time to Incapacitation in Smoke Atmospheres

In general, there is evidence for some possible interactions between toxic fire gases, but whether these are likely to be important in practice depends upon the composition of actual fire atmospheres, which is discussed in a later section of this chapter. For most practical situations, the composition of fire atmospheres will be such that for asphyxiant effects CO will be the most important toxic product, and that the most important interaction will be an increased rate of CO uptake due to hyperventilation caused by CO_2. The additional effects of HCN and low-oxygen hypoxia will contribute to the effects of CO-induced asphyxia, and may significantly reduce time to incapacitation in some situations.

On this basis the fractional dose equation for asphyxiation would be*

$$F_{IN} = [(F_{I_{CO}} + F_{I_{CN}} + FLD_{irr}) \times V\mathrm{CO}_2 + \mathrm{FED}_{I_O}] \text{ or } F_{I_{CO_2}} \quad (21)$$

where

F_{IN} = fraction of an incapacitating dose of all asphyxiant gases

$F_{I_{CO}}$ = fraction of an incapacitating dose of CO

$F_{I_{CN}}$ = fraction of an incapacitating dose of HCN (and nitriles, corrected for NO_2)

FLD_{irr} = fraction of an irritant dose contributing to hypoxia (This term represents a correction for the effects of irritants on lung function and is developed in the section on irritants. This term may be omitted if the effects of asphyxiant gases only are under consideration)

$V\mathrm{CO}_2$ = multiplication factor for CO_2-induced hyperventilation

FED_{I_O} = fraction of an incapacitating dose of low-oxygen hypoxia

$\mathrm{FED}_{I_{CO_2}}$ = fraction of an incapacitating dose of CO_2

Each individual term in the FED equation is itself the result of the following equations, which give the FED for incapacitation for each gas and the multiplication factor for CO_2, where t is the exposure time at a particular concentration in minutes. The FED acquired over a each period of time during the fire are summed until the total FED_{IN} reaches unity, at which point incapacitation (loss of consciousness) is predicted. In order to allow for differences in sensitivity and to protect susceptible human subpopulations a factor of 0.1 FED should allow for safe escape of nearly all exposed individuals. Death is predicted at approximately two to three times the incapacitating dose.

For a 1-minute exposure to each gas at a concentration C

$$F'_{I_{CO}} = \frac{8.2925 \times 10^{-4} \times \mathrm{ppm\ CO}^{1.036}}{30}$$

$$F'_{I_{CN}} = \frac{(\exp([\mathrm{CN}]/43))}{220} \quad (11)$$

where CN represents the concentration of cyanide corrected for the presence of other nitriles besides HCN and for the protective effect of NO_2. CN can be calculated as [CN] = [HCN] + [total organic nitriles] − [NO_2]

$$V\mathrm{CO}_2 = \exp\frac{[\mathrm{CO}_2]}{5}$$

$$\mathrm{FLD}_{irr} = \mathrm{FLD}_{HCl} + \mathrm{FLD}_{HBr} + \mathrm{FLD}_{HF} + \mathrm{FLD}_{SO_2} + \mathrm{FLD}_{NO_2} + \mathrm{FLD}_{CH_2CHO} + \mathrm{FLD}_{HCHO} + \Sigma\mathrm{FLD}_x \quad (22)$$

*The effect of CO_2-induced hyperventilation will be to increase the rate of uptake of inhaled gases as a function of the increase in ventilation. Another approach to the quantification of this effect would be to multiply the concentration of each gas by $V\mathrm{CO}_2$ in the FED expression for that gas rather than in Equation 21. This would produce a similar result to Equation 21, except for the effect of HCN inhalation, for which a greater value of $F_{I_{CN}}$ corrected for $V\mathrm{CO}_2$ would result. This may represent a more correct approach and is currently under consideration.

where ΣFLD_x = FLDs for any other irritants present

$$F'_{I_O} = \frac{1}{\exp\,[8.13 - 0.54(20.9 - \%O_2)]}$$

$$F'_{I_{CO_2}} = \frac{1}{\exp\,[6.1623 - 0.5189 \times \%O_2]}$$

Figure 2-6.19 shows an expanded detail of asphyxiant gas profiles during the first 10 minutes of the single armchair room burn that is presented in more detail in Figure 2-6.15. The histograms show the average concentrations of each gas at minute intervals during the first 6 min of the fire, the figures for which are given in Table 2-6.6. The HCN concentration was not measured in this fire, but it is likely to have been present as a major toxic product. Possible HCN concentrations have therefore been suggested for inclusion in the model and are shown in a histogram.

Applying the expressions for the fractional incapacitating dose of each gas to the data in Table 2-6.6, the total fractional dose of all asphyxiant gases for each minute during the fire (F_{IN}) has been calculated according to Equation 21, and summed for each successive minute during the fire, as shown in Table 2-6.7. Incapacitation (loss of consciousness) is predicted at 5 min when the fractional incapacitating dose exceeds unity ($F_{IN} = 1.2$).

Irritant Fire Products

Unlike the incapacitating effects of asphyxiants, which are clear-cut and well understood, the incapacitative effects of irritants are much more difficult to determine. Irritant fire products produce incapacitation during and after exposure in two distinct ways. During exposure the most important form of incapacitation is sensory irritation, which causes painful effects to the eyes and upper respiratory tract, and to some extent also the lungs. Although exposure may be painful and thus incapacitating, it is unlikely to be directly lethal during exposure unless exceptionally high concentrations of irritants are present. However, the second effect of irritants penetrating into the lungs is an acute pulmonary irritant response, consisting of edema and inflammation which can cause respiratory difficulties and may lead to death 6 to 24 hr after exposure.[80,81] The effects do not show the sharp cut off of asphyxiation, but lie on a continuum from mild eye irritation to severe pain, depending upon the concentration of the irritant and its potency.[24,82,83] For sensory irritation the effects do not depend upon an accumulated dose but occur immediately upon exposure, and usually lessen somewhat if exposure continues.[16,24] For the later inflammatory reaction the effect does depend upon an accumulated dose, approximately following Haber's rule, and there seems to be a threshold below which the consequences are minor, but when this dose is exceeded severe respiratory difficulties and often death occur, usually 6 to 24 hr after exposure. However, for most sensory irritants the ratio between the concentration producing severe irritation and

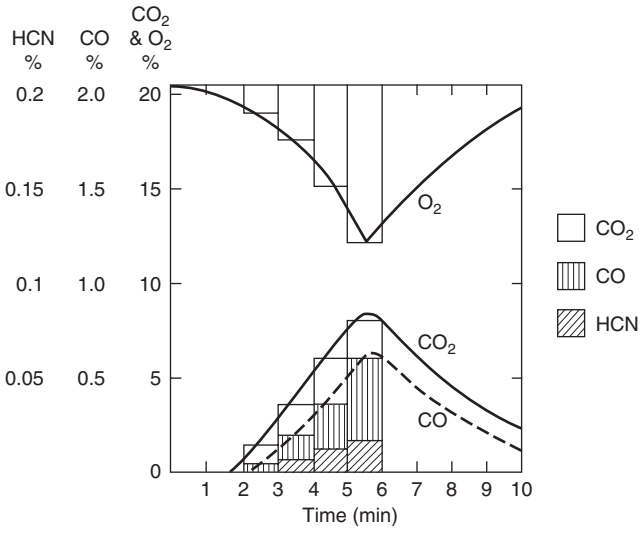

Figure 2-6.19. ***Expanded detail from Figure 2-6.15—average concentrations of asphyxiant gases each minute (histograms) from gas profiles (curves) measured during the first 10 min of a single armchair (polystyrene with polyurethane cushions and covers) room burn.[56] Since HCN was not measured, but was likely to have been present as an important toxic product, possible concentrations have been suggested for inclusion in the model.***

F_{IN} = 1.2 at 5 minutes due to the combined effects of CO, HCN, and low-oxygen hypoxia, the uptake of which was increased by CO_2, and incapacitation is predicted at between 4 and 5 minutes. Although carbon dioxide was present at concentrations sufficient to have caused significant hyperventilation, the fractional incapacitating dose for asphyxiation by carbon dioxide was only 0.065 at 5 min, and this is therefore unlikely to have had any effect.

the dose causing death is usually large (15 to 500 times)[84,85] for 30-min exposure times. (See Table 2-6.1.)

The effects of low concentrations of irritants can best be considered as adding to the obscurational effects of smoke by producing mild eye and upper respiratory tract irritation. In this situation irritants may have some effect by impairing the speed of an individual's movement through a building (as would simple visual obscuration), but the combined effects of eye irritation and direct visual obscuration may be more serious, and it has been shown that human volunteers moved more slowly through irritant smoke than through nonirritant smoke.[86] The limitation of escape capability may not be simply restricted to direct physiological effects, but also to psychological and behavioral effects such as the willingness of an individual to enter a smoke-filled corridor.[86]

At the other end of the scale, when irritants are present at high concentrations, there is some disagreement about the likely degree of incapacitation. Some investigators believe that the painful effects on the eyes and upper respiratory tract would be severely incapacitating, so that, for example, escape from a building would be rendered extremely difficult.[87] Others believe that the effects peak at moderate concentrations, and that although the effects may be very unpleasant they would not significantly impair the ability to escape from a building, and would provide a strong stimulus to escape that might almost be beneficial.[85]

One of the main difficulties in attempting to predict the consequences of exposure to irritants is the poor quality of data available on humans. Obviously very few controlled studies have been made of the effects of severe irritancy in humans, so that most data are anecdotal, derived from accidental industrial exposures, with only a vague knowledge of exposure concentrations. Reports of the severity of the effects also tend to be very subjective, so that the term "severe irritation" could cover a wide range of sensations with varying degrees of actual incapacitation. Another problem is that since sensory irritation covers a continuous range from mild eye and upper respiratory tract irritation to severe pain, there are no simple objective end points or thresholds. The most extensive studies of the effects of severe irritancy in humans have been performed on volunteers exposed to riot-control agents such as CS (o-chlorobenzylidine malonitrile) or CN (α-chloroacetophenone). Even these studies do not really show how the ability to escape from a building might be affected, but they do to some extent convey the severity of the effects.

The effects of CS, which are probably similar to those of any severe sensory irritant, have been described by Beswick et al.[24] They consist of an almost instantaneous severe inflammation of the eyes accompanied by pain, excessive lacrimation (tearing), and blepharospasm (spasm of the eyelids). There is irritation and running of the nose with a burning sensation in the nose, mouth, and throat, and a feeling of intense discomfort during which the subjects cough, often violently. If the exposure continues, the discomfort spreads to the chest and there is difficulty in breathing. Many subjects describe a tightness of the chest or chest pain as the worst symptom of CS exposure. The respiration pattern is irregular and the breath is held for short periods. Attempts to avoid the irritation by breath-holding, followed eventually by fairly deep breaths, are reported as being extremely unpleasant. At this stage most individuals are acutely apprehensive and highly motivated to escape from the smoke. However, if exposure continues there is some remission of signs and symptoms. When subjects were exposed to 0.08 ppm CS, they found the immediate effects very unpleasant but after 4 to 5 min were able to play cards. Another finding with CS, perhaps related to the development of tolerance, was that subjects could endure a relatively high concentration (~0.8 ppm CS) if it was achieved gradually even over as short a period as 10 min (as is likely to occur in fires) while they were totally unable to bear an immediate exposure to the same concentration.[24,83]

Reports are conflicting among fire victims. Some persons say they went through dense smoke without experiencing any great discomfort, while others say that respiratory difficulties prevented them from entering smoke-filled areas.[94] This seems to depend upon the type of fire. For example, the smoke from some well-ventilated fires involving primarily cellulosic materials has been reported as irritant but not seriously incapacitating, while that from some plastic materials (e.g., the interior of a burning car) was found to cause severe effects when only a small amount of smoke was inhaled. Anyone who has had bonfire smoke in their eyes will know the pain of the experience. However, the effects can be mitigated by blinking or shutting the eyes, and the effects on the nose can be mitigated by mouth breathing and breath-holding. Also, it is known that people in emergency situations are often unaware of painful stimuli.[95] It is therefore likely that irritant smoke products do have some severe effects on the escape capability of fire victims, but it is difficult at present to predict accurately the likely degree of incapacitation.

Animal Models for the Assessment of Irritancy and Their Extrapolation to Humans

Having established that irritancy is likely to be a major cause of incapacitation in fires, it is important to find some way of assessing the potential of fire atmospheres for causing irritancy. The basic effects, consisting of an acute inflammatory reaction of the tissues accompanied by stimulation of pain receptors, are common to all mammals, so that animals can realistically be used to assess the potential for irritancy in humans.

The characteristic response to eye irritation is stimulation of trigeminal nerve endings in the cornea leading to pain, blepharospasm (reflex, or more or less involuntary closure of the eyelids), and lacrimation. Severe damage may also lead to corneal opacity.

The effects of irritants on the upper respiratory tract have been studied in a number of species, including humans, for a wide range of airborne irritants including atmospheres of combustion products.[96,97] The characteristic physiological response (also due to trigeminal nerve stimulation), is a reflex decrease in respiratory rate accompanied by a prickling or burning sensation in the nose, mouth, and throat, often accompanied by mucus secre-

tion. At very high concentrations rapidly developing inflammatory reactions in the upper respiratory tract and laryngeal spasm may cause death during or soon after exposure, but in humans the lung is likely to be the more seriously affected target organ.

In contrast to these effects, the characteristic response to irritants penetrating into the lung is an increase in respiratory rate, generally accompanied by coughing and a slight decrease in tidal volume. There may also be bronchial constriction and increased pulmonary flow resistance, particularly if the victim is hypersensitive to the irritant.[84,96] This is accompanied by tissue inflammation and edema, which at very high concentrations can cause death during, or more often after, exposure.[14,80]

The effect (upper respiratory tract or lung irritancy) that predominates depends upon a number of factors such as the physical characteristics of the aerosol, the aqueous solubility of the irritant, the animal species, and the duration of the insult. An important difference between mice and rats (which are often used to measure irritancy) and primates, including humans, is that in rodents the nasal passages are complex in structure and have a large surface area, so that soluble gases are readily taken up and particulates are readily deposited. A decrease in respiratory rate in the upper respiratory tract is the major response in rodents, which tends to protect them from exposure. Their great tolerance to hypoxia (and possible circulatory adaptations similar to the diving reflex) also enables them to maintain greatly reduced breathing for long periods. In humans and other primates the nasal passages are simply structured with a relatively small surface area, and in humans particularly, mouth breathing is common. Thus, although upper respiratory tract irritation occurs initially and is accompanied by some respiratory rate decrease, a greater proportion of the inhaled irritant is carried into the lungs, so that lung irritation is generally a more pronounced effect. In primates, including humans, a transient respiratory rate depression is followed rapidly by the increased respiratory rate characteristic of lung irritation.[16,79] (See Figures 2-6.20 and 2-6.21.)

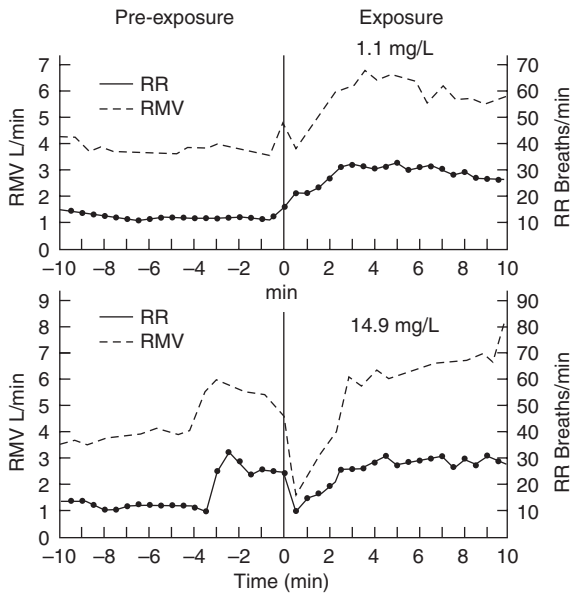

Figure 2-6.20. ***Respiratory effects of polypropylene decomposed under nonflaming oxidative conditions—cynomolgus monkey.***

Rodent Respiratory Rate Depression Test

The method most commonly used to quantify upper respiratory tract irritancy both for pedigree chemicals and combustion products is the mouse respiratory rate depression test.[97,98] The basic method involves measurement of the percentage decrease in respiratory rate during exposure over a range of different atmosphere concentrations. From this measurement the RD_{50} (the concentration required to produce a 50 percent decrease in respiratory rate) is calculated. Since the basic irritant mechanisms are the same in all mammals, it is certainly possible to identify an individual substance, or mixture (such as a combustion atmosphere), that is likely to be irritant to humans; however, it may also be possible to predict the degree of irritation in humans. As a result of comparisons of data from humans with results from mice, Alarie[93] has demonstrated a relationship between the potency of known sensory irritants in humans and a derivative of the mouse RD_{50}. When the log of the TLV (often based on symptoms of irritancy in man) is plotted against the log of 0.03 multiplied by the RD_{50} in ppm, most chemicals known to be sensory irritants in humans fall into a linear relationship with the respiratory effects in mice. Chemicals that are highly irritant in humans such as acrolein or chlorine have low RD_{50} measures in mice while mild irritants such as ethanol have a high mouse RD_{50}.[93] (See Table 2-6.7.)

Such methods appear to give good predictions of irritancy at low levels that are suitable for fixing hygiene standards, but for the high concentrations occurring in fires it is necessary to predict which concentrations will produce sufficient incapacitation to cause serious impairment of escape capability, and also which concentrations will cause serious lung damage after exposure. As stated previously, such predictions of incapacitation in humans are difficult because of the variable and subjective nature of irritancy. However, Alarie states that a human exposed at the mouse RD_{50} concentration of any substance would find the atmosphere severely irritating and would be seriously incapacitated within 3 min.[87] Certainly this seems to be justified in terms of some individual chemicals. For example, the work with CS[24,83] shows that, although it is very difficult to measure intolerable irritancy in humans, there does seem to be a reasonable agreement between the human and mouse data. Thus the mouse RD_{50} (4 mg/m^3, 0.52 ppm) is very close to the concentration found to be immediately intolerable when humans were exposed for up to 12 min (5 mg/m^3, 0.6 ppm), and the list of RD_{50} levels and concentrations reported as highly irritant in humans[21] given in Table 2-6.1 shows a reasonable correspondence, particularly for the irritants commonly found in fires.

However, these apparent irritancy correlations between rodents and humans still do not enable the exact

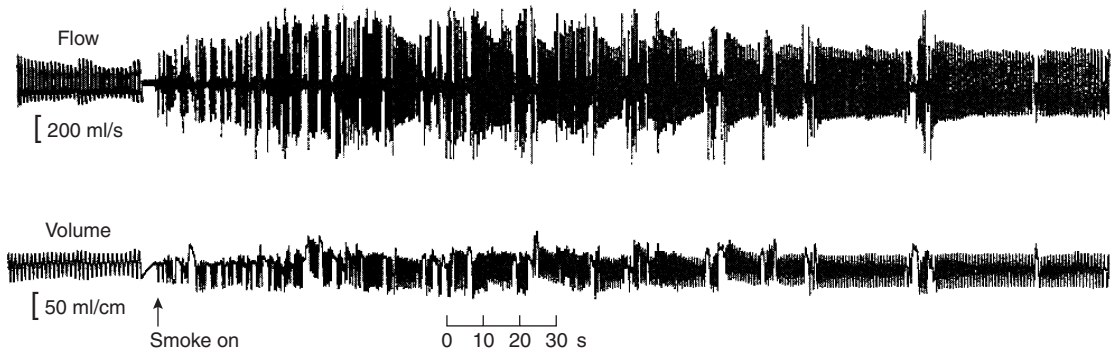

Figure 2-6.21. ***Effects upon respiration of exposure to an irritant smoke atmosphere; wood pyrolyzed at 300°C. When the smoke reaches the primate there is an initial sensory irritant response consisting of a decrease in respiratory rate with pauses between breaths. This rapidly gives way to a pulmonary irritant response consisting of an increase in respiratory rate and volume, which is maintained for the duration of the exposure.[16]***

prediction of the degree of incapacitation likely in humans, and in some cases there is evidence that the mouse model does not even give a good prediction of the degree of sensory irritation, although it can be used to demonstrate when sensory irritation is likely to occur in humans. Three experiments, two involving nonhuman primates and the other involving humans may illustrate the difficulties of extrapolating from the RD_{50} and physiological effects in mice to the degree of irritancy, incapacitation, and physiological effects in primates. In a series of experiments the irritant effects of smoke produced by the nonflaming oxidative decomposition of polypropylane were evaluated in cynomolgus monkeys.[16,31] The effects of breathing smoke through a face mask were mild at concentrations (NAC mass charge) of up to 4 mg polypropylene/L, consisting of a transient decrease in respiratory rate lasting approximately 30 seconds (a sensory irritant response), followed by an increased respiratory rate (lung irritant response) with a slight increase in RMV. (See Figure 2-6.20.) The respiratory response pattern is illustrated in Figure 2-6.21, where similar effects occurred during exposure to pyrolysis products from wood. For polypropylene the lung irritant response was the most sensitive effect with a threshold of 1 mg polypropylene/L. At concentrations above 6 mg/L the irritant effects were more marked, and although recovery appeared complete immediately after exposure, signs of nasal and pulmonary inflammation occurred some hours later. One animal died following an exposure of 30 minutes at 8 mg polypropylene/L. When free-moving monkeys trained to perform a behavioral task were exposed, there was evidence of some eye irritation and mild disruption of behavioral performance at a concentration of 1.85 mg polypropylene/L, the effects of exposure at 0.92 mg/L being very slight. However, the mouse RD_{50} for the same polypropylene atmosphere was found to be 0.1 mg/L. According to the model this concentration should have been highly irritant to the monkey, and yet in practice only the mildest of signs occurred at concentrations more than an order of magnitude higher. Similarly, in another study Potts and Lederer[99] exposed mice and humans simultaneously to smoke from the pyrolysis of red oak (mouse RD_{50} 0.37 mg/L). At this concentration the smoke was barely visible and all human subjects stated that although the smoke was unpleasant and irritating, in no sense were they physically incapacitated, and they were quite capable of performing tasks such as threading nuts and bolts of various sizes.

The third experiment was performed on two pedigree substances, hydrogen chloride and acrolein, often regarded as important irritants in smoke. In these experiments baboons were trained to press a lever in order to escape from a chamber after a 5-min exposure.[85] It was found that the animals could perform this task efficiently even at the incredibly high concentrations of 2780 ppm acrolein or 16,570 ppm HCl, although in both cases the animals died from lung inflammation after exposure. These concentrations compare with mouse RD_{50}s of 1.68 ppm for acrolein and 309 ppm for HCl, and at these concentrations both substances are highly irritant in humans. (See Table 2-6.8.)

As a result of this work on irritants in rodents, nonhuman primates, and humans, it would seem that the rodent models are good methods for identifying smoke atmospheres or individual substances likely to be irritant to humans and even for ranking irritants in order of potency and setting hygiene standards. However, when predicting concentrations of smoke atmospheres that would seriously impair the ability to escape from a fire, there is a need for more work to establish the effects of known irritants in humans and to establish the relationship between the rodent response and human incapacitation.

Lung Inflammatory Reactions

Just as it is difficult to predict the degree of incapacitation from sensory irritation likely to occur in victims during fire exposure, it is also difficult to predict concentrations likely to cause death in humans from lung inflammatory reactions, although experiments in rodents should enable some estimates to be made from postex-

Table 2-6.8 ***Irritancy Data***

Acrolein[a]

Mouse $RD_{50} = 1.68$ ppm[87]

Marked irritation of eyes and nose in humans—1 ppm[21]

Severe irritation of eyes and nose in humans—5.5 ppm[21]

Henderson and Haggard[21] state that 10 + ppm is lethal in humans within a short time due to pulmonary irritation. However 10 ppm for 3.5 hr in cats was nonlethal[21]

Kaplan[85] has reported that baboons can escape from a chamber after 5 min exposure at up to 2780 ppm. One animal died due to pulmonary effects following exposure at 1025 ppm, and another following 2780 ppm. No signs of pulmonary effects were observed following exposure at 505 ppm and below

A case has been reported of a man dying following exposure to 153 ppm for 10 min[91]

The 6-hr mouse LC_{50} is 66 ppm[91]

The 30-min rat LC_{50} is 135 ppm[91]

Hydrogen chloride[b]

Mouse $RD_{50} = 309$ ppm[87]

Strongly irritant to humans at 50 to 100 ppm for 1 hr[21]

Brief exposure at 1,000 to 2000 ppm is regarded as dangerous to lethal in humans[82]

Humans LCLO 1300 ppm for 30 min[91]

Kaplan exposed baboons for 5 min to concentrations of up to 16,570 ppm and found that they were able to perform escape maneuvers. One animal suffered permanent lung damage at 11,400 ppm and two died at approximately 17,000 ppm (≃2830 ppm for 30 min).

[a]From these rather variable data the concentration lethal to humans following a 20-min exposure would be 80 to 260 ppm. A severe irritant effect on the upper respiratory tract would be expected at around 5 ppm, but from Kaplan's work[85] this may not be unbearable, even up to several hundred ppm.

[b]Therefore, anything over 100 ppm is likely to be highly irritant and over a 20-min period approximately ten times this concentration may cause permanent lung damage or endanger life.

posure LC_{50} data. When rodents are exposed to smoke atmospheres in small-scale combustion toxicity experiments, death occurs principally either during exposure due to asphyxiant gases (CO, HCN) or some time after exposure, due to lung irritation. In cases where the majority of deaths occur after exposure and are accompanied by signs of lung irritation, measurements of the concentration causing postexposure deaths give some indication of concentrations likely to be hazardous to humans.

Since the effects of asphyxiant gases can be predicted without animal exposure, while the potential for causing sensory irritation and lung inflammation cannot, measurements of sensory irritancy by the respiratory depression test (RD_{50}) and measurements of the concentrations causing postexposure deaths (LC_{50}) are important uses for small-scale toxicity tests. It is also important to stress that whereas sensory irritation occurs immediately upon exposure, and is concentration related, the inflammatory reactions resulting from lung irritancy are dose related and depend approximately upon the product of exposure concentration and duration (Ct product). When an LC_{50} concentration is quoted, it is also important to quote the exposure duration. For combustion toxicity experiments exposure times are usually 10 or 30 min, and the 30 min LC_{50} should be approximately one third of the 10 min LC_{50} when postexposure irritancy is the cause of death. It is also important to know the time over which the deaths were scored. Thus some studies quote LC_{50} levels only in terms of animals dying during exposure (which will be due to asphyxia or very high concentrations of irritants). Other studies include deaths occurring both during or up to 24 hours after exposure, while other studies use the standard method for inhalation toxicology studies which includes deaths during exposure and for up to 14 days after. For the assessment of toxic hazard in possible fire scenarios, it is important to take all these factors into account when considering different building designs or applications of materials.

Irritant Components of Thermal Decomposition Product Atmospheres

If mathematical models are to be constructed to predict the potential for sensory irritancy and later lung inflammation of exposures in fires, it is important to attempt to identify the main irritant chemical species occurring in fires and to measure their potency individually and in combination. This is an area where knowledge is still inadequate, but large numbers of known irritant chemicals have been found to occur in fire atmospheres.[16,17] (See Table 2-6.1.) The irritant chemicals released in fires are formed during the pyrolysis and partial oxidation of materials, and the combinations of products from different materials are often remarkably similar.[17] Some materials release irritant components simply upon pyrolysis, such as HCL from PVC, isocyanates from flexible polyurethanes, and various substances from natural materials such as wood. However, for all organic materials and particularly for simple hydrocarbon polymers such as polypropylene or polyethylene, the main pyrolysis products, which consist of various hydrocarbon fragments, are innocuous. Thus when polypropylene is pyrolyzed in nitrogen the products listed in Table 2-6.9 are produced, and such an atmosphere was found to have no effect upon primates.[16,80] However when these products are oxidized during nonflaming decomposition in air, some are converted to highly irritant products as shown in the table, and such atmospheres were indeed found to be highly irritant to both mice and primates.[31]

Table 2-6.9 ***Pyrolytic and Oxidative Decomposition Products of Polypropylene at 500°C Showing Percentage Yields of Major Irritants as Indicated, and Threshold Limit Values (TLVs) Where Available from American Conference of Governmental Industrial Hygienists[21]***

[a]Oxygen-containing products

[b]Weight percentage conversion of polymer

These atmospheres produced by the nonflaming oxidative decomposition of materials are always the "worst case" for any material in terms of irritant potency. Both the chemical profile and the irritant potency as determined by the mouse RD_{50} test are often similar for different materials, the majority lying within a range of approximately one order of magnitude.[32] However, when materials flame, these organic irritants are destroyed in the flame to produce CO_2 and water, so that the irritancy of the atmosphere depends upon how much irritant escapes the actual flame zone and the efficiency of combustion. Thus "clean," smoke-free flames, involving efficient combustion such as those that occur in a gas burner or well-ventilated fire, are relatively nonirritant, whereas "dirty," smoky flames resulting from inefficient combustion may contain high concentrations of irritants, and produce these irritants at a greater rate than under smoldering or nonflaming conditions. In primates the atmosphere produced by flaming polypropylene was found to retain some irritancy, although considerably less than under nonflaming conditions.[16] In mouse experiments, some fire retardant materials, which could be induced to flame only intermittently, with considerable smoke production, were found to produce atmospheres up to 300 times more irritant than the same polymer in its non-fire retardant state, which burned cleanly.[100]

The picture is again confused regarding the role of specific chemical products in smoke. Table 2-6.1 shows some irritants identified in smoke atmospheres in order of their sensory irritancy, and includes data on the LC_{50}, due principally to lung inflammation, where these were obtainable from the literature. In some cases there was a considerable range of estimates for both sensory irritancy and lethality, and these are indicated. The lethality data are mostly for rodents, and have been normalized to a 30-min exposure period assuming that lethality is dose-related according to Haber's rule. Table 2-6.8 gives more detailed data for the effects in humans and animals of the best known fire irritants, hydrogen chloride and acrolein. One point to note from Table 2-6.1 is that irritants vary enormously in their potency, over five orders of magnitude. The most important irritants are probably the ones near the top of the list, including isocyanates (from polyurethanes), the unsaturated aledehydes acrolein and crotonaldehyde, and the first of the saturated aldehyde series—formaldehyde (which is produced by nearly all materials when decomposed). Irritants with a moderate potency, such as phenol and the halogen acid gases HCl, HF, HBr may be important in some fires if they are present in high concentrations, while it is difficult to conceive of any product with an RD_{50} of more than 1000 ppm, such as acetaldehyde, methanol, or any hydrocarbon, being of significance as a smoke irritant.

A difficulty in predicting the irritancy potential of fire atmospheres is that it is not known exactly how the various irritant components of an atmosphere interact, although there are indications that some degree of additive effect occurs. However, a more serious problem is that where comparisons have been made between the mouse RD_{50} of combustion atmospheres and their chemical composition as revealed by GC-MS analysis, the atmospheres in most cases turn out to be much more irritant than can be accounted for by a knowledge of their components. It is possible that small amounts of short-lived reactive chemical species with a very high irritant potency ($RD_{50} < 1$ ppm) are responsible, and more work is needed in this area.[105]

Prediction of Incapacitation Due to Sensory and Lung Irritation

In previous sections a model for the prediction of asphyxia in fires has been presented. This model is realistic because it is based on the following facts:

1. Asphyxiation in fires gives two well-defined endpoints, loss of consciousness and death, both of which are likely to occur during the fire exposure.
2. Time and dose to these endpoints can be predicted from established data.
3. Asphyxiation in fires can be shown to depend upon a few known products.
4. The effects of each product are well known, and so to some extent are their interactions, so that predictions of asphyxia based on gas profile measurements show a good agreement with observations of animal exposures.

However, it is very difficult to develop a predictive model for irritancy because

1. Sensory irritation does not have a clear endpoint, but lies on a continuum of increasing eye and respiratory tract pain. Although this pain may be considered incapacitating, sensory irritation does not cause obvious incapacitative effects such as loss of consciousness, and it is not lethal, except under extreme conditions.

   Lung inflammation appears to cause relatively minor effects until near lethal levels of exposure are reached, so the main predictable endpoint is death, although this does not usually occur until several hours after exposure.
2. The identity and number of the irritant products important in fires are unknown. There is also a poor correlation between the composition of experimental fire atmospheres in terms of known irritants and their actual irritant effects on animals.
3. The concentration/time/dose effects of irritants and the degree of interaction between different irritants are also unknown.

For these reasons it is currently possible only to develop an approximate mathematical model to predict irritant effects from a knowledge of fire profiles in terms of known irritant products. An alternative is to base a model empirically on the effects on animals of smoke atmospheres produced in small-scale tests (which are described in a later section of this chapter).

To use small-scale test data, it is first necessary to ensure that the test fire model reasonably represents the decomposition conditions in the type of fire of interest (smoldering, early flaming, or post-flashover). The concentration of irritants may then be represented in terms of mass charge or mass loss of the test material per liter of diluent air.

Sensory irritation may then be measured in terms of the mouse RD_{50} test. Although this test relates primarily to upper respiratory tract irritation, the results also show some correlation with eye irritation;[93] sensory irritation may also be assessed directly if required in terms of the severity of eye lesions occurring in the mice (ranging from lacrimation through chromodacryorrhoea to ocular opacity).

Lung edema and inflammation may be measured in terms of the mouse or rat LC_{50} where deaths occur principally after exposure and are accompanied by signs of inflammation such as increased lung weights or histopathological lung lesions.

Attempts may then be made to relate the RD_{50} and LC_{50} to possible effects in humans, but as described there are difficulties with these extrapolations. Fortunately, for most different materials the rodent RD_{50} and LC_{50} levels cover relatively narrow ranges (approximately one order of magnitude) under some given thermal decomposition conditions. For these reasons it is difficult with current knowledge to give guidance on irritancy for hazard modeling. Rough, general tenability limits can be presented, based upon observations of the sensory and lethal lung irritant effects of exposures of rodents and primates (and humans) to combustion product atmospheres from a range of materials decomposed under a range of conditions. It is therefore suggested that irritancy should be treated as follows:

1. Sensory irritation occurs immediately on exposure and is primarily concentration-related, not increasing with exposure duration.
2. All fire atmospheres are likely to be highly irritant, and at low concentrations the irritant effects should be regarded as adding to the obscurational effects of smoke through eye irritation, and possibly causing mild behavioral disruption by effects on the respiratory tract. At higher concentrations the disruptive effects of severe sensory irritation on vision and breathing may seriously limit escape capability, and as a rough approximation nonflaming atmospheres are likely to cause severe sensory irritation at a nominal atmosphere concentration (mass loss) of around 1 mg material/L air. This may occur when the optical density of the smoke is very low (<0.01/m) or even where there is no detectable smoke. It is therefore proposed that an NAC (mass loss) of 1 mg/L should be used as a tenability limit, although this may be modified in the light of RD_{50} or other data on the particular material and fire condition of interest.
3. Lung edema and inflammation are most likely to occur some hours after fire exposure, and severity of these is basically dose-related, approximately following Haber's rule.
4. Dangerous lung edema and inflammation are likely to occur following a 30-min exposure to an NAC (mass loss) of approximately 10 mg material/L, representing a Ct product of approximately 300 mg/L min. This figure may be replaced by LCt_{50} data on the materials involved in individual fires.
5. These exposure limits for sensory and lung irritation are based largely on exposures to nonflaming atmospheres. Flaming atmospheres may be somewhat less of an irritant, depending upon the efficiency of combustion and the severity of the fire.
6. Data for some common fire irritants are shown in Tables 2-6.1 and 2-6.8.

A Model for the Prediction of the Effects of Optically Dense, Irritant Smoke on the Eyes and Respiratory Tract

Although it is difficult to make precise predictions of the effects exposure to irritant smoke has on escape behavior, the degree of incapacitation, and the post-exposure

effects on lungs, it is important to consider these effects in engineering design, and to be able to make some estimates of the likely effects of exposure. Herein is presented a current "best estimate" model for likely effects.

Evaluation of the Effects of Optically Dense, Irritant, Smoke on Visibility

Optically dense smoke affects exit choice and escape decisions, as well as wayfinding ability and the speed of movement of occupants. These effects depend upon the concentration (optical density) of the smoke and its irritancy to the eyes and upper respiratory tract. Fundamental work on this subject was carried out by Professor Jin in Japan. In experiments where people were asked to walk down a smoke-logged corridor, Jin found that for nonirritant smoke, walking speed decreased with smoke density, and that at an optical density of 0.5/m (extinction coefficient 1.15) walking speed decreased from approximately 1.2 m/s (no smoke) to 0.3 m/s (Figure 2-6.22).[101] Under these conditions people behaved as if they were in total darkness, feeling their way along the walls. When people were exposed to irritant smoke, made by heating wood chippings, movement speed was reduced to that in darkness at a much lower optical density (optical density 0.2 OD/m, extinction coefficient 0.5), and the experience was found to be more distressing.

In addition to these effects upon movement speed, there is the problem of deciding whether people will move at all. In a number of studies of fires in buildings, a proportion of people (approximately 30 percent) were found to turn back rather than continue through smoke-logged areas[41,102] (see Section 3, Chapter 12[103]). The average density at which people turned back was at a "visibility" distance of 3 m (0.33 OD/m, extinction coefficient 0.76), and women were more likely to turn back than men. These effects are summarized in Table 2-6.10. A difficulty with this kind of statistic is that in many fires in buildings there is a choice between passing through smoke to an exit or turning back to take refuge in a place of relative safety such as a closed room. In some situations people have moved through very dense smoke when the fire was behind them, while in other cases people have failed to move at all. Behavior may also depend on whether layering permits occupants to crouch down to levels where the smoke density is lower, and if low-level lighting is used to improve visibility. However it is likely that some people will not move through dense smoke.

Based upon considerations such as those described above for the optical density and irritancy of the smoke it is possible to set tenability limits for smoke density appropriate to particular fire scenarios, in relation to the physiological effects on the ability of occupants to see sufficiently well to escape efficiently, and possible psychological effects on their escape behavior. Appropriate limits will depend upon the building and occupant characteristics. For example, for small spaces with short travel distances to exits, it may be possible to set less stringent tenability criteria if occupants are familiar with the building. For large spaces it may be necessary to set more stringent tenability limits, particularly if occupants are likely to be unfamiliar with the building and need to be able to see much further in order to orient themselves to find exits. With regard to the effects of irritancy on the ability to see, it may be necessary to use more stringent smoke density tenability criteria for scenarios where the smoke evolved is likely to be highly irritant to the eyes. Other factors to be taken into consideration would be the complexity of the space, the lighting, and the visibility of the signage. Suggested tenability limits are presented in Table 2-6.10. Jin[86] suggests tenability limits of extinction coefficient 0.15/m (OD/m = 0.06) for subjects familiar with an escape route or 0.5/m (OD/m = 0.2) for subjects unfamiliar with the escape route. Rasbash[160] suggests a 10-m visibility limit (equivalent to OD/m = 0.08), while Babrauskas[56] suggested a tenability limit of extinction co-

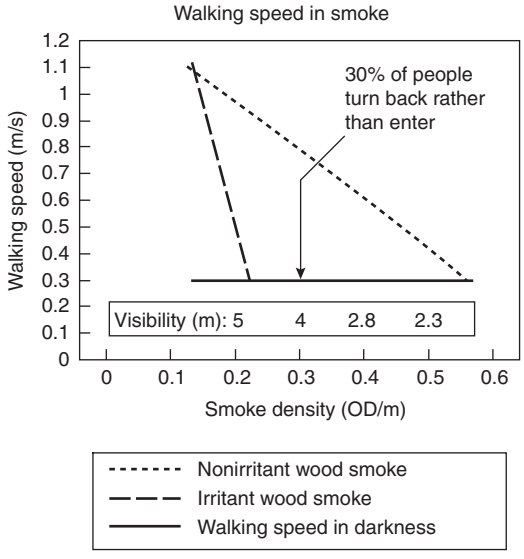

Figure 2-6.22. ***Walking speeds in nonirritant and irritant smoke.[101]***

Note: Visibility distance scale relates to opacity of non-irritant smoke and does not allow for physiological effects of irritants on vision.

Table 2-6.10 ***Reported Effects of Smoke on Visibility and Behavior***

Smoke Density and Irritancy OD/m (extinction coefficient)	Approximate Visibility (diffuse illumination)	Reported Effects
none	Unaffected	Walking speed 1.2 m/s
0.5 (1.15) nonirritant	2 m	Walking speed 0.3 m/s
0.2 (0.5) irritant	reduced	Walking speed 0.3 m/s
0.33 (0.76) mixed	3 m approx.	30% people turn back rather than enter
Suggested tenability limits for buildings with:		
—Small enclosures and travel distances:		OD/m 0.2 (visibility 5 m)
—Large enclosures and travel distances:		OD/m 0.08 (visibility 10 m)

efficient 1.2/m (OD/m = 0.5) in the context of domestic fires. In order to assess the visual obscuration effects of smoke, a concept of fractional effective concentration (FEC) has been developed, whereby the smoke concentration is expressed as a fraction of the concentration considered to significantly affect escape efficiency. If the total FEC_{smoke} reaches unity, then it is predicted that the level of visual obscuration would be sufficient to seriously affect escape attempts.

$$FEC_{smoke} = [OD/m]/0.2 \text{ for small enclosures or } [OD/m]/0.08 \text{ for large enclosures} \quad (23)$$

Setting Tenability Criteria for Sensory/Upper Respiratory Tract and Lung Irritancy

The work by Jin and others does provide some possibility to determine the effects of smoke obscuration on escape speed and efficiency, but a problem remains in determining the likely irritancy of the smoke and the likely severity of the effects of the irritants. It seems from the experience of people exposed in fires that there is a considerable variation in irritant severity between different types of fire effluent. Some fires produce large amounts of sooty smoke that is optically obscuring but relatively nonirritant. Other fires produce smoke that is both optically obscuring and irritant, while in some cases a highly irritant fire atmosphere has been reported when there was little or no visible smoke. From work at BRE Ltd., Fire Research Station (FRS), it has been found that smoke irritants consist of inorganic acid gases (such as hydrogen chloride) and organic compounds, particularly low molecular weight aldehydes (formaldehyde and acrolein). More than twenty irritant substances have been detected in smoke and it is considered that others remain to be identified (see section on irritants). The yields of inorganic acid gases in fires depend mainly on the elemental composition of the materials being burned, while the yields of smoke and organic irritants depends mainly upon the decomposition conditions in the fire. In general, smoldering or vitiated flaming fires (fires burning inefficiently) tend to produce irritant smoke while well-ventilated flaming fires, if burning efficiently, tend to produce nonirritant smokes.

The first effect of exposure to smoke irritants is sensory irritation, which consists of painful stimulation of the eyes, nose, throat, and lungs. Sensory irritation depends on the immediate concentration of irritants to which the subject is exposed, rather than a dose acquired over a period of time, with the effects lying on a continuum from mild eye irritation to severe eye and respiratory tract pain. Most people are familiar with the effects of smoke with a high irritant potency from exposure to bonfire smoke in the garden. The effects can be temporarily incapacitating with severe eye pain, closure of the eyes and tears. If the smoke is inhaled, coughing and breathing difficulties occur. It is easy to imagine how difficult it must be to find one's way through the escape routes in a building under such conditions. One of the best scientific descriptions of the effects of exposure to a sensory irritant is in a paper on the effects of experimental exposures of human volunteers to a substance designed to cause incapacitation due to sensory irritation, CS riot control gas.[24] The effects described consisted of an almost instantaneous severe inflammation of the eyes, accompanied by pain, excessive lacrimation (tearing), and blepharospasm (involuntary closure of the eyes due to spasm of the eyelids). There is irritation and running of the nose with a burning sensation in the nose, mouth, and throat, and a feeling of intense discomfort during which the subjects cough, often violently. If the exposure continues, the discomfort spreads to the chest and there is difficulty in breathing. Many subjects describe a tightness of the chest or chest pain as the worst symptom. The breathing is irregular and the breath is held for short periods. Attempts to avoid the irritation by breath-holding, followed eventually by fairly deep breaths, are reported as being extremely unpleasant. At this stage most individuals are acutely apprehensive and highly motivated to escape from the smoke.

In evaluating this aspect of irritancy in fires, the aim is to predict what concentration of mixed irritant products is likely to cause such pain and difficulty in breathing that escape attempts would be slowed or rendered less efficient, and what concentration is likely to seriously disrupt or prevent escape (a degree of incapacitation approximately equivalent to that at the point of collapse resulting from exposure to asphyxiant). For example, with regard to hydrogen chloride it is considered that concentrations from approximately 100 to 500 ppm would be painfully irritant, producing effects similar to those described for the CS experiments, and that the effects may slow escape but probably would not prevent it. However, at approximately 1000 ppm and above it is suggested that the effects might be so severe as to prevent escape.[104] The effects of exposure to different concentrations of an acid gas irritant (HCl), detailed in Table 2-6.8, are shown in Table 2-6.11. Figure 2-6.23 shows the respiratory depression response of mice to exposure to a sensory irritant atmosphere from PVC decomposed under nonflaming oxidative conditions.

Table 2-6.11 ***Example of the Effects of Exposure to an Acid Gas Irritant—Hydrogen Chloride***

No Odor ppm	
<5	Minor nasal irritation can be detected below 5 ppm (the OEL)
10–50	Perceived as irritant, but work is possible at up to approximately 50 ppm
50–100	Strongly irritant, and some people report exposure to 100 ppm as being excruciatingly painful to the eyes and respiratory tract
309	Mouse RD_{50}
1000–2000	Brief exposure regarded as being dangerous to lethal to humans
3800	Lethal exposure dose to rats for a 30-min exposure, representing an exposure dose of 114,000 ppm·min
15,000	5-min lethal exposure concentration in rats and baboons is around 15,000 ppm

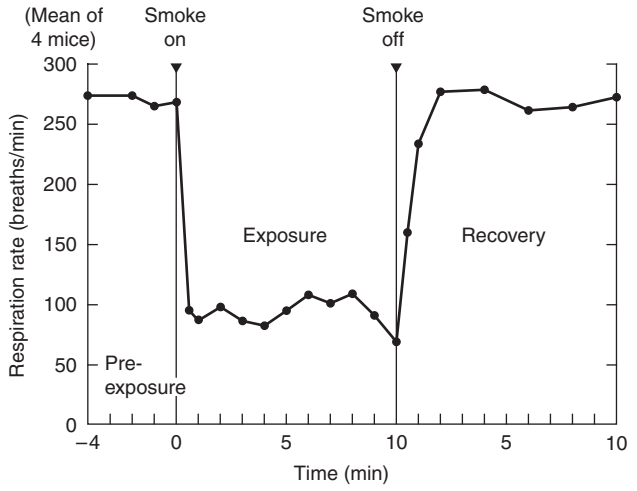

Figure 2-6.23. ***Concentration-effect relationships for sensory irritants: effect of exposure on mouse breathing rate of thermal decomposition products from PVC-J (0.72 g·m^{-3}).[105]***

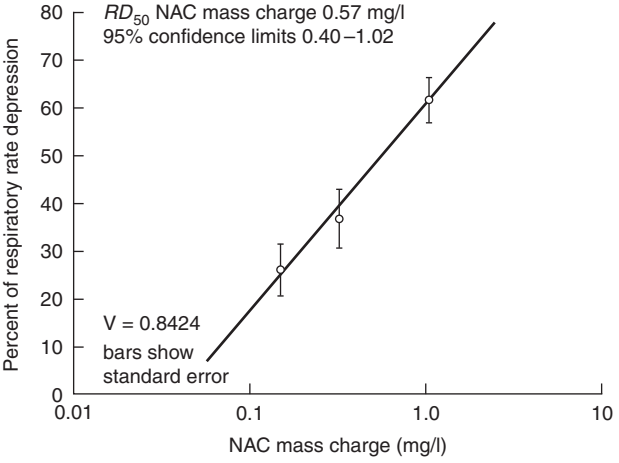

Figure 2-6.24. ***Concentration-effect relationships for sensory irritants percent breathing rate depression in mice is proportional to log concentration.[105] RD_{50} PVC-I 0.57 g·m^{-3}.***

Figure 2-6.24 shows the logarithmic concentration–effect relationship. In the absence of detailed information on irritant mixtures it is assumed that all irritants would be additive in their effects, since they are all capable of causing damage to lung tissue. In large-scale fire tests it is possible to measure inorganic irritants directly, but it is difficult to assess the degree of irritancy from organic products, which form a very important component. In general, the effects of organic irritants depend on the concentration of partially oxidized organic species in the smoke. For example, smokes from smoldering wood or polyolefines decomposed under smoldering or vitiated flaming conditions have a high organic content and are highly irritant, and are characterized by low CO_2/CO ratios and high smoke yields. Under well-ventilated flaming conditions, the organic content of the effluent is low, and irritancy is low. In general, it is predicted that smoke from a mixed fuel source with an optical density/meter of 0.5 would be strongly irritant to the eyes and respiratory tract. However, for a given smoke density, there are differences between different types of fires.

It is difficult to quantify these irritant effects exactly because the database on the effects of individual irritants or irritant mixtures on escape behavior in humans is poor, and, because the effects lie on a continuum of severity, there are no precise endpoints. Assessment has to be based upon a small number of human experimental exposures, usually at relatively low concentrations, accidental exposures, and the results of bioassay studies. For ethical reasons it is never going to be possible to obtain direct data for effects on humans so that estimates of this important parameter must be based on existing data and the judgment of physiologists. Further details of data from human and animal exposure to HCl and other irritants are given in reference[104] and the section on irritants.

Another concern is the range of susceptibility in the human population. Some individuals, particularly those with respiratory diseases, are likely to be more susceptible than others, while others, particularly fit individuals or those used to working in irritant environments, are likely to be more resistant. It is also likely that the subjective irritancy of an exposure is on a log scale of sensitivity for humans, as it is in rodents. Figure 2-6.25 shows a suggested likely distribution of sensitivity for a human population for HCl, in terms of the proportion of the population likely to suffer severe irritancy, to have impaired escape efficiency at different concentrations, and to suffer incapacitation. This is based upon existing human and animal data, and the judgment of the author. While most individuals are considered to be likely to be affected at around 200 ppm, some may be affected by low concentrations of around 100 ppm, but some may be able to tolerate exposure to very high concentrations of over 500 ppm without suffering serious effects on escape capability.

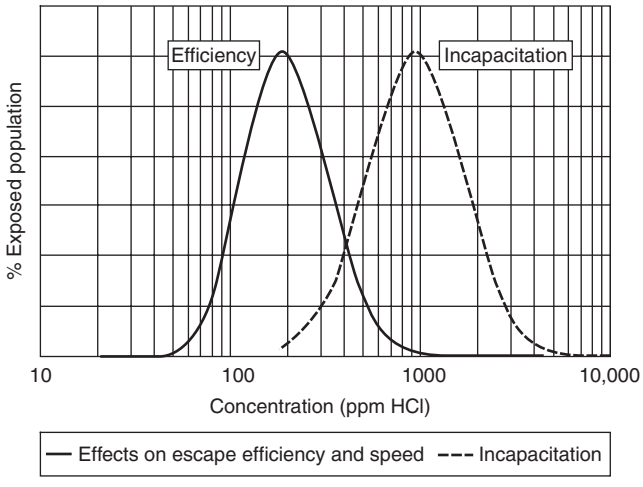

Figure 2-6.25 ***Estimated sensitivity distribution for human population to HCl exposure.[106]***

In order to assess the combined effects of irritants, a concept of fractional irritant concentration (FIC) has been developed, whereby the concentration of each irritant present is expressed as a fraction of the concentration considered to be severely irritant. The FICs for each irritant are then summed to give a total FIC. If the total FIC reaches unity, then it is predicted that the smoke atmosphere would be highly irritant, sufficient to slow escape attempts. If the total exceeds unity by a factor of approximately four or more, then it is likely that escape would be prevented, and possible that collapse might occur due to static hypoxia from bronchoconstriction or laryngeal spasm. On the basis of available data, current estimates of the concentrations of each gas likely to be highly irritant are as shown in Table 2-6.12.

It is predicted that each gas at the above concentrations is likely to be sufficiently irritant to affect escape efficiency in the majority of subjects and may cause incapacitation in susceptible individuals. A factor of 0.3 FEC for escape impairment should allow for safe escape of nearly all exposed individuals.

On the basis of the assumption that all irritants capable of damaging lung tissue are additive in their effects the overall irritant concentration FIC is then given by Equation 24:

$$\begin{aligned} FIC = {} & FIC_{HCl} + FIC_{HBr} + FIC_{HF} + FIC_{SO_2} \\ & + FIC_{NO_2} + FIC_{CH_2CHO} + FIC_{CH_2O} + \sum FIC_x \end{aligned} \quad (24)$$

where $\sum FIC_x$ = FICs for any other irritants present.

Current Concerns Regarding Effects of Sensory Irritants

In the preceding sections, the background data and considerations from which guidance on the effects of irritant have been derived have been presented in some detail. The proposed tenability limits can never be precisely verified since the human experiments needed cannot be performed, but by the same token it is not possible to determine accurate lower safety limits. For this reason the best guidance can only be given by toxicologists familiar with the background human and animal data. The figures presented have been derived in this way, and are very similar to those proposed by an expert panel of toxicologists in an International Standards Committee (ISO/TC992/SC3). Concerns have been expressed from some quarters that the proposed limits are too low for application to practical fire safety engineering and provide too wide a limit of safety. An important point to consider in this context is that the proposed tenability limits are designed to be applied at the breathing zone of a potential building occupant and not at the fire source. In a fire scenario, it is likely that some time will elapse from ignition to the time these tenability limits are breached in the breathing zone of a building occupant some distance from the fire source. With regard to the actual limits used, these have been chosen in the context of escape and survival in an emergency situation, and are considerably in excess of hygiene levels. Even with regard to emergency situations, other expert groups of toxicologists have proposed similar or even lower tenability limits. One set of limits developed for dangerous acute exposures in an industrial context by the American Industrial Hygiene Association is the Emergency Response Planning Guidelines (ERPG). These are expressed in term of three limit levels, two of which are relevant to survival in emergencies such as fires. These are

ERPG-3: maximum levels designed to prevent death

ERPG-2: maximum levels below which nearly all individuals could be exposed for up to one hour without experiencing or developing irreversible or other serious health effects or symptoms that could impair an individual's ability to take protective action

For irritant gases, there are two issues: concentrations at which individuals are likely to experience serious health effects or symptoms likely to impair escape or ability to take protective action, and exposure doses which might cause life threatening health effects. For example, with respect to hydrogen chloride:

ERPG-2 set at 20 ppm on the basis that >20 <100 ppm would be expected to cause serious eye and respiratory tract irritation (which might impair an individual's ability to take protective action). This reflects the immediate effect of exposure concentration.

ERPG-3 set at 100 ppm on the basis that exposure exceeding this level for one hr may be expected to produce severe health effects such as pulmonary edema and possibly death in a heterogeneous human population. This reflects the effect of an exposure dose. The same principle applies to the other irritant gases.

In the context of ability to escape from a fire, the ERPG-2 level would therefore represent the appropriate tenability limit. This is, in fact, an order of magnitude more stringent than the design tenability limit proposed here for fire engineering design. It is considered that although 20 ppm HCl would be sufficiently irritant to adversely affect most people, it is unlikely that concentrations as low as this would seriously inhibit the ability of most people to perform the actions necessary to escape from a fire. On this

Table 2-6.12 ***Irritant Concentrations of Common Fire Gases***

Gas	Concentration Predicted to Impair Escape in Half the Population (ppm)	Concentration Predicted to Cause Incapacitation in Half the Population (ppm)
HCl	200	900
HBr	200	900
HF	200	900
SO_2	24	120
NO_2	70	350
CH_2CHO (acrolein)[a]	4	20
HCHO (formaldehyde)[a]	6	30

[a]Where the concentrations of acrolein and formaldehyde (or other important irritants) are unknown, a term derived from smoke density 0.5 OD/meter may be used as an indication of irritancy likely to impair escape efficiency.

basis, the higher concentration of 200 ppm is proposed as a tenability limit for the average person, although it is likely that a proportion of the population might suffer some degree or impairment at lower concentrations as indicated in Figure 2-6.25. Table 2-6.13 shows the ERPG levels for some sensory irritants commonly occurring in fire atmospheres.[107]

The other important effect of irritants is that a proportion of those inhaled penetrate into the deep lung. If a sufficient dose is inhaled over a period of time, a lung inflammatory response can occur, usually some hours after exposure. The deep-lung effects of irritants may be increased by the presence of smoke particulates. This may cause respiratory failure and death, or permanent lung damage in survivors. The 30-min exposure doses (30-min exposure LC_{50} concentrations multiplied by 30) likely to be lethal for each irritant gas are as shown in Table 2-6.14.

The effects depend upon the exposure dose, which can be quantified approximately in terms of the product of concentration (c) and exposure time (t) to give the ct product exposure dose (ppm·min). During a fire, when the concentrations of the toxic products vary with time, it is possible to predict when an incapacitating or lethal dose has been received by using the FED method. For this method the ct product doses for small periods of time during the fire are expressed as a fraction of the dose causing a toxic effect, and these FEDs are summed until the fraction reaches unity, when the toxic effect is predicted. The fraction of a lethal dose (FLD) for each irritant is calculated as the ct product exposure dose during a period in the fire (for example in ppm·min) expressed as a fraction of the lethal exposure dose. The lethal effects of the different irritants are assumed to be additive on the same basis as the irritant effects, so that the total FLD_{irr} for each time period is given by Equation 22:

$$FLD_{irr} = FLD_{HCl} + FLD_{HBr} + FLD_{HF} + FLD_{SO_2} + FLD_{NO_2} + FLD_{CH_2CHO} + FLD_{HCHO} + \Sigma FLD_x \quad (22)$$

where ΣFLD_x = FLDs for any other irritants present.

The FLD_{irr} for short periods of time during the fire are summed until the FLD_{irr} reaches unity, when it is predicted that a lethal dose has been inhaled.

Table 2-6.13 ***Emergency Response Planning Guidelines for Common Fire Irritants***

Definition	HCN	HCl	HF	Acrolein	Formaldehyde
ERPG-3 (ppm) The maximum airborne concentration below which is believed that nearly all individuals could be exposed for up to 1 hr without experiencing or developing life threatening health effects	25	100	50	3	25
ERPG-2 (ppm) The maximum airborne concentration below which is believed that nearly all individuals could be exposed for up to 1 hr without experiencing or developing irreversible or other serious health effects or symptoms that could impair an individual's ability to take protective action	10	20	20	0.5	10
ERPG-1 (ppm) The maximum airborne concentration below which is believed that nearly all individuals could be exposed for up to 1 hr without experiencing other than mild, transient adverse health effects or without perceiving a clearly defined objectionable odor	na	3	5	0.1	1

Table 2-6.14 ***Lethal Exposure Doses of Irritants Contributing to Asphyxia and Lung Damage[106]***

Gas	Exposure Doses Predicted to Be Lethal to Half the Population (ppm·min)
HCl	114,000
HBr	114,000
HF	87,000
SO_2	12,000
NO_2	1,900
CH_2CHO (acrolein)[a]	4,500
HCHO (formaldehyde)[a]	22,500

[a]where the concentrations of acrolein and formaldehyde (or other important irritants) are unknown, a term derived from smoke density and time of 90 OD/m·min may be used as an indication of lethal organic irritant exposure dose

Chemical Composition and Toxicity of Combustion Product Atmospheres

In the preceding sections the effects of individual asphyxiant gases and irritant chemical products known to occur in fires have been described together with their interactions. In this section the occurrence of these products in large-scale fires and laboratory-scale thermal decomposition experiments and the extent to which the toxicity can be interpreted in terms of these common products will be examined. In the next section the application of these data to fire scenarios and the interpretation of fire victim statistics will be examined.

From the point of view both of product composition and toxic hazard, it is possible to distinguish four basic types of fire situations.

1. Nonflaming thermal decomposition/smoldering fires
2. Early/developing flaming fires
3. Small oxygen vitiated flaming fires
4. Fully developed or post-flashover fires

The work of Woolley and his colleagues at the U.K. Fire Research Station[17] has shown that at midrange temperatures (400 to 700°C) such as those found in smoldering fires or in the vicinity of early flaming fires, materials are decomposed into pyrolysis products and oxidation fragments containing a mixture of asphyxiant and irritant gases and particulates. Under these conditions the highest yields of a variety of potentially toxic products are formed (Tables 2-6.9 and 2-6.15), and since incomplete oxidation is favored, CO yields are high with CO_2:CO ratios approaching unity. For many materials the product mix remains fairly constant over this temperature range, although the yields may increase somewhat with temperature.

Once flaming occurs, the high-temperature well-oxygenated flames of early flaming fires consume most of these combustion products to form simple, mostly innocuous products such as carbon dioxide and water. The CO_2 to CO ratios are very high initially, even up to the 500 to 1000 range. Since CO is only approximately 10 to 50 times as toxic as CO_2, it is conceivable that in this type of fire CO_2 could present more of a toxic hazard than CO. However, as the CO_2 concentration in the fire compartment approaches 5 percent and the O_2 concentration decreases towards 15 percent, the combustion becomes less efficient and the CO_2 to CO ratios decrease to the region of 50 to 100, CO becoming a more important toxic factor. Nevertheless, as Figure 2-6.15 shows, the atmosphere obtained in a rapidly growing fire can contain asphyxiant concentrations of CO_2 (>5 percent), CO (>1000 ppm) and low oxygen (<15 percent O_2). With such flaming fires, the yields of irritant, oxidized fragments and of CO are generally lower than under nonflaming conditions. However, due to the rapid growth and development of such fires the rate of production of these toxic products is often very high. Another factor that has been found to influence the yield and rate of production of toxic products (at least in small-scale experiments)[37,106,108] is the efficiency of combustion. When materials burn with efficient, nonsmoky flames, most CO, HCN, and organic irritants are consumed so the resultant atmosphere is relatively nontoxic. However immediately after ignition, and during intermittent flaming of some materials when combustion is inefficient and smoke production tends to be high, it has been found that high yields of CO, HCN, and irritants are produced, giving highly toxic atmospheres.

Under the severe conditions found in high temperature postflashover fires (exceeding 800°C) where oxygen concentrations are low, there is a major qualitative change in decomposition in that the main pyrolysis products break down into low molecular weight fragments and can contain high concentrations of asphyxiant substances such as CO and HCN, with low CO_2 to CO ratios. (See Table 2-6.15.)

Chemical product formation and the resultant toxicity can vary in different types and stages of fires,[16] as shown in a series of experiments. In the experiments, a number of materials were decomposed under a range of temperatures and oxygen supplies designed to simulate some of the conditions described previously. In one series of experiments, a study was made of the effects of temperature on the pyrolysis of three materials—polyacrylonitrile, flexible polyurethane foam, and wood. These were decomposed at 300, 600, and 900°C to cover as far as possible the full temperature range known to occur in fires, simulating conditions where oxygen supply might be limited. Another set of experiments were then carried out on a further range of polymers to examine the effects of nonflaming and flaming oxidative decomposition on toxicity over midrange temperatures (440 to 700°C). These conditions were chosen to embrace the conditions known to give the greatest complexity of products, particularly with polymers that are known to be sensitive to oxidation in product formation. In this series the test materials were rigid polyurethane foam, polypropylene, polystyrene,

Table 2-6.15 ***Classification of Toxic Hazards in Fires as Revealed by Large-Scale Fire Simulation Tests***

Fire	Rate of Growth	CO_2/CO	Toxic Hazard	Time to Incapacitation	Escape Time Available
1. Smoldering/nonflaming: victim in room of origin or remote	Slow	≃1	CO 0 to 1500-ppm low O_2 15 to 21% irritants, smoke	Hours	Ample if alerted
2. Flaming: victim in room of origin	Rapid	1000 decreasing toward 50	CO 0 to 1% CO_2 0 to 10% low O_2 10 to 21% irritants, heat, smoke	A few minutes	A few minutes
3. Small vitiated flaming: victim in room of origin or remote	Rapid, then slow	<10	CO 0.2 to 4% CO_2 1 to 10% O_2 < 12% irritants, heat, smoke	A few minutes	A few minutes
4. Fully developed: (Post-flashover) victim remote	Rapid	<10	CO 0 to 3%[a] HCN 0 to 500 ppm some irritants, smoke, and possibly heat	<1 min near fire, elsewhere depends on degree of smoke dilution	Escape may be impossible, or time very restricted. More time at remote locations

[a]Concentrations depend on position relative to fire compartment.

and nylon. In all cases, the sublethal toxic effects of exposure were evaluated using primates.

With the series of pyrolysis experiments, it was found that up to midrange temperatures a rich product mix occurred, while at 900°C clear atmospheres containing high yields of simple, low molecular weight products occurred. Thus for wood, which contains oxygen in its structure, the principal products at lower temperatures were oxidized organics, which caused upper respiratory tract and lung irritancy. There was a relatively low CO yield with wood, causing signs of asphyxia at sufficiently high wood nominal atmosphere concentrations. Polyacrylonitrile produced relatively low yields of HCN and other nitriles, causing signs of cyanide intoxication.[16] With the flexible polyurethane foam, the lower-temperature atmospheres consisted principally of a dense yellow isocyanate smoke which was a powerful lung irritant capable of causing severe pulmonary inflammation after exposure.[16,80,109,110] Low yields of CO and HCN resulted with this foam.

At 900°C, the isocyanate smoke from flexible polyurethane foam was destroyed, giving a clear atmosphere consisting mainly of HCN and CO, the main signs being of cyanide poisoning. Polyacrylonitrile also produced high yields of HCN, causing cyanide intoxication, and wood produced clear atmospheres consisting principally of CO.

An example of the effects of oxidation on product formation and toxicity is given by the effects of polypropylene decomposition products. Under pyrolytic conditions, polypropylene decomposed to give a nontoxic atmosphere consisting of hydrocarbon fragments. (See Table 2-6.9.) Under nonflaming oxidative conditions, some of these fragments are oxidized to form a highly irritant atmosphere that caused upper respiratory tract and lung irritation during exposure and severe pulmonary inflammation after exposure.[16,80] There were also minor signs of CO-induced asphyxia. Under flaming conditions the pyrolysis and oxidation products were partially destroyed, with the most important products being carbon monoxide, carbon dioxide, water, and some irritants. The principal toxic effect of this atmosphere was CO intoxication with some signs of irritancy. With flaming atmospheres, however, the nature and degree of toxicity depends upon the efficiency of combustion. By varying the decomposition conditions it is possible to substantially alter the toxicity.

From the animal exposures to these thermal decomposition and combustion product atmospheres, the major findings were that despite the great complexity in chemical composition of the test atmospheres, the basic toxic effects were relatively simple. For each individual atmosphere, the toxicity was always dominated either by a asphyxiant gas (CO or HCN) or by irritants. The toxicity of each atmosphere was therefore basically that of the major component that was present at its most toxic concentration. For asphyxia, the effects of individual atmospheres were virtually identical to those of either CO or HCN as individual gases at the same concentrations as they were present in the smoke atmosphere.

There were some minor exceptions. For those atmospheres containing HCN, the asphyxia appeared to be marginally less than that for an equivalent HCN/air atmosphere. However, the asphyxiant effects of atmospheres containing CO were identical to those of equivalent CO/air mixtures. The presence of low concentrations of hydrocarbons (which are potentially asphyxiant at high concentrations) and of CO_2 in the 1000 to 7000 ppm range did not contribute to the asphyxia. The effects of irritant products on respiratory patterns for primates did not affect the pattern of CO or HCN asphyxia. There may have been a marginal additive effect of CO on HCN toxicity, but in these cases the pattern of asphyxia and times to incapacitation were very similar to those produced by equivalent HCN/air mixtures. Irritant effects did, of course, occur in these exposures in conjunction with asphyxia, but there was no interaction between them, in that irritancy did not affect the progress of asphyxia, and asphyxiant gases did not affect the response to irritants.

Implications for Human Asphyxiation Models for Fire Exposures

As a result of this work, it can be stated with some confidence that the asphyxiant effects of fire atmospheres should be predictable on the basis of the common asphyxiant gases CO, HCN, low O_2, and CO_2, and that the models derived from the work on individual gases should be valid. It is not possible with current knowledge to predict exactly the potential of a fire atmosphere to cause sensory irritation or lung inflammation from a chemical analysis of the product composition, but the model presented is considered a reasonable best estimate.

Smoke

Smoke comprises the total effluents from a fire and consists of two parts: the invisible vapor phase and the visible particulate phase. From a toxicological standpoint, all of the asphyxiant fire products occur in the vapor phase, while irritant products may occur in both phases. The particulate phase consists of solid and liquid particles covering a wide range of particle sizes, depending upon the nature and age of the smoke. These particles may contain condensed liquid or solid irritant products; or irritant products including gaseous ones may be dissolved in liquid particles (as in acid mists), or be absorbed onto the surface of solid, carbonaceous particles. Particle size is of great toxicological importance since it determines how "deeply" particles penetrate into the respiratory tract and the patterns of subsequent deposition. Particles with a mean aerodynamic diameter of less than 5 μm are capable of penetrating deep into the lung, while larger particles tend to deposit in the nasal passages and upper airways. Generally speaking, the smoke from smoldering or nonflaming decomposition tends to consist mainly of small particles (less than 1 μm mean aerodynamic diameter, as in cigarette smoke) which are highly respirable. Smoke from flaming fires contains larger particles, particularly as it ages and the particles agglomerate; however, reports on fire victims usually record smoke penetration well into

the lung.[49] At very high concentrations, smoke deposits may physically clog the airways. This could occur even with biologically inert particles at concentrations in excess of 5 mg/L, and is more probable with irritant smoke particles that are likely to acutely inflame tissues. Apart from the toxic effects of these particles on the lung, they may also be important in increasing the thermal capacity of the smoke and increasing the likelihood of lung burns (see next section of this chapter).

The Exposure of Fire Victims to Heat

There are three basic ways in which exposure of fire victims to heat may lead to incapacitation and death: by (1) heat stroke, (2) body surface burns, and (3) respiratory tract burns.

Heat Stroke (Hyperthermia)

If a subject is exposed to a hot environment, especially if the humidity is high and the subject is active, there is a danger of incapacitation and death due to hyperthermia. The time to effect and the type of hyperthermia depend principally upon the heat flux to which the subject is exposed, and are greatly affected by factors such as the amount and type of clothing and degree of work performed. A detailed analysis of the parameters that determine heat transfer to subjects over a range of environmental conditions and levels of activity, and the protective effects of different types of clothing, is given by Berenson and Robertson,[111] and Simms and Hinkley.[112]

Simple hyperthermia involves prolonged exposure (approximately 15 minutes or more) to heated environments at ambient temperatures too low to cause burns. Under such conditions, where the air temperature is less than approximately 120°C for dry air or 80°C for saturated air, the main effect is a gradual increase in the body core temperature.[113] Increases above the normal core temperature of 37°C up to approximately 39°C are within the physiological range and can occur at normal ambient temperatures during hard exercise, but once 40°C is reached consciousness becomes blurred and the subject becomes seriously ill. Further increase causes irreversible damage, with temperatures above 42.5°C being fatal unless treated within minutes.[111,114] The time taken to reach such a state depends upon a number of variables including those mentioned. Figure 2-6.26, adapted from Blockley,[80] shows approximate tolerance times for unclothed subjects at rest, under conditions of low air movement (30 m/min). At temperatures below 120°C tolerance is limited by hyperthermia, whereas above this temperature pain followed by burns become important. The data points A to D (for clothed subjects) were taken from various authors, and are added for comparison. At temperatures below 120°C evaporative cooling from sweat is important, so that humidity has a considerable influence on tolerance time. Clothing, therefore, offers some immediate protection at temperatures above 120°C, but at lower temperatures may reduce tolerance time by impeding heat loss due to evaporative cooling. Details of the data points and authorship are given in Table 2-6.16.

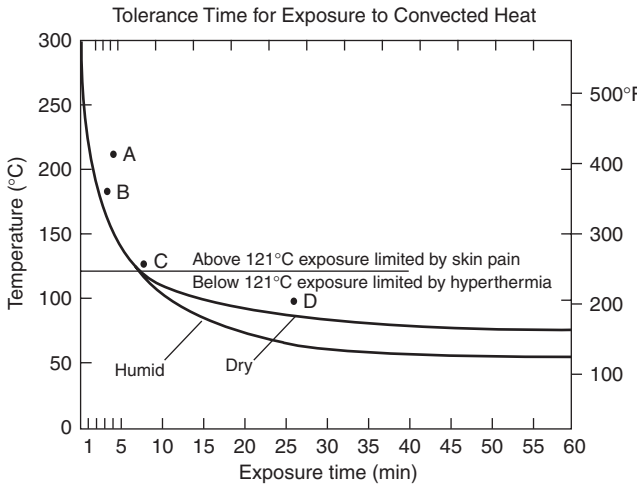

Figure 2-6.26. ***Thermal tolerance for humans at rest, naked skin exposed, with low air movement (less than 30 m/min). Adapted from Blockley.[113] See text and Table 2-6.16 for discussion of data points A to D.[112,115,116]***

Experiments conducted with pigs by Moritz et al.[118] confirm the basic signs of hyperthermia, with death occurring principally due to circulatory collapse associated with severe cardiac irregularities (ventricular tachycardia).

A second situation described by Moritz et al.[118] involves exposure to high temperatures for short periods (less than 15 minutes), and here hyperthermia is accompanied by cutaneous burns (in pigs at temperatures above 120°C). When deaths occurred soon after exposure to severe heat (within 30 minutes) the cause was considered to be due not to burns but to a rise in blood temperature. In

this situation the exposure duration was insufficient to raise the body core temperature greatly, but if the temperature of the blood in the heart reached 42.5°C, the animal died within a few minutes from circulatory collapse.

It therefore seems that a victim exposed for more than a few minutes to high temperatures and heat fluxes (exceeding 120°C) in a fire is likely to suffer burns and die either during or immediately after exposure, due principally to hyperthermia. Victims surviving the hyperthermia phase may die later due to burns of the upper respiratory tract, particularly the larynx, or due to the secondary effects of skin burns. A victim or fire fighter exposed to temperatures unlikely to cause burns (less than 120°C) may also suffer heat stroke after a prolonged exposure (exceeding 15 min), especially if the humidity is high and the person is working hard.

Skin Burns

According to Buettner,[119] pain from the application of heat to the skin occurs when the skin temperature at a depth of 0.1 mm reaches 44.8°C, which agrees with the finding of Lawrence and Bull[120] that discomfort was experienced when the interface between a hot handle and the skin of the hand reached 43°C. The sensation of pain is followed soon afterward by burns, causing incapacitation, severe injury, or death depending upon their severity. The time from the application of heat to the sensation of pain, and from pain to the occurrence of burns of various degrees of severity, depends upon the temperature, or more properly, the heat flux to which the skin is exposed. The effects of heating the skin are essentially the same whether the heat is supplied by conduction from a hot body, convection from air contact, or by direct radiation.[119,121] Curves for the relationship between time and effect have been published for conducted heat from a "hot handle"[121] and radiant heat. The relationship between time and effect is exponential. (See Figure 2-6.27.) Thus for conduction from heated metal at 60°C, pain occurs after 1 s and a burn after 10 s, while at 80°C pain occurs at 100 ms and a burn after 1 s contact.

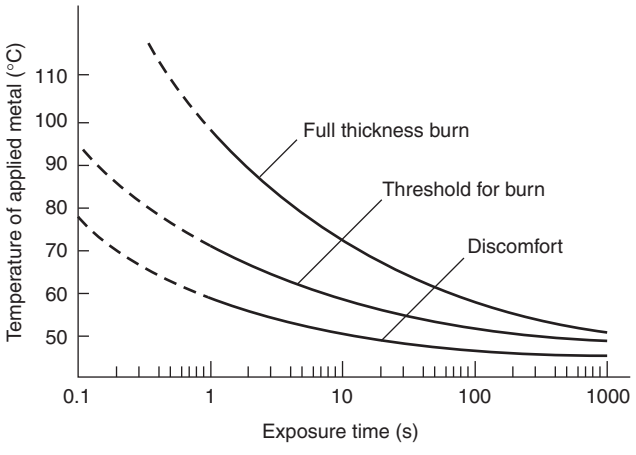

Figure 2-6.27. ***The relation between time and the temperature of metal to cause thermal injury to skin (values below 1 s are extrapolated).[121]***

Pain therefore occurs when the difference between the rate of supply of heat to the skin surface exceeds the rate at which heat is conducted away by an amount sufficient to raise the skin temperature to 44.8°C. The thermal inertia of human skin is similar to that of water[119] or wood[121] with a value of $k\rho c$ for the surface (depth 0.1 mm) of 1.05 W/m·K. For the skin surface the rate of heat removal is not considered to be affected by blood supply[119] except for the fingertips, where blood flow may be sufficient to remove a significant amount of heat.[119] However, blood supply may have some effect on the occurrence of burns, especially to the deeper layers of the skin.[121] Obviously, rates of heating and the occurrence of pain and burns are greatly affected by the extent and type of clothing,[112,118,122] but only effects on naked skin are considered here. The temperature increase of the skin for the situation in which constant radiant heat is absorbed by the upper surface of the skin, or heat from a hot air current is applied to the skin, may be calculated as follows:[119]

$$T - T_0 = \frac{2Q\sqrt{t}}{\sqrt{\pi k\rho c}} \tag{25}$$

where

T = final temperature of skin at 0.1 mm depth
T_0 = starting temperature of skin at 0.1 mm depth
Q = heat supply (W/m²)
$k\rho c$ = 1.05 W/m·k
t = time (s)

Conducted heat: The effect of conducted heat is related to the temperature of the hot object and its thermal inertia, depending upon the interface temperature between the object and the body tissue at the skin surface,[121,122] as illustrated by the examples in Table 2-6.17.

A skin temperature of 43°C causes pain and some cellular damage, while a temperature of 60°C coagulates tissue protein. A brass block heated to 60°C will produce a partial thickness skin burn within 10 s, pain within 1 s and a full thickness burn after approximately 100 s.[121] The time/temperature relationships for these effects of conducted heat are shown in Figure 2-6.27.

Convected heat: For a victim attempting to escape from a fire, the most important sources of heat exposure are ra-

Table 2-6.17 ***Theoretical Contact Temperatures between Skin at 35°C and a Selection of Hot Bodies at 100°C[121]***

diation from hot areas and convection from hot gases. Pain and the likelihood of skin burns occur at air temperatures above approximately 120°C. The rate of heat transfer from hot air to the skin depends upon the rate of ventilation, humidity, and the protective value of clothing as well as air temperature. The effects of these parameters are described by Berenson and Robertson,[111] and Simms and Hinkley.[112] However, for unprotected areas such as the head, data on naked skin are relevant, and the data shown in Figure 2-6.26 for temperatures above 120°C provide limits for tolerance to the painful effects of contact with hot air.

Apart from the problem of hyperthermia, dry air has been tolerated by humans as shown in Table 2-6.16. Moritz et al.[118] state that dry air at 300°C injured unprotected skin within 30 s in pigs and dogs. Pigs also suffered burns at 150°C after 100 s and after 400 s at 100°C. However, it was considered that humans would be more resistant to burns, especially at temperatures below 120°C, due to the protective effect of sweating. Air with a high level of humidity not only reduces or prevents heat loss through sweat, but also delivers more heat to the skin. Thus Moritz et al.[123] found that steam at 100°C destroyed the epidermis of dogs within a few seconds.

Figure 2-6.26 shows curves for tolerance time of convected heat for both dry and humid air. A search for the original data used to produce these curves has not been successful, but upon careful consideration it seems likely that the humid curve must represent air that was humid (perhaps saturated) at *room* temperature, which was then heated subsequently, and was therefore nowhere near saturated with water vapor at higher temperatures. This must be the case because the capacity of air for water vapor increases dramatically at temperatures above 60°C, so that the amount of deliverable latent heat also increases. In practice, 60°C has been found to be the highest temperature at which 100 percent water-vapor saturated air can be breathed. Since all fires produce a considerable amount of water from combustion, it is possible that the presence of water vapor may be an important neglected hazard in fires.

Radiant heat: For radiant heat, clothing also greatly influences tolerance times, but again, data on naked skin are relevant to exposure of unprotected areas such as the head. Figure 2-6.28,[111] shows the relationship between time to skin pain and radiant heat flux. Data points A to E, taken from a number of authors (detailed in Table 2-6.18) have been added for comparison. Points B through E agree with the curve presented by Berenson, but data from one source (Perkins et al.)[124] (points labeled A) deviate somewhat from the rest. From Perkins's data (which were produced by experiments where thermal injury was caused by exposing subjects to radiant heat from a searchlight), the heat fluxes for erythema (reddening of the skin said to coincide with pain[121]) appear rather higher than the heat flux limits for pain supplied by the other authors. This is possibly due to differences in the wavelength, and thus degree of penetration, of the radiation.[119] The searchlight data do, however, show the relationship between time to erythema, time to partial skin burn, and time to full thickness skin burn. The shape of the radiant heat tolerance curve suggests a fairly obvious tolerance limit for exposure to radiant heat of 0.25 W/cm² (2.5 kW/m²) which is that suggested by Babrauskas.[56]

Consequences of body surface burns: Apart from the immediate pain caused by exposure to heat and by skin burns, as well as the accompanying psychological shock and fear, incapacitation may result from body surface burns during or after a fire due to physiological shock. In this situation loss of body fluids into the burn results in circulatory failure and a fall in blood pressure, which may lead to collapse and even loss of consciousness.[14,118] The immediate effect of burns and the later chances of recovery depend upon a number of factors such as the site and extent of the burn, the depth of the burn, the age of the victim, and the treatment received.[121] While victims may continue to function for some time with severe burns, and survivals have occurred with up to 80 percent body surface area burns,[121] in general, if 35 percent or more of the body surface area is burned the chances of survival are low. Young adults generally have the best chance of survival, with a 50 percent chance of surviving a 50 percent body surface area burn, while children and old people are the most vulnerable, with a 50 percent chance of surviving a 20 percent body surface area burn in the elderly.[14,121] The depth of burn is classified on a scale of six degrees. First-, second-, and third-degree burns involve damage to the skin from which it can recover, while fourth-degree burns require skin grafts. Fifth- and sixth-degree burns involve destruction of muscle and/or bones, respectively.[14] Another scheme classifies burns as partial thickness skin burns, which will heal, or full thickness burns, which require grafts.[121]

If the victim survives the initial period of shock, death may occur over a period of up to a few weeks due to secondary effects on the brain, heart, lungs, liver, and kidneys.[14] The most common secondary effect and cause of death involves the lungs,[14,126–128] consisting of pulmonary edema resulting from effects on the circulatory system secondary to shock and metabolic acidosis. Post-exposure treatment to replace body fluids and control acidosis are important in improving the prognosis for survival. If the victim survives the respiratory distress resulting from edema during the first week after exposure, pneumonia may then develop as a further, possibly fatal complication.[14,129–131]

This fatal damage to the lungs may occur following body surface burns when there has been no inhalation of heat or toxic gases. In many fire victims, however, damage to the respiratory tract and lungs results from a combination of all three causes.[14,129–131]

Thermal Damage to the Respiratory Tract

Thermal (as opposed to chemical) burns to the respiratory tract never occur in the absence of burns to the skin of the face.[81,131] Heat damage to the respiratory tract is even more dependent upon the humidity of inhaled hot gases than are skin burns. As a result of the low thermal capacity of dry air and the large surface area of the airways, which are lined with a wet surface and good blood supply, thermal burns are not induced by dry air below the top of the trachea. However, steam at around 100°C is capable of causing severe burns to the entire respiratory tract down to the deep lung, due to its higher thermal capacity and the latent heat released during condensation. These effects of inhaled hot gases are demonstrated by the work of Moritz et al.[118] in which anesthetized dogs and pigs breathed hot air, flame from a burner, or steam, supplied through a cannula to the larynx. Dry air at 350°C and flame from a blast burner at 500°C caused damage to the larynx and trachea, but had no effect on the lung, while steam at 100°C caused burns at all levels. In these experiments the most important site of damage was the larynx, and death resulted from obstructive edema of the laryngopharynx within a few hours of exposure. This work was taken further by Zikria[131] using steam burns in dogs, induced by a 15 s application of steam at 100°C via an endotracheal tube. The animals survived the initial effects and a number of phases of reaction were observed. The first phase consisted of necrosis and edema in the tracheobronchial airway, and early lung parenchymal edema within one hour. This was followed by increasing parenchymal edema, sloughing of the mucosa, and collapse of lung segments. The next phase after 24 hours consisted of bronchopneumonia behind respiratory tract obstructions.

All these features occur in fire victims, but it is difficult to separate the effects of thermal inhalation burns from edema and inflammation due to burns caused by irritant chemical smoke products, or edema secondary to body surface burns, all of which may be involved.[14,129–131] Thus fire victims with facial burns subjected to endoscopy have been found to have burns well into the respiratory tract.[81] If these lesions are caused by heat, it would imply that fire atmospheres resemble steam rather than dry air in terms of their thermal capacity. However, it is possible that such lesions are caused by chemical smoke irritants, which have been shown to produce fatal pulmonary edema and inflammation in the absence of heat.[80] Unfortunately, data on the thermal capacity and latent heat of actual fire atmospheres are not readily available, although it may be possible to calculate probable values from a knowledge of fire atmosphere temperature and composition.

The situation is therefore complicated, but from a fire engineering standpoint a number of basic points may be useful.

1. Thermal burns to the respiratory tract will not occur unless the air temperature and/or humidity are sufficient to cause facial skin burns.
2. Dry air at around 300°C may cause burns at the larynx after a few minutes. This may result in life-threatening obstructive edema of the larynx within an hour if not treated, although damage to the deeper structures of the lung is unlikely. It is possible that such laryngial burns may occur at lower temperatures down to approximately 120°C depending upon the duration of exposure, and breathing dry air at these temperatures would be painful. Laryngial burns followed by obstructive edema are common findings in fire victims, and are important causes of incapacitation and death during and immediately after fires.[14,129–131]
3. Humid air, steam, or smoke with a high thermal capacity or latent heat (due to vapor content or suspended liquid or solid particles) may be dangerous at temperatures of around 100°C, causing burns throughout the respiratory tract. It may be possible to predict the likely effects of hot-smoke atmospheres if thermal capacity or latent heat were measured.

4. In practice, fire victims may be affected by the inhalation of chemically irritant smoke, by hot humid gases, and by the secondary effects on the lung of body surface burns, all of which may combine to cause fatal respiratory tract lesions during the hours, days, or weeks following the fire exposure. However, these effects are probably less likely to be fatal during exposure to the fire atmosphere over periods of less than 30 minutes.
5. Heat flux and temperature tenability limits designed to protect victims from incapacitation by skin burns should be adequate to protect them from burns to the respiratory tract.

Model of the Prediction of Time to Incapacitation by Exposure to Heat in Fires

There are three basic ways in which exposure to heat may lead to incapacitation: through heat stroke (hyperthermia), skin pain and burns, or respiratory tract burns. Thermal burns to the respiratory tract from air containing less than 10% by volume water vapor do not occur in the absence of burns to facial skin. Therefore, tenability limits with regard to skin pain and burns are normally lower than for thermal burns to the respiratory tract. Thermal burns to the respiratory tract may occur upon inhalation or air above only 60°C when saturated with water vapor, as may occur when water is used for fire extinguishment.

The tenability limit for exposure of skin to radiant heat is approximately 2.5 kW/m^2, below which exposure can be tolerated for at least several minutes. Radiant heat at this level and above causes skin pain followed by burns within a few seconds, but lower fluxes can be tolerated for more than 5 min. For situations where occupants are required to pass under a hot smoke layer in order to escape, this radiant flux corresponds approximately to a hot layer temperature of 200°C. Above this threshold, time (minutes) to incapacitation due to radiant heat $t_{I\text{rad}}$, at a radiant flux of q kW/m^2, is given by Equation 26.[132,133]

$$t_{I\text{rad}} = \frac{133}{q^{1.33}} \tag{26}$$

The effects of heat on an occupant response may depend upon the situation. The threshold for pain occurs at approximately 1.333–1.667 (kW·m^{-2})$^{4/3}$ min, second degree burns at 4–12.17 (kW·m^{-2})$^{4/3}$ min and third degree burns at approximately 16.667 (kW·m^{-2})$^{4/3}$ min. Radiant heat tends to be directional in fires, so that the main problem tends to be local heating of particular areas of skin. The air temperature, and hence that of the air breathed and that in contact with other parts of the body, may be relatively low, even when the radiant flux is high. For this reason the main hazard is pain and burns to the skin, rather than hyperthermia. Skin temperature depends upon the relationship between the rate of heat supply to the skin surface and the removal of heat from inner layers by the blood. There is, therefore, a threshold radiant flux below which significant heating of the skin is prevented, but above which rapid heating of the skin occurs.

For exposures of up to two hours to convected heat from air containing less than 10% by volume of water vapor, the time (min) to incapacitation $t_{I\text{conv}}$ at a temperature T (°C) is calculated from Equation 27, which is derived from Figure 2-6.26.

$$t_{I\text{conv}} = 5 \times 10^7\, T^{-3.4} \tag{27}$$

As with toxic gases, the body of a fire victim may be regarded as acquiring a "dose" of heat over a period of time during exposure, with short exposure to a high radiant flux or temperature being more incapacitating than a longer exposure to a lower temperature or flux. The same fractional incapacitating dose model as with the toxic gases may be applied and, providing that the temperature in the fire is stable or increasing, the fractional dose of heat acquired during exposure can be calculated by summing the radiant and convected fractions using Equation 28:

$$\text{FED} = \sum_{t_1}^{t_2} \left(\frac{1}{t_{I\text{rad}}} + \frac{1}{t_{I\text{conv}}} \right) \Delta t \tag{28}$$

Note: $t_{I\text{rad}}$ will tend to zero as q tends to <2.5 kW/m^2

Thermal tolerance data for unprotected skin of humans suggest a limit of about 120°C for convected heat, above which considerable pain is quickly incurred along with the production of burns within a few minutes. Depending upon the length of exposure, convective heat below this temperature may still result in incapacitation due to hyperthermia. Examples of tolerance times to different radiant fluxes and air temperatures are shown in Table 2-6.19. Conducted heat is physiologically important only when skin is in contact with hot surfaces, such as door handles. A 1-s contact with metal at 60°C can cause burns.

Example of a Calculation of Time to Incapacitation for Physical Fire Parameters and Irritancy

In a previous section the single armchair room burn shown in Figure 2-6.15 was used to illustrate how the model for prediction of asphyxiation could be applied to a practical fire scenario. To complete the incapacitation model it is necessary to include calculations for the effects of physical parameters (heat, smoke optical density), and mass loss concentration as an indication of irritancy. The curves for radiant heat, air temperature, smoke extinction

Table 2-6.19 ***Limiting Conditions for Tenability Caused by Heat[106]***

Mode of Heat Transfer	Intensity	Tolerance Time
Radiation	<2.5 kW·m^{-2}	>5 min
	2.5 kW·m^{-2}	30 s
	10 kW·m^{-2}	4 s
Convection	<60°C 100% saturated	>30 min
	100°C <10% H_2O[a]	12 min
	120°C <10% H_2O	7 min
	140°C <10% H_2O	4 min
	160°C <10% H_2O	2 min
	180°C <10% H_2O	1 min

[a] v/v

coefficient, and mass loss during the first ten minutes of the armchair burn are shown in Figure 2-6.29.

Of the physical factors likely to affect a victim during the fire exposure, the majority are basically concentration or intensity-related rather than dose-related, and for these factors tenability limits have been set (radiant heat, smoke optical density, and sensory irritancy). The other two factors, convected heat and lung irritancy, are primarily dose-related, but lung irritant effects are likely to be relatively minor until after exposure. This leaves the fractional incapacitating dose of convected heat to be calculated. The average temperatures per minute during the first minutes of the fire are shown as histograms in Figure 2-6.29 with Table 2-6.20 showing the fractional incapacitating dose calculation.

Convected heat: The effects of exposure to convected heat increase dramatically in this type of fire as shown in Figure 2-6.29. Incapacitation, mainly due to skin pain and burns, is predicted sometime during the fourth minute, when the air temperature is 220°C. The situation then rapidly worsens, and it would seem likely that severe and probably fatal burns or fatal hyperthermia would be sustained by any victim remaining in the fire during the fifth minute. Even if the victims were protected to some extent by clothing, they would sustain burns to the face and probably fatal burns to the larynx. The occurrence of lung burns would depend on the thermal capacity (principally the latent heat) of the smoke.

Radiant heat: From Figure 2-6.29, it would seem that the effects of radiant heat would be relatively minor in this fire compared to the effects of convected heat. The radiant heat peaks at just above 3kW/m^2 during the sixth minute, and therefore just exceeds the tenability limit. Nevertheless, the radiation alone would probably be sufficient to cause some burns and seriously inhibit escape during the sixth minute, and there would almost certainly be some degree of additive effect with convected heat.

Smoke: From the point of view of its obscurational effects, incapacitation by smoke is concentration-related rather than dose-related. For this series of chair burns, Babrauskas sets a tenability limit of extinction coefficient 1.2/m (OD/m 0.52).[56] This would give approximately 2 m visibility, which should be adequate for escaping from a room, and could be used as a tenability limit for input into the model. Incapacitation due to visual obscuration would occur at the end of the second minute. The smoke curve is rising very steeply at this point, with an OD/m of 1 at the beginning of the third minute. Escape would therefore become extremely difficult, and certainly slow during the third minute, unless the victim was fa-

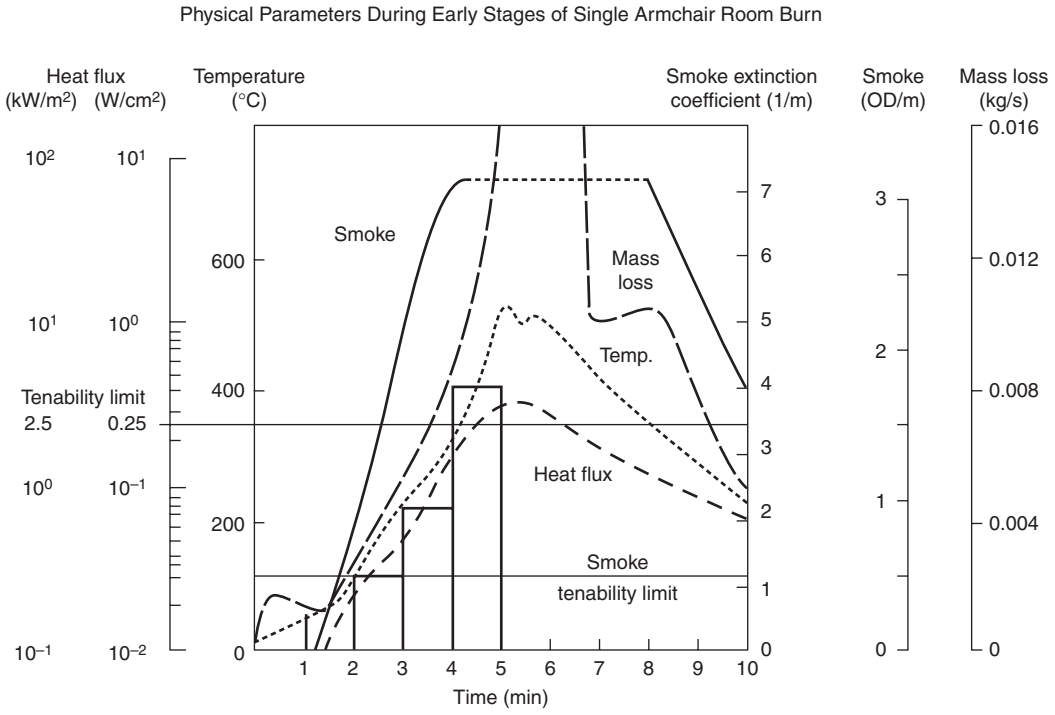

Figure 2-6.29. ***Profiles for heat (radiant flux and temperature), smoke and mass loss rate during the first 10 min of a single armchair (polystyrene, with polyurethane cushions and covers) room burn.[56] (Expanded detail from Figure 2-6.15.) Histogram shows average temperature each minute during the first five minutes.***

Table 2-6.20 ***Calculation of Fractional Incapacitating Accumulation of Convected Heat for the Single Armchair Room Burn Data Shown in Figure 2-6.29. (Calculated According to Equation 34.)***

Time (min)	1	2	3	4	5	6
Average temp. (°C)	20	65	125	220	405	510
F_{lh}	0	0.033	0.170	2.273	355	6236
Cumulative F_{lh}			0.203	2.476		

Incapacitation occurs when $F_{lh} = 1$, and is therefore predicted during the fourth minute of exposure.

miliar with the surroundings and able to find the exit in the dark.

Irritancy: As stated in the section of this chapter on irritancy, there are two factors to consider: the immediate incapacitation due to the painful effects of sensory irritation of the eyes and respiratory tract, adding to the obscurational effects of smoke and disrupting escape behavior, and the later inflammatory effects on the lung which may cause death after exposure.

The first consideration is whether the victim would be able to escape from the fire. In this context, sensory irritation is the most important. This is concentration-related; to predict the irritancy of the smoke, it is necessary to know the RD_{50} concentration of the atmosphere produced by the materials involved under the particular decomposition conditions existing in the fire. Most importantly, it is necessary to know the concentration/time profile of the fire products in terms of mass loss per liter of air (NAC mass loss). Although the mass loss curve for the armchair is shown in Figure 2-6.29, there are no data on the volume of air into which this mass was dispersed during the fire; so for the purposes of this example it will be necessary to make an estimate of possible mass loss concentration. Also, since the RD_{50} of the polyurethane and polystyrene components of the chair under flaming conditions are unknown, it will be necessary to use estimated values.

In the discussion of irritancy, a general tenability limit for severe sensory irritation was set at a concentration of 1 mg/L NAC mass loss, and an incapacitating dose for serious postexposure lung inflammation was set at 10 mg/L NAC mass loss for 30 minutes (a Ct product of 300 mg·min/L). From the general conditions, the smoke curve, and the CO concentration curve, it is estimated that the tenability limit for sensory irritancy would be exceeded during the third minute, greatly adding to the deleterious effects of smoke on vision and escape behavior.

With regard to lung irritation, it is estimated that the average mass loss concentration over the first five minutes of the fire would be approximately 10 mg/L. If so, this would represent a fractional incapacitating dose of 50 mg·min/L, which would probably be insufficient to cause significant lung damage after exposure, compared to the more serious effects of heat exposure. However, if the average mass loss concentration over the first five minutes should reach 60 mg/L, serious effects on the lung would likely occur after and probably during exposure.

Interactions: In terms of physiological effects, it is likely that there would be some degree of interaction between asphyxia and several of these physical factors, but it is likely that most would be relatively minor during the fire, except for some possible enhancement of pulmonary irritation due to the hyperventilatory effect of CO_2 during the fourth to sixth minute of the fire. A reasonable model can be used in which asphyxia, sensory irritancy, and the effects of heat and visual obscuration can be treated separately. Interactions may be more important at the behavioral level. The interaction between sensory irritation and visual obscuration has been mentioned and there is some experimental evidence for such an interaction in humans.[86] After exposure, as mentioned in the section on heat, the effects of skin burns, respiratory tract burns, and chemical irritation (and even possibly CO asphyxia) all combine to increase the probability of fatal pulmonary edema and inflammation.

Summary: From the analyses performed, the effects on a victim exposed to the conditions in the armchair room burn (Figure 2-6.15) are predicted as follows:

1. Toward the end of the second minute and beginning of the third minute, the smoke optical density and mass loss/liter would sufficiently exceed the tenability limits for visual obscuration and sensory irritancy to severely inhibit escape from the room.
2. During the fourth minute, the average temperature was 220°C, and sufficient heat would be accumulated in the skin surface to cause skin burns resulting in incapacitation.
3. During the fifth minute, a victim is likely to lose consciousness due to the combined effects of the accumulated doses of asphyxiant gases.
4. It is predicted that a victim escaping or rescued after the fourth minute would suffer severe postexposure effects due to skin burns, plus pulmonary edema and inflammation which might well be fatal (due to the combined effects of inhaled hot gases, chemical irritants, and the pulmonary secondary effects of skin burns). After the sixth minute, it is likely that a rescued victim would die at some time between a few minutes and one hour due to the effects of asphyxia and circulatory shock.

It is unlikely that an otherwise healthy adult would be able to escape from a fire such as this if he or she remained longer that three minutes after ignition. However, three minutes is a long time in which to leave a room, so that providing the victim is awake and aware of the fire, is not otherwise incapacitated, and does not stay after two minutes in an attempt to fight the fire or rescue belongings, it is likely that he or she would be able to escape without serious injury. In the next section, data on real fire victims is examined in an attempt to relate fire conditions to actual injury and death statistics.

Worked Example of a Simplified Life Threat Hazard Analysis

In the previous sections, the various elements of a physiological FED model for predicting time to incapacitation of occupants during full-scale fires have been developed. The following section consists of a worked example including tenability calculations for all toxic and physical hazards: time-to-escape efficiency impairment from the effects of optical obscuration by smoke, time-to-escape efficiency impairment from sensory irritation, time to incapacitation by asphyxiant gases, time to incapacitation due to skin pain and burns from radiant and convected heat, and time to inhale a lethal exposure dose of lung irritants. Table 2-6.21 shows the input data and calculation results for the life threat hazard analysis cal-

Table 2-6.21 ***Illustration of Life Threat Analysis for the First Six Minutes of a Furniture Fire Based upon a Single Armchair Room Burn. (The armchair is polystyrene with polyurethane cushions and covers. The room is 39 m^3 with open doorway. CO, CO_2, O_2, smoke, temperature, and radiant flux are as measured in doorway at 2.1-m height. Other gases are estimates to illustrate calculation method.)[106]***

The endpoint, escape impairment (for smoke obscuration and irritancy), or incapacitation (for heat and asphyxiant gases) is reached when the FIC or FED value reaches 1.

Limiting values are emboldened. Lethal values are approximately 2–3 times incapacitating levels for dose related parameters, and incapacitation 5–10 times the FIC.

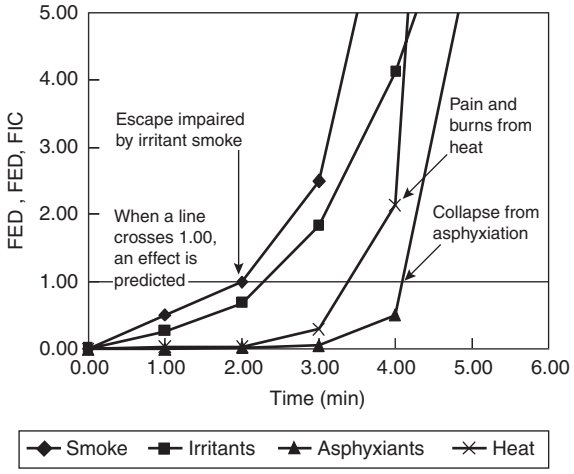

Figure 2-6.30. ***Example of an FED analysis.***[106]

culation using the methods described. The results of the analysis are presented in Figure 2-6.30. This figure shows plots of the FED for smoke, FIC for sensory irritation and FED values for each hazard parameter as they increase with time. The endpoints of escape impairment or loss of tolerability (for smoke obscuration and irritants) and incapacitation (for heat and asphyxiant gases) are reached when the line for each parameter crosses 1. Higher FECs and FEDs indicate more severe effects. For irritancy, incapacitation is predicted at FEC_{irr} values of approximately 5–10 and for asphyxiation death is predicted at FED_{in} values of approximately 2–3.

The analysis is designed to predict the severity of each hazard and the time during the fire at which it becomes significant. The toxic gas concentrations, smoke optical density, temperature, and radiant heat flux have been averaged over each of the first six minutes of a theoretical furniture fire, but are generally similar to conditions obtained in the smoke layer at head height in some experiments performed in ISO room tests. The analysis shows that the smoke obscuration is the first hazard confronting a room occupant. The level of obscuration exceeds the tenability limit for irritant smoke in a small enclosure after the second minute, with an FEC of 1. The second hazard to confront the occupant is irritancy. This becomes significant during the third minute, reaching an FIC of 1 at 3 minutes. The tenability limit designed to protect vulnerable individuals (FIC 0.3) is exceeded approximately one minute earlier. It is therefore predicted that after the second minute the level of obscuration and the irritancy of the smoke would be sufficient to impair and possibly prevent escape from the room due to difficulty in seeing and increasing pain in the eyes and respiratory tract. The effects of radiant and convected heat then become significant, crossing the tenability limit during the fourth minute and reaching an FED_{heat} value of 2.14, so that it is predicted that a room occupant would suffer severe skin pain and burns due to the effects of convected heat, which would be lethal during the fourth or fifth minutes.

During the fifth minute the radiant flux reaches the tenability limit of 2.5 kW/m^2, so that skin pain would be predicted within seconds due to radiation alone, were it not that the temperature has already exceeded the limiting exposure dose. Also during the fifth minute the FED_{IN} reaches 5.5, predicting that anyone breathing the smoke would lose consciousness due to asphyxia, and might die after six minutes. The level for exposure to asphyxiants considered to provide protection for vulnerable subpopulations (FED_{IN} of 0.1) is crossed at approximately 3.5 minutes, half a minute before the FED_{IN} reaches 1. The exposure dose of irritants is very small during the first six minutes of the fire, so that there should be little danger of post-exposure lung damage. An important point about all these parameters is that the FIC and FED curves are rising very steeply after the tenability threshold (FIC or FED of 1) is crossed. This means that even if the true exposure concentrations or exposure doses required to cause incapacitation were higher than the tenability limits chosen there would be little effect on predicted time to incapacitation.

The overall prediction is that for this fire, escape would become difficult during the third minute and incapacitation could occur due to the effects of irritant smoke. A person remaining in the room after this time would suffer severe pain and burns after 4 minutes, which would probably be lethal. In this analysis it is assumed that the head of a room occupant would be in the smoke at all times. In practice, if the room doorway was open, the hot, effluent-rich layer would descend from the ceiling to a level probably between 1 and 1.2 m above the floor as the chair reached its peak burning rate. A more sophisticated analysis could allow for the possibility that a room occupant might be at, or move to, a lower level in the room. If the height of the smoke layer with time is measured then it is possible to allow for this in the calculation.

Fire Scenarios and Victim Incapacitation

From the point of view of both product composition and toxic hazard, it is possible to distinguish four basic types of fire situations (see Table 2-6.15).

1. Smoldering fires where the victim may be in the room of origin of the fire or a remote location
2. Early flaming fires where the victim is in the room of origin
3. Small oxygen vitiated fires in poorly ventilated enclosures where the victim may be in the room of origin or a remote location
4. Fully developed or postflashover fires where the victim is remote from the fire

In the U.K., 80 percent of fire deaths and injuries occur in domestic dwellings, and in most cases the casualties occur in the compartment or origin of the fire. This class of fire is responsible for the highest incidence of deaths (60 percent) and a high incidence of injuries (39 percent). These fires occur mostly in living rooms or bedrooms, and in upholstery or bedding.[3] In these cases, fire is often confined to the material first ignited. The toxic hazard in such fires depends upon whether there is a long period of smoldering or a rapidly growing flaming fire.

Smoldering Fires

With smoldering fires, the decomposition temperatures are relatively low (~400°C) and materials are decomposed into a mixture of pyrolysis and oxidation fragments containing mixtures of asphyxiant and irritant gases and particulates. Under these conditions, the highest yields of a great variety of products are formed, many of which are irritant.[16,17] Incomplete oxidation is favored and CO_2 to CO ratios approach unity, so CO is likely to be an important toxic factor. The formation of high yields of HCN is, however, not normally favored.[17]

Although toxic products are formed under these conditions, the rate of evolution is slow, smoke is seldom dense, and room temperatures are relatively low. A potential victim therefore has ample time to escape if alerted sufficiently early, but may be overcome by fumes after a long period of time if unaware of the danger, particularly if asleep. The main danger here is almost certainly asphyxia by CO, with possibly a small contribution from low oxygen if the victim is in a room with a poor air supply.[16,106,134,135] It is not possible from fire statistics to determine how often this type of fire occurs, since in many cases smoldering fires become flaming fires before they are detected. However, it is likely that fires estimated to have burned for 30 min or more before discovery have involved long-term smoldering, and it may be relevant that for victims in the 19–49 age group, deaths are 20 times more likely in this situation than for fires discovered within 5 min of ignition, which are often rapidly growing flaming fires.[3]

The ability of smoldering fires to build up concentrations of CO capable of causing incapacitation and death in potential victims has been shown in large-scale fire tests.[136] A good example of such a situation is presented by a series of tests carried out at NIST,[137,138] where two armchair types made from a standard and a fire-retarded polyurethane foam with cotton covers (combustible mass 5.7 kg) were burned in a simulated small apartment (volume 101 m^3) consisting of a burn room (11.8 m^3), connected via a corridor 12 m long to a target room (volume 12.08 m^3). (See Tables 2-6.22 and 2-6.23.) The armchairs were tested by flaming ignition of the seat back, and also by smoldering caused by one or two cigarettes placed in the seat angle for approximately 1 hour, followed either by spontaneous flaming or ignition from a flaming source. Under smoldering conditions, approximately 1 kg of foam was decomposed in just over 1 hour. The smoke layer had reached the floor after 1 hour, but there was a concentration gradient for smoke and toxic gases between the burn room and the target room. The major asphyxiant gas present was CO, which gradually increased in concentration in the burn room from 180 ppm during the first 13 min to 1000 ppm between 67 to 75 min. This was sufficient to have caused incapacitation (i.e., loss of consciousness) in just over 1 hour in the burn room, but probably not in the target room where the concentration was lower. When flaming ignition occurred the armchair burned very rapidly, and produced high concentrations of asphyxiant gases that would have been almost immediately fatal in the burn room. Within the target room an occupant would have become unconscious within less than 1 min and received a fatal dose within 2 min. The smoke in the system was also very irritant, and it is likely that anyone spending more than 1 hr in the burn room would have suffered serious and possibly fatal lung damage, even if that person had been rescued. This example illustrates the dangers of smoldering conditions, which can continue for several hours and spread lethal products throughout a building, creating danger for the sleeping, trapped, or otherwise incapacitated occupant. Since such fires often change to flaming before they are discovered, it is difficult to know the true incidence of incapacitation and death occurring during the nonflaming phase of fires.

By 71 min the mass loss exposure dose of irritants was approximately 300 g·m3·min, which may cause some lung damage.

For this example, both the standard and FR chairs would have caused incapacitation after 1 hr in the burn room, but due to its higher yield of CO and irritants, the FR chair would also cause incapacitation in the target room soon after, and death in the burn room after 1.5 hrs of smoldering. The standard foam death at both locations would occur within 1 min of the spontaneous transition to flaming after 75 min. These dangers can be overcome by the provision of detection and warnings, but the siting of detectors can be important for effective operation.

Flaming Fires

For flaming fires where the victim is in the room of origin, the hazard relates to the early stages of fire growth. Such fires often grow quickly, but even the most rapidly growing flaming fires take approximately 3 min to reach levels of heat and gases hazardous to life,[56] which should allow ample time to escape from a room, and of course most people do escape. As Figure 2-6.15 shows, the hazard in this situation relates to a number of factors, all of which may reach life-threatening levels simultaneously as the fire reaches the rapid phase of exponential growth. As stated previously, in the high temperature, well-oxygenated flames of early flaming fires, much of the thermal decomposition products are consumed to form simple, comparatively innocuous products such as CO_2 and water, the CO_2 to CO ratios being high initially and then decreasing to the region of 50 to 100 as the oxygen concentration decreases toward 15 percent. The yields and relative rates of production of CO_2, CO, and irritant smoke depend upon the rate and efficiency of combustion. As Figure 2-6.15 and Table 2-6.15 show, the atmospheres obtained in a rapidly growing fire can contain asphyxiant concentrations of CO_2 (greater than 5 percent), CO (greater than 1000 ppm), and low oxygen (less than 15 percent O_2), as well as dense irritant smoke from products escaping the flame zone. A victim in this situation is therefore likely to be confronted simultaneously by high temperatures and heat radiation, smoke, and high concentrations of CO and CO_2 accompanied by low O_2, any one of which could incapacitate and prevent escape.

The inability of victims to escape from such fires seems to depend upon a number of factors. Casualties include a higher proportion of young children and the elderly than does the general population. (In 1978, fatalities in bedding fires for those over 65 were seven times those expected from the distribution in the 1978 population.)[3,14] People who are incapacitated by a previous period of smoldering or by some other infirmity (such as a physical disability or alcohol or drug intoxication) are obviously more at risk.[14] However, there seem to be two other factors of importance: (1) the behavior of the victim and (2) the exponential rate of fire development.

In many cases, the victim has a short period in which to carry out the correct actions enabling escape, after which he or she is rapidly trapped. Some victims may be asleep during this critical escape "window," but there are also reports of situations where the victim was aware of the fire from time of ignition, but remained in an attempt to extinguish the fire, or for some other reason failed to leave before the phase of very rapid fire growth when heat and asphyxiant gases rapidly reach life-threatening levels. Another, perhaps surprising, finding is that victims often appear to be unaware of the fire, and are discovered in a burned out chair or bed where they have remained. The insidious nature of CO intoxication has been described; it also seems that irritant smoke products often fail to wake sleeping victims, although a sudden noise such as of breaking glass may do so. It may seem odd that acrid fumes may fail to alert sleeping victims, but a possible explanation may lie in the adaptation to sensory irritation during continuous exposure reported for the experiments with CS gas.[24] In smoldering fires, the concentration buildup of irritants is slow, allowing time for adaptation to occur. There may be no subsequent

response to a high concentration which, if presented suddenly (as, for example, with smelling salts), would rouse the subject. Other victims appear to have roused themselves at some stage of the fire but have been overcome, again probably by CO or HCN, before they are able to escape, and are found behind a door. There are also cases reported by survivors where a victim has attempted to extinguish a rapidly growing flaming fire, but failed to leave in time and is discovered near the fire having been overcome by fumes.[108,134] Unfortunately, reports of such effects on victims are largely anecdotal, and systematic studies of fire victim experience are lacking. The apparent anomaly of why so many casualties occur in the room of fire origin when theoretically there should be ample time to escape would seem to be a particular area that needs further investigation. The following pilot study has therefore been made of this problem.

Pilot Study of Room-of-Origin Deaths

As stated, the results of large-scale fire tests suggest that even in a worst-case situation there should be a period of at least three minutes before conditions in a rapidly growing flaming fire become untenable, and in many cases fire growth will take considerably longer. From a knowledge of the toxicity of fire products, it would therefore seem that a normal, healthy, waking individual should be able to escape from such situations without much difficulty, while a sleeping or otherwise incapacitated victim may be overcome by a smoldering or slowly growing fire, as well as by a rapidly growing fire. To test this hypothesis, an examination was made of the 1981 U.K. statistics, specifically for textile fires in dwellings for casualties in the 19 to 49 year age group, a group most likely to be active and able bodied. The data are summarized in Table 2-6.24 for fires estimated to have been discovered within 5 min of ignition (most likely to have been rapidly growing flaming fires) and for fires where the time to discovery is estimated to have been 30 min or more (most likely to have involved a period of prolonged smoldering before severe flaming).

The preliminary data show that there were 23,082 fires in the first category, but only 4 fatalities, while for the second category there were fewer fires (5,870) but 20 fatalities, a ratio per fire of 1:20. Obviously, a number of interpretations could be put on these data, but it does seem that people in this active age group are able to escape from rapidly growing fires in domestic-sized compartments. Fatalities are much more likely in fires that have undergone a period of prolonged smoldering, when victims may have been overcome by prolonged, low level exposure to asphyxiant fumes. If this is the case, perhaps there should be more concern about the ability of materials to continue smoldering, with toxic gas buildup over a long period of time, at least in the context of this class of fire.

Table 2-6.24 ***Fatal Casualties in Room of Fire Origin (Textile Fires in Dwellings for 1981,[3] Age Group 19–49 Years)***

Time to Discovery (min)	Number of Fires	Number of Fatalities
< 5	23,082	4
> 30	5,870	20
		Ratio 1:20

Small Restricted Ventilation Fires in Closed Compartments

Closed-room fires are hazardous situations, wherein a smoldering, or especially a flaming, fire quickly uses up the available oxygen, and as the oxygen concentration falls after a minute or so of burning the combustion becomes inefficient, producing a dense smoke rich in carbon monoxide and other toxic products. These, together with the lowered oxygen concentration in a room, can produce a rapidly lethal atmosphere. An example is a recent fire involving an adult and a four-year-old child. Both were in a small bedroom for a short time during which the adult went to sleep and the child is thought to have ignited a small piece of foam using a cigarette lighter. The fire was discovered after a few minutes, when the door was opened by a family member, who extinguished the very small fire with a bucket of water. Both the adult and child were dead, with blood carboxyhemoglobin concentrations of about half a lethal level. Based upon the dimensions of the room, it is calculated that the decomposition of approximately 0.5 kg of material would be sufficient to lower the oxygen concentration to 10 percent and give carbon monoxide concentrations of approximately 1 percent or more, which together with other toxic products would cause incapacitation and death within a few minutes. With such small fires it would seem that early detection and warning, coupled with materials giving a slow fire growth, would greatly increase the probability of escape and survival.

During the period when most occupants are at risk, the majority of fires in small enclosed buildings (such as houses, flats, hotels, boarding houses, cellular offices, and small shops) are likely to be restricted ventilation (vitiated) pre-flashover fires. However if external windows or doors are open, or (as often happens) are opened at a later stage of the event, then flashover may occur. The characteristics of restricted ventilation fires are that there are three main regions at which combustion reactions occur. One is at the interface between the solid (or liquid) fuel and the base of the flame, where fuel materials are decomposed and partially oxidized by heat to form the gaseous fuel for the fire. The second is in the lower part of the flame zone, where air and fuel gases combine to produce heat and primary products. The third is in the vitiated hot zone in the upper part of the flame and beyond where hot, partially combusted fuel gases react in a restricted oxygen atmosphere to produce high yields of irritant and asphyxiant smoke products. These conditions occur when the upper layer has filled down to a low level above the fire in the fire enclosure and where partially combusted fire effluent may be recycled into the fire from outside the fire enclosure. Such fires are usually relatively small, often being limited to the item first ignited, sometimes involving some decomposition (nonflaming or vitiated flaming) of combustible materials at high levels in

the room (such as paint, coving or objects placed on cupboards or the upper levels of bookcases or racks).

The main hazards from such fires during the critical stages are likely to be from irritant smoke and asphyxiant gases. Inefficient combustion leads to high yields of these toxic smoke products. Apart from the immediate vicinity of the fire, the temperatures in the fire enclosure and beyond are not particularly high, so that heat is usually not the primary hazard.

These descriptions of fire scenarios illustrate that fire hazards, particularly the toxic hazards, vary considerably depending upon the combustion conditions. In buildings, the majority of fires hazardous to occupants are likely to involve vitiated flaming combustion conditions to some extent, either pre- or post-flashover depending upon the scenario. This is likely to be especially true of fires in domestic dwellings, which account for the vast majority of injuries and deaths. Most fire deaths in the United Kingdom (61 percent in 1992)[3] result from small fires when the victim is in the room of fire origin. In order to study the development of hazardous conditions in typical domestic fires and to develop a series of realistic design fires for smaller enclosures with restricted ventilation, a series of 23 fires had been carried out at the Fire Research Station over a number of years. These fires were carried out in three experimental rigs (Figure 2-6.31), consisting of a room corridor–rig, a room–corridor–room rig, and a typical domestic two story house. The first rig simulates conditions for a fire in a small enclosure connected via a corridor to a source of ventilation, such as an open door or window, or a much large interior space. The second rig simulates conditions in a small single story apartment, while the third simulates conditions for house fires. For all these experiments the fire was in one room and the developing fire conditions were measured in the fire room and other locations throughout the experimental rigs. The majority of fires involved single items of upholstered furniture (armchairs).

In order to give an example of the developing conditions in a typical fire in a domestic house and the likely hazards faced by occupants, one of these experiments is described. This experiment involved a common situation in which a fire was started in the seat of an armchair. The armchair was typical of modern furniture, upholstered with combustion modified foam and fire retardant back coated acrylic covers. A flaming ignition source was used, consisting of a No. 7 wood crib, which is approximately equivalent to two sheets of newspaper. The armchair was placed in the downstairs lounge with the door to the hallway open. Upstairs, the front bedroom door was open and the back bedroom door shut. The kitchen and bathroom doors were also shut. Figures 2-6.32 and 2-6.33 show the developing conditions in the lounge and bedroom, with estimates of the developing hazards faced by occupants of the lounge and open bedroom. For each of Figures 2-6.32 and 2-6.33 the lower graphs show the gas and smoke concentrations, while the upper graphs show the hazard development at head height for a standing occupant. The hazard development is expressed in terms of the FEC (smoke), FIC (fractional irritant concentration), or FED (fractional effective dose) for each hazard parameter. This means that for each parameter a tenability limit is

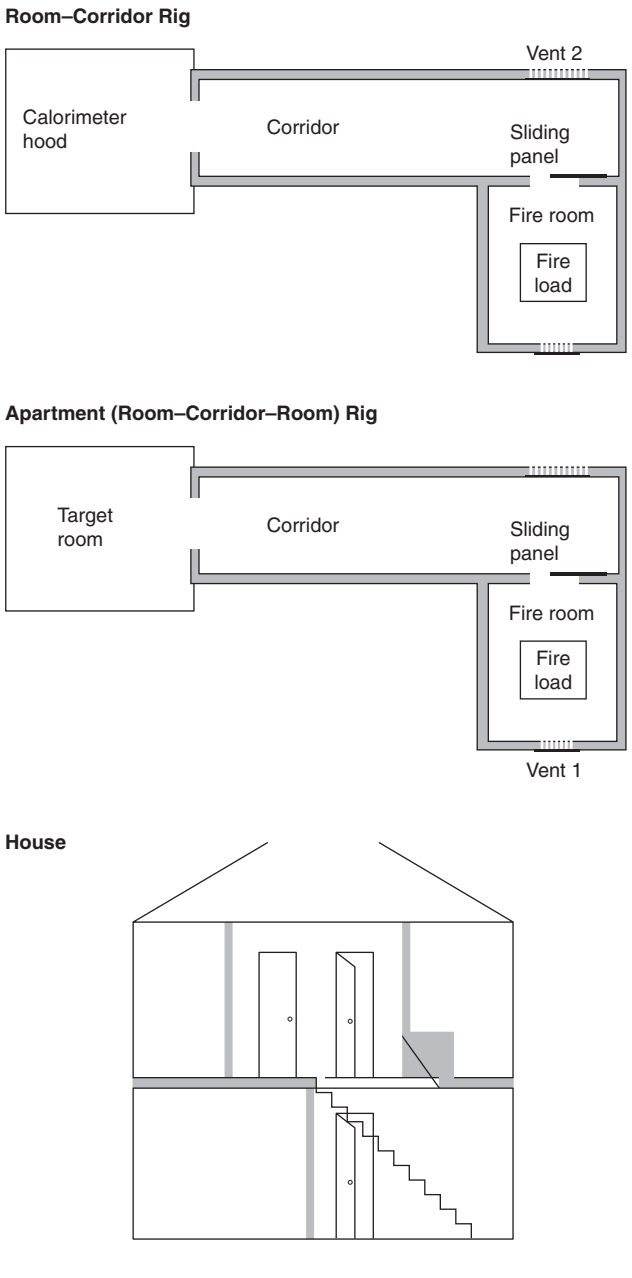

Figure 2-6.31. ***Full-scale fire test rigs.***[106]

reached when the line crosses 1 on the *Y* axis. The graphs for the fire gases show that in the lounge the fire grows slowly at first producing some smoke, but then grows more rapidly after about 4 min. From about 5 min the oxygen concentration in the fire room starts to decrease so that at around 9 min the fire self-extinguishes. The peak temperature at the ceiling in the hottest region above the fire was 350°C. The peak carbon monoxide concentration was 1.1% and the peak hydrogen cyanide concentration 1100 ppm. The ionization smoke detector in the lounge was triggered at 0.5 min and the optical detector at 1.5 min. The first hazard confronting an occupant of the

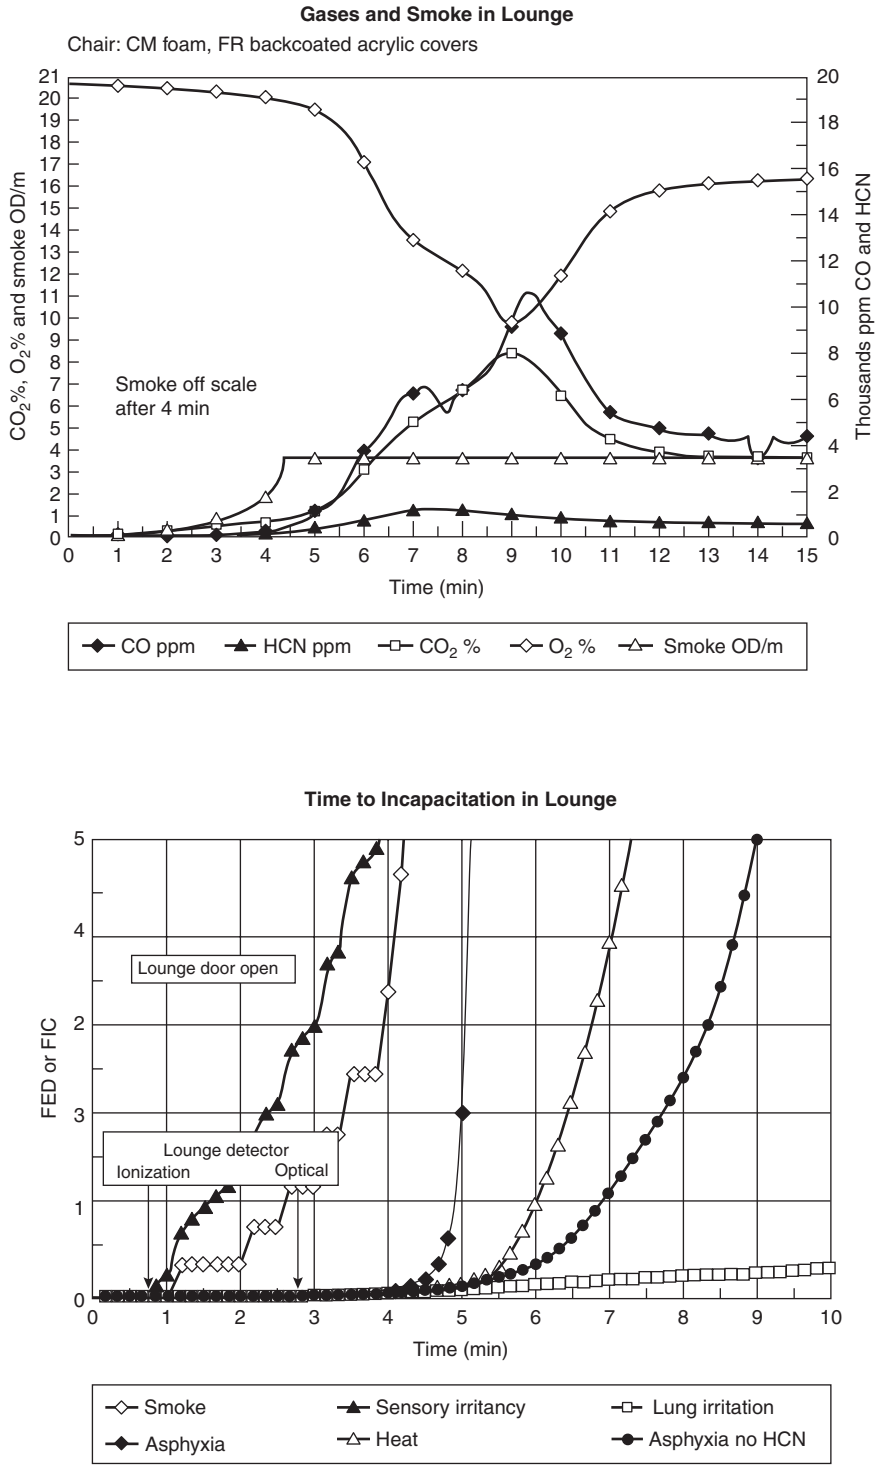

Figure 2-6.32. ***Gases, smoke, and hazard analysis in lounge for armchair fire in house.[106]***

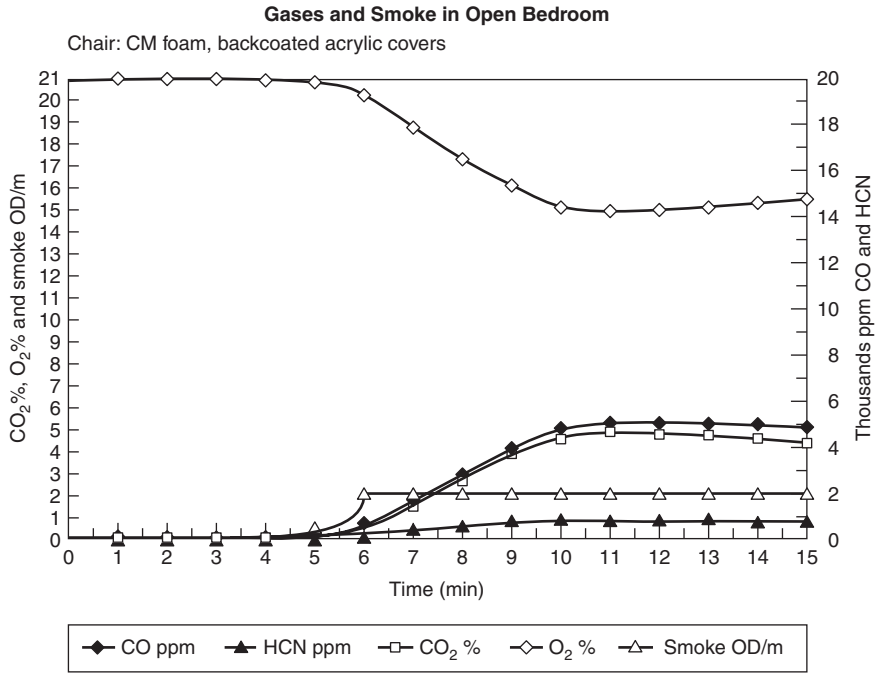
lounge would be smoke, and from the smoke analysis it is considered that the smoke would be irritant. The line for irritant smoke crosses the tenability limit at around 1.5 min in the lounge. From this point, a room occupant would experience difficulties in seeing due to painful eye irritation and the presence of smoke, and breathing difficulties. It is likely that these effects would hamper, but probably not prevent, a room occupant from finding their



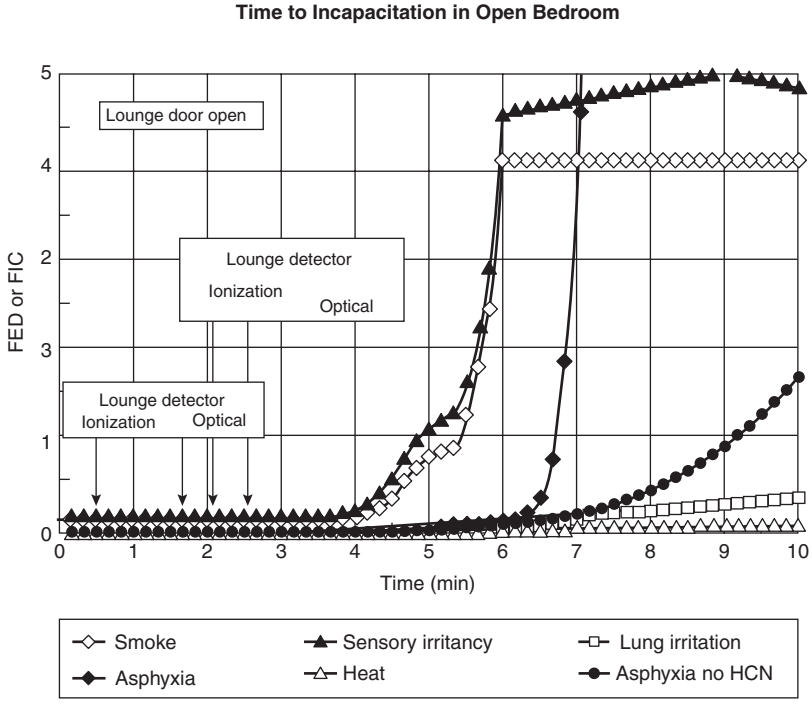


Figure 2-6.33. ***Gases, heat, and hazard analysis in open bedroom for armchair fire in house.***

way out of the room to the front door. One minute later, the purely visual obscuration effects of the smoke (i.e. assuming the smoke was non-irritant) reach the tenability limit of 2 m visibility. If an occupant was still in the room at 5 min, it is predicted that they would collapse unconscious due to the effects of asphyxiant gases. This collapse is largely due to the presence of hydrogen cyanide. If there was no cyanide present, it is predicted that collapse

would not occur for a further 2 min (at 7 min). At 8 min it is predicted that an occupant would be overcome by heat, suffering burns to unprotected skin.

Figure 2-6.33 shows the conditions in the open upstairs bedroom. The smoke and gases start to increase significantly from around 4 min, but there was sufficient smoke on the upstairs landing to trigger the ionization smoke detector at around 2 min and the optical detector at around 2.5 min. The gas and smoke concentrations increase more gradually than in the lounge, since they are well mixed by the time they reach the bedroom. From around 11 min the smoke and gas concentrations are similar throughout the house. The temperature in the bedroom peaked at around 60°C after 9 min. The hazard analysis shows that irritant smoke is predicted to be a problem from around 4.5 min. After this time a bedroom occupant might experience some difficulties in finding their way out of the room and down the stairs. They would also have to decide whether it would be better to close the bedroom door and stay in the room until the fire brigade arrived, or to attempt to escape via the door or window. Analysis of the conditions in the closed bedroom showed protection for some 20 min or so if the door was closed throughout. If an open bedroom occupant was still in the room after approximately 5.5 min, it is predicted that they would collapse unconscious from the effects of asphyxiant gases. As with the lounge, this is predominantly due to the effects of hydrogen cyanide, conditions remaining tenable for around 9.5 min if this gas is absent. The temperature in the bedroom is insufficient to cause incapacitation.

This example shows how typical flaming furniture fires are likely to develop and threaten the occupants of a domestic house. The main hazards are firstly irritant smoke and secondly asphyxiant gases, particularly hydrogen cyanide and carbon monoxide. The fires are often small, being limited to the item first ignited, and self extinguish when the oxygen concentration decreases. In practice, many domestic fires begin by a variable period of nonflaming/smoldering before flaming ignitions occurs. This may last for several hours. Depending upon the nature of the smoldering materials, a hazard may develop, primarily from carbon monoxide. The house fills with a slowly thickening and irritant smoke, which may trigger detectors before the situation becomes dangerous. Another possibility is that the fire will grow rapidly, possibly to flashover. This is particularly likely if external doors or windows are open (or if windows break and fall out). Such large fires commonly develop when occupants are roused during the early stages and open external doors or windows during the fire to affect escape or rescue. The conditions rapidly become fatal, due to the large amounts of heat and toxic smoke produced, and there is often considerable damage resulting from fire spread throughout the building. All data from the 23 fire tests have been placed on a CD-ROM database. Further details of the fire loads and results of tests are given in Purser et al.[139] Table 2-6.25 shows examples of four fires in terms of times to alarm and different tenability limits. Figures 2-6.34 and 2-6.35 illustrate the times between ignition, detection and the various tenability criteria in the lounge and bedroom for these and other fires.[106,139]

For all fires except Experiment CDT 16, the fire room door was open to the remainder of the apartment or house. Figure 2-6.34 shows similar results in the apartment rig to those in the two story house for the same type of chair (Experiments CDT 11, 21, and 23), but when fire retarded covers were used, the tenability times for asphyxia are increased by approximately 1.5 min (Experiments CDT 17 and 18). The importance of HCN as a primary cause of incapacitation in these fires is shown by comparing the asphyxia with HCN bar with asphyxia without HCN bar. If no HCN were present, the time to asphyxia is increased by up to 2.5 min. For flaming fires in the fire room, ionization detectors triggered 1–2 min earlier than optical detectors, although optical detectors would be expected to trigger earlier if the fires had been initiated by a nonflaming source. Times in Figure 2-6.34 are for optical detectors on the upstairs landing ceiling. For this location there was only a small difference between ionization and optical triggering times as shown in Figure 2-6.35. Figure 2-6.35 shows the situation in the open upstairs bedroom. In this situation the results are similar to those from the fire room, in that times to loss of tenability from asphyxia are several minutes longer for the chairs with fire retarded covers.

Hazardous situations in fires develop as a result of a complex interaction between the building, the burning contents, and the occupants. When evaluating materials, it is important to consider not just the toxic potency of the combustion products, but the overall fire risk and burning behavior of the item. Although some modern materials and fire retardant systems may present possible toxic potency and environmental problems, they give rise to considerable overall benefits if they reduce the number of fires occurring. It is also obvious that slow fire development, buying time for occupants to escape, is beneficial, particularly when linked with efficient detection and warning systems. It is likely that a combination of these factors has led to recent reductions in fire deaths compared with the early 1980s. Although the majority of fires and toxic effluent derive mainly from building contents rather than the structure, it is evident that the building and its systems are very important factors in the development of the fire and its hazards. In the domestic context, the type, maintenance, and placement of smoke alarm systems are likely to be important in the provision of early warnings to occupants. The simple expedient of closing doors and windows on unoccupied rooms is also likely to considerably reduce fire hazards while providing a tenable escape route. The use of sprinklers and smoke venting systems are other important strategies, particularly in nondomestic buildings.

Fully Developed Fires

The third scenario involves large, fully developed fires where casualties occur remote from the source of the fire. This type of fire has progressed beyond the stage of local growth and has spread from the material first ignited to others. The fire may still be largely confined to the compartment or area of origin, but large amounts of toxic smoke are formed, which spread throughout build-

ings, giving rise to lethal atmospheres remote from the actual fire. Apart from being a common occurrence in domestic dwellings, such situations often occur in public buildings where there may be major loss of life in a single incident. Materials in such fires are subjected to substantial external heat flux and in some cases to oxygen deficient environments. Under the severe conditions found in such high temperature, postflashover fires with low oxygen concentrations, the basic pyrolysis products break down into low molecular weight fragments and can contain high concentrations of asphyxiant substances such as CO and HCN, with CO_2 to CO ratios of less than 10.[17]

Under such conditions, a building can fill rapidly with a lethal smoke capable of causing incapacitation and death within minutes. Fires where the victim is remote from the compartment of origin are responsible for the highest incidence of nonfatal casualties (48 percent) and a large proportion of deaths (37 percent) in the United Kingdom.[3] The victim is five times more likely to be killed by smoke than by burns, and is often unaware of the fire during the crucial early phase, so that the gases may not penetrate to the victim until the fire has reached its rapid growth phase and the victim is already trapped. The major causes of incapacitation and death in this type of fire are almost certainly asphyxiant gases, particularly CO, which can build rapidly to high concentrations (although the role of irritants in causing incapacitation and impeding escape attempts may be crucial to victim survival).

An example of such a fire is provided by some studies of the effects of the penetration of a large external fuel fire into the cabin of an airplane, as happened in the Manchester Airtours fire.[140] Table 2-6.26 shows the results obtained inside the cabin of a Boeing 707 containing a few rows of seats opposite an open doorway, outside which was 50 gal of burning aviation fuel.[137] The rapid involvement of the cabin contents gave rise to a dense smoke containing large amounts of carbon monoxide and hydrogen cyanide at a measurement point half way down the fuselage. Incapacitation is predicted just after 2 min followed rapidly by death, mainly from the effects of hydrogen cyanide (high concentrations of which were found in the blood of the Manchester victims).

Although in many large fires the original fuel and the major source of heat and toxic products may be the contents, a significant contribution may be made by construction products. Of great importance in some cases are surface coverings or components with a large surface area, such as doors or partitions. Surface coverings may contribute to flashover spread (as in the Dublin Stardust disco fire) and may release a bolus of toxic products very quickly, which may have a serious incapacitating effect on victims. An example would be vinyl wall coverings or the

vinyl laminates used in aircraft cabins. PVC releases all its hydrogen chloride at a low temperature (approximately 250 to 300°C), so that, as a fire develops and the hot layer reaches this temperature, HCl may be suddenly released. In another aircraft fire test conducted by the FAA, high concentrations of HCl and HF occurred in the cabin atmosphere before other gases reached toxic levels.[104]

In general, although in some cases fire and heat may eventually kill victims, this is usually preceded by dense, highly toxic smoke that can spread rapidly throughout a space or a building, and it is this that is usually responsible for the initial incapacitation of occupants, as well as being the cause of many deaths.

A common feature in many major fire disasters is a failure in early detection and effective warnings. In many cases the fire was detected at an early stage, and some attempts were made to deal with the fire, but often there was a failure to instruct people to leave while the fire was small and a failure to realize that a small fire grows with exponential speed into a life-threatening one. For example, in Summerland[141] the initial fire was considered nonthreatening, and occupants were encouraged to remain seated rather than to leave. At the Manchester Woolworth's fire[142] people continued to eat in the restaurant area while the fire was growing on the other side of the sales floor. At the Bradford stadium fire people watched the early fire development at the end of the stand and did not begin to move until a late stage. At the Dupont Plaza hotel, the fire began in an unoccupied furniture storage area, but was discovered and fought at an early stage; however, mass evacuation of the hotel did not occur until after the fire went to flashover and started to spread. At the Beverly Hills Supper Club fire,[141] 20 min elapsed between discovery and evacuation instructions. At the Kings Crossing fire,[141] the escalator fire was burning for some time before attempts were made to close the station. At the Dublin Stardust disco, the fire grew unnoticed behind a partition. It could be said that when a person is able to perceive a fire as a possible threat to their life, it may already be too late to escape. In the majority of these cases, evacuation occurred at a late stage and there were failures in the provision of accurate, authoritative, and informative evacuation instructions.

General Comment

The severe asphyxiant incapacitation and subsequent death of many fire victims are almost certainly due to the common asphyxiant gases. However, the importance of irritants in impeding escape is an important consideration, and it is not obvious from asphyxiant gas profiles why so many fatalities occur in the room of fire origin.

Table 2-6.26 ***Average Concentrations of Toxic and Physical Hazards and Fractional Incapacitating Doses over 30-s Periods during Aircraft Cabin Fire***

Time to exceed smoke tenability limit: 1 min 40 sec

Time to incapacitation by asphyxiant gases: 2 min 15 sec

Time to incapacitation by convected heat: 2 min 45 sec

Time to tenability limit for radiant heat: 2 min 45 sec

Effects of irritants:

Over period between 1 and 4 min: average respirable particulates 6.7 mg/l
average total particulates 11.6 mg/l
average HCl concentration 1027 ppm
average HBr concentration 1228 ppm

It is considered that the oily, organically rich, particulate collected, with its very high acid gas content, would be highly irritant and extremely painful to eyes and breathing, causing incapacitation and impairing escape attempts. It is considered likely that these irritants reached high concentrations (approaching 1000 ppm total acid gases) early in the fire at approximately 1 to 1.5 min, from which time escape capability would be significantly impaired. It is likely that sufficient irritants would be inhaled up to 4 min to cause life-threatening post-exposure lung damage.

Useful information may be obtainable from survivors who have experienced exposure to dense, irritant smokes, and from case studies of room of origin fires.

Possible Routes to Mitigation of Toxic Hazard

For smoldering fires it would be advantageous if materials were designed to self-extinguish, and if the formation of products other than CO during decomposition (such as oxidized hydrocarbon fragments or CO_2) could be encouraged. Early audible warning by smoke alarms may be particularly advantageous, as sound often appears to alert victims where the presence of irritant smoke or heat fails.

For early flaming fires where the victim is in the room of origin, any measure that limits the rate of growth once ignition has occurred will give a victim more time to extinguish a small fire or escape from a growing one.

For fully developed fires where the victim is remote from the point of origin, the most important mitigating factors are probably early warning and containment of the fire and gases within the original fire compartment.

The development of hazardous situations in a fire involves a whole range of factors, including fire development from ignition to the post-flashover spread of fire and smoke, toxicity, and the interaction of the fire with the structure and with passive and active fire protection, as well as escape-related factors, including detection, warnings, the provision of escape routes, wayfinding, physiological and behavioral impairment, and escape movements or rescue. In designing a system to be safe in fire, all these factors should be considered, and the ultimate evaluation of safety depends upon whether it is possible to ensure, by performing a life-threat hazard and risk assessment, that the occupants can reasonably be expected to have escaped before they are exposed to

levels of heat and smoke that may endanger health and threaten life.

The Use of Small-Scale Combustion Product Toxicity Tests for Estimating Toxic Potency and Toxic Hazard in Fires

Essential Criteria for Test Methods

The evolution of toxic products in large-scale fires is determined essentially by two sets of parameters.

One set of parameters relates to the large-scale structure and development of fire scenarios that determine the growth and spread of the fire, the decomposition conditions under which products are formed, and their rate of evolution. It is not possible to model these features in a single small-scale test, although they are the most important factors determining the toxic hazard in a fire. This is the main reason why it has not been possible for experts to agree on standard test methods suitable for regulatory control of materials.

The other set of parameters that contributes to the determination of toxic hazard, and that can be modeled using small-scale fire tests (albeit only in a general way) is the set of thermal decomposition conditions encountered by materials at different stages or in different types of fires. Basically, the thermal decomposition products given off by any material depend upon the temperature and oxygen supply to which it is subjected, and whether it is flaming or nonflaming. Although it is possible to identify a number of subsets, there are three basic thermal decomposition conditions, namely:

1. Nonflaming oxidative/smoldering decomposition at mid-range temperatures
2. Flaming decomposition in a local environment at mid-range temperatures
3. High temperature/low oxygen conditions encountered in fully developed or postflashover fires

If it can be demonstrated that a particular small-scale test method can model one or more of these conditions, then it has the potential, if used with a suitable bioassay procedure, to produce toxicity information that can be used as one item in a toxic hazard evaluation. To produce such information, a number of essential test criteria must be fulfilled.

1. The most important criterion for any small-scale fire model is that it should be capable of producing atmospheres with broadly similar compositions to those formed in one or more of the basic stages of a fire.
2. Following from this, it is essential that measurements should be made of the temperature and/or radiant flux to which the sample is subjected, the air/fuel ratio, the smoke optical density, and whether the sample is flaming or nonflaming. The chemical composition of the atmosphere must also be characterized as fully as possible, the minimum being in terms of CO, CO_2 (with calculation of the CO_2 to CO ratio), O_2, and HCN (if the material contains nitrogen), or hydrogen halides (if F, Cl, or Br are present). These measurements are important for two reasons: first, because they define whether one of the basic fire conditions is being adequately simulated; and second, because they should enable the key products responsible for the animal toxicity to be identified, or at least make it possible to decide if unusual toxic products are present.

   The time/concentration profiles of the key toxic products can then be measured in large-scale fire tests, or predicted by mathematical fire modeling. Estimates of likely toxic hazard in realistic fire scenarios can then be attempted.

   If possible, a fuller product analysis including GC-MS measurements of the profiles of organic products should be made for more accurate correlations with the observed toxicity. In addition, comprehensive measurements of product composition in small-scale tests enable comparisons to be made with product profiles in large-scale fire tests, and a judgment of how well the small-scale decompositions are able to reproduce the chemical "cocktails" present in different large-scale fire conditions.[17]
3. The bioassay method must be capable of detecting and measuring the particular types of toxic effects experienced by human fire victims. It must also be possible to make a reasonable extrapolation from the toxic effects in the animal model to those likely to occur in humans. It is therefore essential to determine both the qualitative and quantitative aspects of toxicity, and the time during or after exposure when they occur. People in fires experience incapacitating effects that may crucially impair their ability to escape, causing them to remain in the fire to be killed later by heat or CO, so a simple body count (LC_{50}) animal test without any description of preterminal toxicity is of very limited usefulness for input to toxic hazard models.
4. Some estimate of dose must be made. This should be reported in terms of concentration and duration of exposure as mass charged and mass consumed of material per liter of diluent air, and concentrations of basic toxic products as described previously. By carrying out tests at different concentrations, estimates should then be made of dose/time/response relationships.

Practical Methods for Toxic Hazard Assessment

There are essentially two ways in which toxic hazard in fire can be assessed.

1. From large-scale fire tests that include measurements of the concentration/time profiles of the major toxic gases, and existing knowledge of the toxic effects of these gases
2. From a battery of small-scale tests and mathematical models, or simple large-scale tests. The essential components are
   (a) the toxic potency data for materials [lethal mass loss exposure dose ($g \cdot m^{-3} \cdot min$)] obtained from small-scale tests using animal exposures or analytical methods
   (b) the mass loss/concentration curve for the fire

Of these, full-scale simulations and large-scale tests are the most valuable, since they enable the first two major parameters (fire growth and product yield) to be measured directly. For the third parameter (toxicity), an algorithm for calculating times to incapacitation and death for humans from toxic gases, heat, and smoke obscuration from large-scale fire data has been developed, and a simplified version is presented in ISO/IEC TR 9122-5.[143] Full-scale tests are already in use for a number of purposes (such as the furniture calorimeter and room calorimeter used for heat release measurements). With the addition of a few simple gas measurements, they can be extended to provide the data for full-scale hazard assessment. Although the use of full-scale tests for regulating fire performance has been criticized on grounds of cost, this approach has been used successfully in California.

The other notable method is to make use mainly of small-scale test data. Small-scale tests suffer from the difficulty that they are several steps removed from a full-scale fire, so that it is important to determine the validity of the parameters measured with respect to real fire conditions.

It has been claimed that some small-scale tests can be used to give a direct indication of the toxic hazard presented by a material in a full-scale fire, including elements of ignitability, fire growth and toxic potency. The UPITT test and the NIBS test are claimed to be usable in this way to produce hazard rankings for materials. However, small-scale tests cannot successfully model the complex growth and development of a full-scale fire, so that such methods are considered invalid. It may however be possible to extract a number of characteristics of the fire behavior of a material from a single test protocol, and use these as inputs to mathematical models for making hazard assessments. An example is the use of the cone calorimeter for measurement of both heat release and toxic gas yield from a material.

Nevertheless, the main job of small-scale toxicity tests is to provide data on the toxic *potency* of the combustion products from materials so that the data can be used as input to toxic hazard analysis in conjunction with fire growth data obtained from other sources.

The lethal toxic potency of combustion products from materials can be measured in small-scale tests in terms of the LCt_{50}, the lethal exposure dose to rodents. This is expressed in terms of the mass loss concentration of products (the mass of material decomposed in the test) divided by the volume of air into which they are dispersed (g/m^3) and multiplied by the time for which the animals were exposed, to give the exposure dose ($g \cdot m^{-3} \cdot min$). It is possible to quote the toxic potencies of materials in these terms for most small-scale test protocols, so that the results from different tests can be compared directly and so that the data can be used in conjunction with mass loss data from full-scale fire tests or model calculations to make toxic hazard assessments. The toxic hazard presented by the materials in full-scale fires can then be estimated in terms of the time during a fire when a victim will have received a lethal exposure dose, provided that the decomposition conditions in the small-scale test are the same as those in the full-scale fire. This is done by the fractional effective dose (FED) method, in which the mass loss exposure dose generated each minute during the full-scale fire (either measured or calculated) is expressed as a fraction of the lethal mass loss exposure dose for the material, obtained from the small-scale toxicity tests. When the integrated fractions during the fire reach unity, death is predicted. This method has been developed for use in toxic hazard assessments in British Standards[144] and in ISO/IEC.[143]

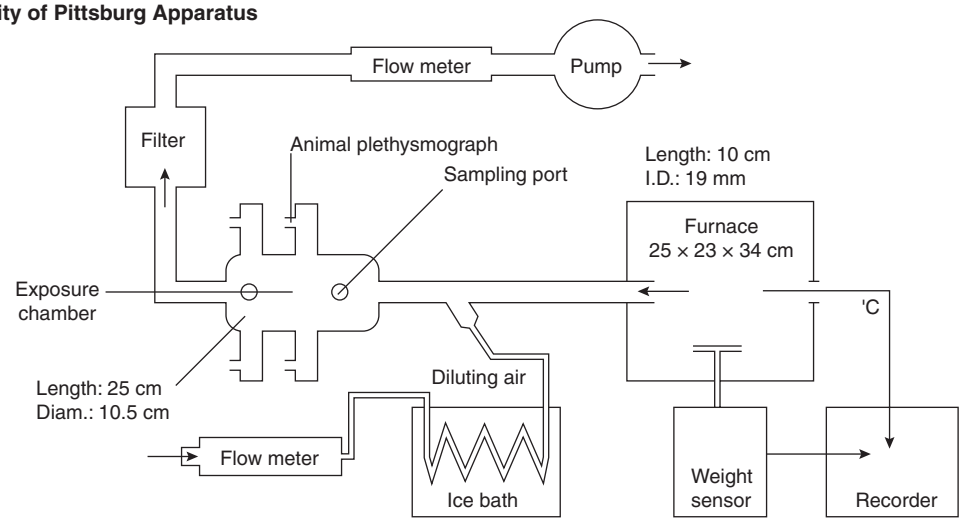
Examples of Small-Scale Test Methods

A variety of different methods have been used to generate combustion product atmospheres and evaluate their toxicity, and it is not possible here to describe these methods or the results obtained from them in detail. There are, however, three test methods that are in relatively wide use in the United States and in Europe—the NBS test method,[9,145] the DIN test method,[42,146,147] and the University of Pittsburgh test method.[98] An excellent description of these and other methods, and of the results obtained from them, is given in Kaplan et al.[15] A brief description of the principles of these three methods and their validity in predicting effects of exposure to large-scale fire environments follows. The methods are illustrated diagramatically in Figure 2-6.36(a) and (b).

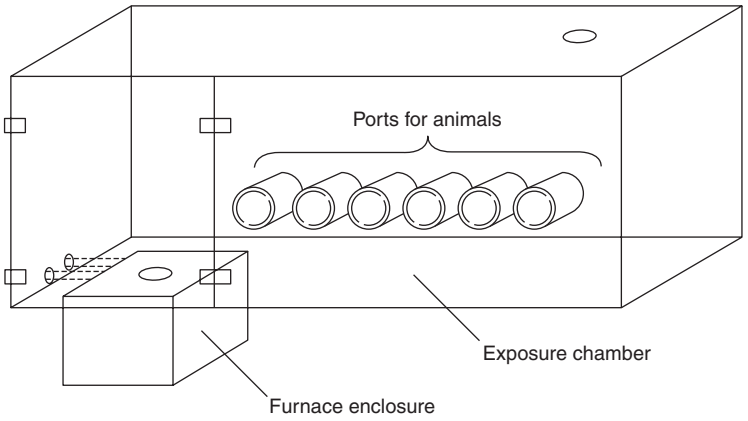
National Bureau of Standards (NBS) Test Method

The NBS test method[9,145] is the simplest of the three. The test apparatus consists of a sealed rectangular polymethylmethacrylate chamber (200-L volume) containing a cup furnace set into the floor at one end. The animals (rats) are exposed nose only and placed in restraining tubes that are plugged into the sides of the chamber. Exposures are carried out under nonflaming conditions 25°C below the ignition temperature of the sample and under flaming conditions 25°C above the ignition temperature. The sample is placed into the preheated cup with the animals already in position, and they are exposed to the atmosphere in the chamber for 30 minutes. For this test there is thus an initial period when the concentration of decomposition products in the box increases as the sample decomposes, followed by a period when the atmospheric composition remains relatively constant for the remainder of the exposure. The concentration of products in the chamber is varied by placing different amounts of sample in the cup. This type of method is referred to as a "static" method, since there is no forced airflow over the sample and no ventilation of the chamber. It is possible to characterize the atmosphere approximately in terms of mass charge per liter of air by assuming a constant composition for the duration of the test. The atmosphere also can be characterized in terms of mass loss by weighing the residue after the test, or by placing the cup on a load cell. Measurements are also made of the chemical composition of the atmosphere in terms of the principle products. The animal toxicity is usually quoted in terms of the LC_{50} concentration of mass charge/L, but it is also common to monitor the asphyxiant effects on the animals by means of the leg flexion test. Effects upon respiration (such as irritant effects) could be monitored if desired.

(a) University of Pittsburg Apparatus



(b) National Bureau of Standards (NBS) Apparatus.[9]



(c) DIN 53436 Apparatus.[148]

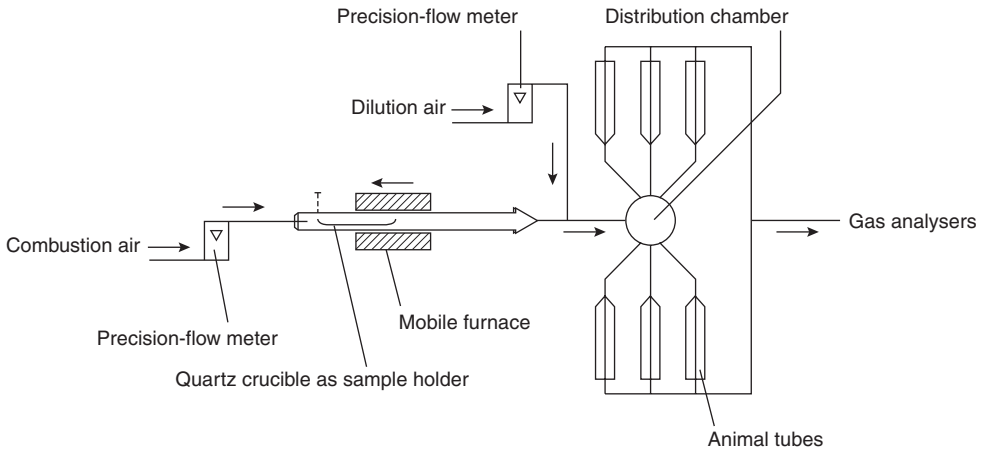


Figure 2-6.36. ***Laboratory-scale combustion toxicity test methods.***

The main advantage of this method is its simplicity, but it has the disadvantage that there is little control over the decomposition conditions. Another disadvantage is that the composition of the atmosphere does not remain constant, since there is a variable period during which the sample is decomposing, followed by a period when the smoke is aging and some products may condense onto the chamber walls. In tests where the decomposition product atmosphere has been compared to that produced in large-scale tests,[17] it has been found that the method gives a reasonably good simulation of the products from a smoldering or nonflaming fire, and also of the conditions during the early stages of a flaming fire. However, it was not possible to model the decomposition conditions of a high-temperature, fully developed fire, since when the cup is heated to high temperatures the pyrolysis products tend to escape from the cup before they are fully decomposed. In general, it should therefore be possible to use data from this method as one item in a toxic hazard assessment for nonflaming or early flaming fires.

University of Pittsburgh Test Method

In this method[98] the sample is also heated statically in a cylindrical furnace (early versions of the test used a tube furnace). However, in this case a flow of air is maintained over the sample and then mixed with diluent air before being passed through the animal (mouse) exposure chamber. In this way fresh products are continually passed to the animals under dynamic airflow conditions as they are generated over a 30-min exposure period. The unique feature of this method is that the sample is not maintained at a constant temperature, but is heated by means of a ramped temperature profile, the temperature increasing at 20°C/min. The animal exposure starts when the sample begins to decompose and lose weight as indicated by a load cell. The mice are exposed in the head-only configuration, as with the NBS method. In the University of Pittsburgh method the composition of the atmosphere changes continuously throughout the 30-minute animal exposure, and the atmosphere usually changes from nonflaming to flaming at some stage. The concentration of the decomposition products can be varied by changing the mass of material placed in the furnace (although presumably this could also be achieved by altering the flow of diluent air). It is possible to measure the changing profile of products to which the animals are exposed throughout the test, and also to monitor toxic effects such as asphyxia or irritancy, mainly from recordings of respiratory pattern. However, in its more recent application, the results of the test are usually expressed in terms of the LC_{50} in grams of material charged, which is used to rank different materials.

The main advantage of this method is that it theoretically covers a number of different decomposition conditions within a single test run, ranging from low-temperature nonflaming to high-temperature flaming. It is also said that this situation mimics the conditions in a real fire where materials begin by being cold, and are then heated up until they pyrolize and eventually flame. A feature of the test is that the time/temperature increase taken from the start of the decomposition run to the occurrence of the evolution of smoke, toxic effects, and flaming may be used as criteria for judging materials. Thus a material that flames early or produces smoke early may be judged more hazardous than one that does not start to decompose until a high temperature is attained.

Although ramped heating of a sample may provide a useful model for the specific situation where a material is subjected to a slowly rising temperature, it cannot be said to mimic the changing conditions in a fire. In a fire, a material or its immediate pyrolysis products may be subjected to any of a variety of conditions of temperature or oxygen supply under nonflaming or flaming conditions, and the way in which these conditions change is governed by the nature of the large-scale fire scenario. In order to model these various conditions, it is necessary to subject separate samples of test material to a range of different temperatures (or radiant fluxes) and oxygen supplies. The main problem with ramped heating of a sample is that it does not submit the whole material to the necessary range of conditions, since it causes fractional decomposition of the material. Products evolved at relatively low temperatures will not therefore be present at a later stage to be involved in flame; neither will they be subjected to high temperatures, since they will have left the furnace before higher temperatures are achieved. This may have a profound effect upon the kind of products evolved and hence the toxicity.

Another disadvantage of this test method is the difficulty of characterizing dose, since the composition of the atmosphere changes throughout the test. For comparison with other methods, it would be possible to calculate a very approximate nominal atmospheric concentration in terms of mass charged/L if it is assumed that the decomposition averages out over the duration of the test. A better estimate may be made of the atmosphere concentration in terms of mass loss/L if the mass loss as measured by a load cell is integrated over the exposure period. This might give a reasonable measure of dose to enable an LC_{50} to be calculated, but other estimates of toxicity are complicated by the changing nature of the atmosphere. Thus, if death or asphyxia were to occur at 30 min, for example, it is not possible to determine whether this would be due to the delayed effect of a product evolved at 5 min or an immediate effect of a product from 29 min.

There are thus some difficulties with this method, both as a fire model and as a toxicity assay. But, if the method is backed by a full profile of material mass loss and product concentrations, plus qualitative and quantitative estimates of toxic effects throughout and after the exposure, it may be possible to apply the data in certain special situations.

German DIN 53 436 Test Method

This method[42,146,147] is widely used both in the United States and in Europe. It employs a fully dynamic system in that fresh material is decomposed at a constant rate throughout the test and fresh atmosphere is supplied continuously to the animals. The method has been used with rats, mice, and primates; rats being the principal test animals. The principle of the method is that a strip of test

material is placed in a silica tube under a current of air (or nitrogen for studies of pyrolysis) and a traveling annular furnace is moved along the outside of the tube at a constant rate, thereby continuously decomposing the sample. The products are expelled from the silica tube, whereupon they are mixed with diluent air and passed through the animal exposure chamber for 30 min. The rats are exposed in the head-only manner as with the other methods. The sample weight and volume, the primary air supply to the sample, the diluent air, the decomposition temperature, and the concentrations of products in the exposure chamber are measured. The test may be repeated over a range of temperatures under nonflaming or flaming conditions, and the concentration of the products is varied principally by changing the diluent airflow. This has the advantage that the decomposition conditions remain constant as the product concentration is changed, which is not necessarily the case with the other two methods. However, it is also possible to change the product concentration by altering the furnace load, if necessary. The animal toxicity is usually reported in terms of the LC_{50}, which is expressed in terms of mass charged (mass entering the furnace/min)/L diluent air. It is also possible to calculate the concentration in terms of mass loss from the mass of residue remaining after the test run, since the rate of decomposition is constant. Sometimes the results are expressed in terms of the volume of material consumed. In addition, it is possible to monitor the toxic effects on the animals during and after the test as with the other methods.

The great advantage of this method is its versatility, and in theory it can model any of the three basic fire conditions: nonflaming, flaming, and high temperature, as well as variations on them. It is also possible to carry out static ramped temperature decompositions similar to the Pittsburgh method, if required. In practice the method has been found to provide a good correlation with large-scale nonflaming decomposition conditions, and at high temperatures it provides a reasonable model for the conditions of a fully developed flaming or nonflaming fire (high temperature-low oxygen).[17] However, under standard conditions it does not provide a good model for an early flaming fire (which is reasonably modeled by the NBS method) as the oxygen concentration in the furnace tube tends to be low. Another problem is that the flame tends to travel along the sample more rapidly than the furnace, giving an uneven decomposition. These problems can be overcome by varying the fuel-to-air ratio in the furnace tube and by altering the rate of travel of the furnace.

On balance, the DIN method is reasonably good, and the data obtained could be applied to a number of stages of a fire as one item in a hazard assessment. However, like all small-scale tests it cannot mimic the changing and developing conditions of a large-scale fire; neither can it test materials or objects in their end-use configuration, all of which can have an enormous impact on a developing toxic hazard.

Second Generation Test Methods

Since these small-scale test methods were developed, there has been considerable progress in understanding of how toxic hazard develops in fires, and in particular that hazard depends to a large extent on the general fire properties of materials (in terms of ignitibility, flame spread, rate of fire growth, and smoke evolution), as well as the specific toxicity of the combustion products. Also, critical examination of the fire models used for toxicity test methods (and for small-scale tests for other fire properties such as smoke) has led to the recognition that the models are somewhat inadequate, particularly for the main fire condition of flaming. Another difficulty is that toxicity data are of little value unless they can be related to a range of physical and chemical parameters necessary to characterize the thermal decomposition process, as described in the previous section of this chapter.

There is, therefore, a case for arguing that for many material-based fire properties, a good small-scale test method depends upon a decomposition model that can be convincingly related to the essential features of large-scale decomposition conditions. If such a model could be developed, it could be used to measure simultaneously a number of material-based fire performance parameters ranging from ease of ignition, through growth and heat release characteristics, to smoke and toxicity.

A second generation of small-scale fire test methods is being developed, incorporating, hopefully, some of the best features of existing methods, and designed to measure a range of parameters.

Cone calorimeter: A second generation small-scale test method currently under development is the National Bureau of Standards (NBS—now NIST) cone calorimeter,[149] which has been developed primarily as a heat release apparatus, but which may also offer the possibility of measuring ignitibility, smoke evolution, and toxicity. This would not only enable a range of parameters to be measured simultaneously, but would enable the separate parameters to be related, hopefully providing a more comprehensive data set for comparison with, and inputs for modeling of, large-scale fire conditions.

In practice the cone calorimeter has not proved to be very suitable for measuring toxic potency. It is capable only of reproducing the decomposition conditions in very well-ventilated fires, and the products are subjected to a very large dilution, so that measurement of toxic species is difficult. Attempts are being made to enlarge the range of fire types and stages addressed by modification of the apparatus.

NIST radiant method: A second generation version of the NABS cup furnace method has been developed in which the cup furnace was replaced by a radiant panel heater unit. This method has been developed to address the conditions in post-flashover fires, but as with the cup furnace version, and the cone calorimeter, the combustion process tends to be too well ventilated to reproduce the conditions typical of these fires, which are usually rather vitiated.

Tube furnace method developed at the U.K. Fire Research Station:[37] The most recently developed method intended to address some of the deficiencies of older methods is a tube furnace method based upon the same

concept as the DIN tube furnace method. The new method employs a strip of sample being advanced through a standard tube furnace under a stream of air. (See Figure 2-6.37.) The products are expelled into a chamber where they are diluted with secondary air, and analytical measurements are made or animals can be exposed nose-only. By using a range of different temperatures and airflow rates it is possible to reproduce all the different fire stages and types defined by ISO (and others), including low-temperature non-flaming oxidative decomposition, well-ventilated flaming, and high-temperature vitiated (post-flashover) flaming decomposition conditions. The method also provides stable flaming conditions, solving the problem of mixed, intermittent periods of flaming and nonflaming common with the original DIN method.

Relationship between Toxic Potencies of Materials in Small-Scale Tests and Full-Scale Fires

When the toxic potency of the combustion products from a material are expressed empirically in mass loss terms, the data relate to the toxic effects of the total mixed combustion product evolved. This depends upon the type of toxic products evolved and their yields. The most difficult problem in estimating the toxic potency of a material in a fire is that the yields of toxic products depend very much upon the decomposition conditions, which vary considerably at different stages and between different types of fires. If small-scale test data are to be used as estimates of the likely toxic potency of products evolved in full-scale fires, it is essential that the decomposition conditions in the test be shown to be the same as those in the type or stage of full-scale fire being modeled, otherwise the small-scale test data are not valid.

The decomposition conditions and yields of toxic products evolved from materials in full-scale fires depend mainly upon whether or not the fuel is flaming, the fuel/air ratio (equivalence ratio), and the upper layer temperature. In ISO/IEC TR 9122-4[150] an attempt has been made to define the major categories of fire in these terms, the type of decomposition for flaming fires being expressed in terms of the CO_2/CO ratio. A revised scheme is shown in Table 2-6.27. The six fire types shown in the table contain three major categories: (1) nonflaming, (2) well-ventilated flaming, where the fire size is small in relation to the size of the compartment, the flames are below the base of the hot layer, and fire size is fuel controlled, and (3) less well-ventilated flaming, where the fire size may be large in relation to the size of the compartment, the flames are partly above the base of the hot layer, and fire size is ventilation controlled. The third case includes small vitiated fires in enclosed or poorly ventilated compartments and post-flashover fires in large or well-ventilated compartments. In ISO/IEC TR 9122-4 small-scale toxicity test protocols are judged by the extent to which the test conditions are relatable to one of these categories in terms of temperature or radiant heat flux, oxygen concentration, and CO_2/CO ratio. If they are to be considered useful to measure the toxic potency of

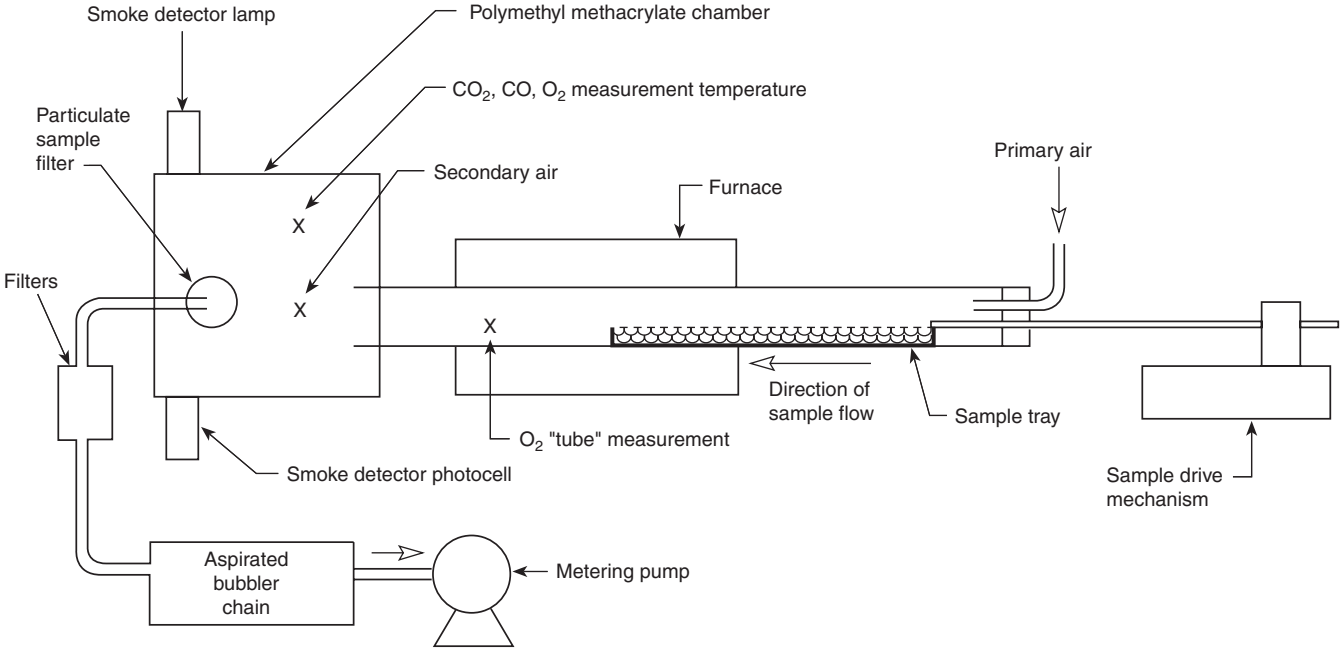

Figure 2-6.37. ***Improved tube furnace method.***

Table 2-6.27 ***Revised Classification of Fire Types***[33]

Fire Stage or Type	Temperature (°C)		Fire Effluents		
	Fire	Hot Layer	Oxygen to Fire (%)	Oxygen from Fire (%)	CO_2/CO (v/v)
1. Nonflaming					
a. Self-sustaining	450–600	RT	21	>20	1–5
b. Oxidative pyrolysis from externally applied radiation	300–600	<50	21	>20	1–5
c. Nonoxidative pyrolysis from externally applied radiation	300–600	<50	0	0	<5
2. Well-ventilated flaming where the fire size is small in relation to the size of the compartment, the flames are below the base of the hot layer and fire size is fuel controlled	>700	RT to 500	>15	5–21	>20[a]
3. Less well-ventilated flaming where the fire size may be large in relation to the size of the compartment, the flames are partly above the base of the hot layer and fire size is ventilation controlled:					
a. Small vitiated fires in closed compartments	>700	RT to 500	<15	0–12	2–20
b. Post-flashover fires in large or open compartments	>700	500 to 1000	<15	0–12	2–20

[a]May be lower if the burning materials contain fire retardants. In order to determine whether flaming decomposition conditions in a particular apparatus fall into category 2 or category 3, it is necessary to use a nonfire-retarded reference material capable of efficient combustion.

the combustion products from materials, the decomposition conditions must relate to one of these fire stages or types, and the results of any small-scale test are then only valid for the particular category being modeled. Based upon the results of full-scale fire tests, and fire death statistics, it is suggested here that the most important toxic hazard situations that should be assessed for all materials are

1. Nonflaming oxidative/smoldering decomposition at low/mid-range temperatures where the potential hazard relates mainly to victims in the compartment of fire origin
2. Early/well-ventilated flaming conditions at mid-range temperatures, and later small vitiated fires in closed compartments, where the potential hazard relates mainly to victims in the compartment of fire origin
3. Fully developed/post-flashover, vitiated decomposition at high temperatures, where the potential hazard relates mainly to victims remote from the fire

In the United Kingdom just over half of all fire deaths in buildings occur in the room of fire origin and most result from exposure to toxic smoke evolved from small fires (which may involve periods of nonflaming and both early and later flaming decomposition). The other major category, particularly related to deaths from smoke exposure, consists of victims in remote locations following fully developed fires. It is this second category that has been identified as the major problem in the United States, particularly in relation to fires in multi-occupation buildings.

Unfortunately, many existing small-scale test protocols do not cover the necessary range of decomposition conditions found in full-scale fires, especially the third category of the fully developed, high-temperature, oxygen vitiated fire. However, a new technique is presented here whereby certain predictions about the toxicity of combustion product atmosphere can be made, based entirely upon analytical data. This enables use of data both from small-scale experiments and full-scale fire tests.

It is considered that the major toxic effects of fire effluents can be explained in terms of a small number of well-known fire gases, so that the effects of fire gases on human fire victims can be predicted to a large extent if the concentrations of these gases during a fire are known. In a similar way, it is now possible to a large extent to predict the exposure dose of combustion products generated in small-scale tests that would be lethal to rodents, if the concentrations of the major toxic gases are measured. If necessary, it is then possible to verify the prediction by carrying out the animal exposures. Experiments of this kind, carried out by Hartzell et al.[151] and Levin et al.,[152] have shown that toxic gases are basically additive in their effects, so that, for example, an exposure to an atmosphere containing half a lethal dose of carbon monoxide mixed with half a lethal dose of hydrogen cyanide constitutes a lethal mixed atmosphere.

The toxic effects of combustion products result mainly from asphyxia and irritancy. Asphyxiation is caused by carbon monoxide, hydrogen cyanide, low-oxygen hypoxia, and carbon dioxide, and so can be quite well predicted if the concentrations of these gases are known. Irritancy is somewhat harder to predict because many irritant organic products and inorganic acid gases occur in fire atmospheres. Where acid gases are present

the concentrations can be measured and their effects added to those of the asphyxiant gases. In small-scale tests where both chemical analysis and animal exposures are used it is possible to calculate the contribution to the overall toxicity made by the measured asphyxiant gases and acid gas irritants. Any residual lethal toxicity can then be reasonably considered to be due to the effects of organic irritants, except in very rare cases where unusual toxic effects occur. For small-scale tests, or even large-scale fires, where analytical data only are available it is possible to calculate a theoretical LCt_{50} in terms of the main asphyxiant fire gases and acid gases. This then represents the *highest* estimate of what constitutes a lethal dose for that atmosphere (i.e., the smoke atmosphere must be at least as toxic as this, and could be somewhat more toxic if substantial amounts of organic irritants are present, or if unusual toxic effects are present. In small-scale tests there is little oxygen vitiation, so this effect can be ignored. On this basis an equation has been developed to predict the lethal FED to rats of a combustion product atmosphere as follows:

$$\text{fractional effective dose (FED)} = [(\text{CO ppm}/LC_{50}\,\text{CO} + \text{HCN ppm}/LC_{50}\,\text{HCN} + \text{ppm each acid gas}/LC_{50}\,\text{each gas} + \text{ppm each organic irritant}/LC_{50}\,\text{each organic irritant}) \times V\text{CO}_2] + A \quad (29)$$

where

$V\text{CO}_2$ is a multiplication factor for CO_2-driven hyperventilation $= 1 + \exp\dfrac{(0.14 \times [\text{CO}_2\%]) - 1}{2}$

A is an acidosis factor $= [\text{CO}_2\%] \times 0.05$

LC_{50} is the lethal exposure concentration for a 30-min exposure for the material in mass loss terms

Currently generally accepted 30-minute LC_{50} concentrations for exposure of rats to common fire effluent gases are given in Table 2-6.28.[33,106]

When the FED for this equation equals unity, then death is predicted, and the mass loss exposure dose for the material producing these gas concentrations is then equal to the LCt_{50} for that material decomposed under the conditions of the test. If the concentrations of the irritants present and their lethal exposure doses are known, then the equation can be solved fully (e.g., the LCt_{50} for HCl is 112,980 ppm·min).[153,154] Where unknown irritants are present, the equation enables the maximum LCt_{50} to be predicted based upon the asphyxiant gases and any known irritants.

This is a powerful technique because it enables a number of things to be done, as follows:

1. Where a material is tested in a small-scale test using only chemical atmosphere analysis, it enables an estimate to be made of the likely approximate toxic potency of the combustion products from the material, without the use of animal exposures.
2. Where a material is tested in a small-scale test using both chemical atmosphere analysis and animal exposures, then it is possible to determine the extent to which the toxicity of the combustion products can be accounted for in terms of the common toxic gases, or if additional toxicants are present.
3. If the toxic effects are almost entirely accountable in terms of the common toxic gases (as is often the case), then it enables the toxic effects of full-scale test atmospheres to be predicted with confidence, without animal exposures, if these gases are measured.
4. Where the LCt_{50} in a small-scale test is estimated from analytical data, or where it is measured using animals, it enables estimates of toxic potency of full-scale fires to be made simply from the mass loss rate and dispersal of products in the fire, provided the full-scale fire is of the same type as the small-scale test decomposition.
5. Where analytical data are available from full-scale tests, they enable some estimates to be made of the toxic potencies of the materials involved.

Table 2-6.28 ***Currently Accepted 30-min LC_{50} Concentrations for Common Fire Gases***

Gas	Concentration (ppm)
CO	5700
HCN	165
HCl	3800

NO_2	170
acrolein	150
formaldehyde	750

[a]Range or results from a number of studies

The following examples show how this technique can be applied, using data from experiments with wood. When samples of Douglas fir were decomposed under flaming conditions in the NABS cup furnace, the LCt_{50} for a 30-min exposure of rats was 1194 $g \cdot m^{-3} \cdot min$. In the test, the CO concentration was 3400 ppm and the CO_2 concentration 3.71 percent, a CO_2/CO ratio of 11/1. According to the FED equation given above, this represents a FED of 1.0. It can therefore be concluded that in this test the observed toxic potency can be fully accounted for in terms of CO and CO_2, and that there was little or no contribution from irritants or other toxic products on lethality. This result is to be expected, since the NBS cup furnace method generally simulates reasonably well-ventilated early flaming conditions where combustion is usually efficient, so that the yield of organic irritants would be expected to be low. However, in this test it is surprising that the CO_2/CO ratio is so low, and more representative of somewhat vitiated burning conditions.

It is now possible to examine some full-scale test data on wood fires of this type, in the knowledge that CO and CO_2 are the main toxic products to consider. Such a test was performed at the U.K. Fire Research Station, where a 5-kg wood crib (Scotch pine) was burned in a closed 26 m^3 room. At 6 min into this fire the CO_2/CO ratio in the smoke was 60/1. Based upon a 44 percent carbon content

for wood, and assuming that all carbon in the mass lost was converted to carbon oxides (CO_2 + CO), it is now possible to calculate what mass loss of wood in a small-scale test would be required for a 50 percent rodent lethality at a CO_2/CO ratio of 60/1. It is to be expected that under these conditions the wood smoke would be less toxic than in the reported NBS test, since the major toxicant is the CO, and the CO yield is low at this moment in the fire. This is indeed likely to be the case, since the FED equation predicts an LCt_{50} of 3750 g·m^{-3}·min under these decomposition conditions, approximately three times less toxic than in the small-scale test.

Major Determinants of Toxicity in Fires and Small-Scale Tests

The toxicity of the combustion products from individual materials in fire, in terms of the type and yields of the major asphyxiant, irritant, and other toxic products depends principally upon three factors.

1. The elemental composition of the material
2. The organic composition of the material
3. The decomposition conditions

The most important toxic products from fires are usually carbon monoxide and hydrogen cyanide, so that the most important elemental determinants of toxic potency are normally the carbon and nitrogen content of the fuel, with the halogen content being important to a lesser extent in some cases, and organic irritants in others.

Nonflaming Oxidative/Smoldering Fires

Nonflaming decomposition is slow, so that a long time is required for the development of hazardous conditions. However, of the small masses of materials decomposed during nonflaming oxidative decomposition, the yield of CO can be quite high, and these conditions generally provide the highest yields or organic products, including irritants, the identity of which is often unknown. In small-scale tests conducted under these conditions, only a small proportion of the observed toxic potency can be accounted for in terms of the common toxic gases. Table 2-6.29 shows two examples of this type, from experiments using the NBS cup furnace method to decompose Douglas fir and a flexible polyurethane foam under nonflaming oxidative conditions. The results show that at the LCt_{50} of wood to rats of 684 g·m^{-3}·min, only 0.47 of the observed toxicity could be accounted for in terms of common toxic gases, and for the flexible polyurethane foam only 0.29 of the observed toxicity could be accounted for. This means that for these (and many other) materials decomposed under nonflaming oxidative conditions, a large part of the toxic potency is due to products other than those normally measured, almost certainly organic irritants, so that the FED method tends to underestimate the toxicity, unless allowance is made for irritancy (such as assuming that approximately half of the toxic potency is likely to be due to irritants for most common materials under these decomposition conditions).

However, the nonflaming condition is adequately replicated by a number of small-scale test methods, and there is a large toxicity data base available for many materials, since by far the greatest amount of published test results are obtained under these conditions.

From a recent review of published toxic potency data from common materials[35] including data from a number of small- and large-scale test methods it is possible to make some general observations regarding the toxic potencies of the decomposition products from materials under a range of fire conditions. For nonflaming oxidative decomposition conditions, the range of LCt_{50} for individual materials covers approximately a factor of 12 from 63 to 767 g·m^{-3}·min.

Early or Well-Ventilated Flaming Fires

In flaming fires, the yields of carbon oxides and nitrogen compounds depend mostly upon the decomposition conditions, particularly the air/fuel ratio. With regard to carbon, the main consideration is the CO_2/CO ratio, which not only determines the toxic potency of the smoke, since CO is approximately 20 times more toxic than CO_2, but to a large extent defines the fire type. In early well-ventilated fires combustion is usually efficient, and the CO_2/CO ratio may be as high as 200/1, although in practice somewhat lower ratios around 60/1 are more

Table 2-6.29 ***Toxic Potency Analysis of Materials Decomposed under Nonflaming Oxidative Conditions in the NBS Cup Furnace***

	Douglas Fir 440°C		Flexible Polyurethane Foam 400°C	
	Concentration	FED	Concentration	FED
Carbon monoxide	2700 ppm	0.47	1261 ppm	0.22
Hydrogen cyanide	0 ppm	0.00	11 ppm	0.07
Carbon dioxide	0.69%	× VCO_2 1.0	0.4%	× VCO_2 1.0
Total FED asphyxiants		0.47		0.29
FED presumed due to irritants		0.53		0.71
LCt_{50} calculated	1455 g·m^{-3}·min		3621 g·m^{-3}·min	
LCt_{50} observed	684 g·m^{-3}·min		1050 g·m^{-3}·min	

typical. Under these conditions the yield of organic irritants is usually low, since combustion is efficient, and the yield of CO is so low that the overall toxic potency of materials containing principally hydrogen and carbon can be expected to be low. The exceptions tend to be fire-retardant materials, "naturally" fire-retardant materials such as PVC, and some largely aromatic materials such as polystyrene, all of which tend to burn inefficiently and give low CO_2/CO ratios even under well-ventilated conditions. This results in high yields of CO and usually of irritants, and somewhat higher toxic potencies than for more easily and cleanly burning materials.

With nitrogen-containing materials, the situation is somewhat analogous to that with carbon, since in well-ventilated, early flaming fires, most nitrogen in materials is oxidized to nitrogen oxides and N_2. The yield of HCN is generally low (with the exception of acrylic materials, and to some extent rigid polyurethanes). Although NO_2, which is a potent lung irritant, can be expected to be present at high yields under these conditions, the general effects seems to be that, since the HCN yield is low, toxic potency tends to be low. With materials like PVC, almost all the chloride is released as HCl under almost all decomposition conditions, including flaming conditions.

The general picture then is that the toxic potency of combustion products from most materials is lowest under early, well-ventilated flaming conditions. Materials that tend to perform comparatively less well under these conditions are FR-materials, and materials like PVC, where the halogen acid gases cannot be destroyed by the flames.

Small-Scale Tests Replicating Well-Ventilated Flaming Conditions

To study the toxic potencies of materials under the decomposition conditions similar to those during the early stages of flaming fires it is necessary to use a test method that provides flaming combustion throughout the test until the material is fully decomposed. The test method must also provide good ventilation of nonvitiated air to the specimen, and have a general temperature environment of around 400 to 700°C (or equivalent radiant flux). Most important, however, it must produce high CO_2/CO ratios (in the range approximately 200/1 to 50/1) from normally combustible (i.e., non-FR) materials.

NBS cup furnace test: Of the small-scale test methods commonly in use, a number perform well in this area. The one for which the most toxicity data are available is the NBS cup furnace test. In this test the material specimen is decomposed in a crucible furnace, and the products are evolved into a 200-L box. The key feature of this test is that it is normally used with quite small specimens, so that the oxygen concentration in the box is not significantly lowered during the test, and studies of the combustion process have shown that air circulates rapidly down into the cup furnace during decomposition, so that combustion tends to be reasonably efficient. The CO_2/CO ratios typically produced in tests are in the 40/1 to 60/1 region, so that, although perhaps not representing the most efficient combustion, they are generally a reasonable model for the results obtained in small, well-ventilated full-scale fire tests.

NIST U.S. radiant (NIBS) test: A more recent development of the NBS cup furnace test is the NIBS test or NIST radiant test. The two versions of the test use the same apparatus, but somewhat different test protocols. For this test a radiant heating unit is placed in a cavity under the NBS chamber, and connected to it by a slit-shaped chimney. Investigations of the combustion mode of this test[21] have also shown that under flaming combustion conditions the circulation of air is such that the specimen is very well ventilated, so that CO_2/CO ratios are generally reasonably high. Data from this test method suggest that it may best represent the decomposition conditions in a well-ventilated fully developed (possibly post-flashover) fire. However, in its present form it does not appear to generate the very low CO_2/CO ratios and high CO and HCN yields found in typical post-flashover fires in compartments.

Cone calorimeter: The cone calorimeter has not been used very successfully with animal exposures, but using the FED model presented in this chapter, it is possible to make some useful estimates of likely toxic potency based on the toxic gas yields and the mass loss of the specimen. The cone calorimeter gives the most efficient combustion conditions of any test method, typically producing CO_2/CO ratios in the 200/1 to 100/1 range for non-FR materials. It can also therefore be used as representative of the decomposition conditions during very early and very well-ventilated fires. So far, attempts to modify the combustion process and decrease the combustion efficiency to model other stages of fire have not proved very successful.

DIN method: For the DIN 53 436 method, decomposition occurs in a tube furnace, the furnace passing over a strip of sample, with decomposition achieved by passing a stream of air through the furnace and over the sample. The products from the tube furnace may then be diluted with secondary air for animal exposures, if required. The atmosphere produced is in a "dynamic steady state," in that the concentrations of decomposition products remain constant because the test material is decomposed at a constant rate throughout the test. The epithet "DIN" has come to represent a number of tube furnace methods based upon the same principle, generally accepted as DIN test results, the important point being to demonstrate that the decomposition atmosphere generated is relatable to real fire conditions, rather than that the apparatus design is standard.

The important feature of this design is its versatility, since the decomposition conditions can be varied over a wide range by varying the sample load, air supply, and furnace temperature. This contrasts with the other methods described, which are very restricted in the range of conditions that can be modeled. The improved tube furnace method, recently developed at the UK Fire Research Station (FRS),[37] is based upon the DIN method concept, and is the only one developed so far that can simulate the decomposition conditions for all fire types, including

nonflaming, early flaming, and fully developed fires with restricted ventilation, particularly post-flashover fires. (See Figure 2-6.37.) A limitation with the official method, in regard to flaming combustion, is that the decomposition conditions tend to be rather vitiated, giving low CO_2/CO ratios, and flaming is unstable. However, this is remedied in the FRS method by increasing the air/fuel ratio in the furnace tube, and the rate of sample advance. In a recent series of experiments it has been possible to increase the ratios to those occurring in early, well-ventilated, full-scale fires, while achieving stable flaming conditions.

UPITT method: The University of Pittsburgh method is considered to give a poor representation of actual fire conditions, and it is considered that it is not possible to relate it to any of the fire conditions shown in Table 2-6.27. For this reason (and others), UPITT data are considered unsuitable for the assessment of toxic potency of materials involved in fires, except in very special cases where the conditions can be shown to be similar to the sequence of events occurring in the UPITT apparatus.

Toxic Potency Data Obtained from Tests under Early, Well-Ventilated Flaming Conditions

Because well-ventilated flaming conditions tend to destroy compounds such as organic irritants, it is to be expected that the toxic potency will be more completely due to the common toxic gases than for the nonflaming fires shown in Table 2-6.29. Table 2-6.30 illustrates this with some examples taken from NBS cup furnace test data. The data for Douglas fir shown that, unlike the nonflaming situation illustrated in Table 2-6.29, the toxic potency can be fully accounted for in terms of carbon oxides, and an LCt_{50} for wood calculated on this basis would be very close to the observed value. For flexible polyurethane (FPU) foam it was not possible to obtain a lethal concentration in the cup furnace under flaming conditions due to limits on the capacity of the apparatus for the size of sample required, but in other experiments a mixture of polyester and FPU were tested. With this mixture of materials it was possible to obtain lethal exposure conditions, and the data are also shown in Table 2-6.30. As with the wood, it was possible to account fully for the observed toxic potency on the basis of carbon oxides and hydrogen cyanide.

For materials that burn less efficiently under these conditions, or which produce inorganic acid gases, the data analyses indicate contributions to lethality from irritants. For example, Table 2-6.31 shows data on PVC and a FR polyurethane foam obtained using the NBS cup furnace method. For the PVC test, the contribution to the total FED from carbon oxides was only 0.19, so that the major cause of death had to be some other factor. Unfortunately the HCl concentration was not measured, but from the mass of PVC decomposed, it can be estimated at approximately 5000 ppm. As the analysis shows this would have been more than enough to have accounted for the observed lethality. With regard to the FR FPU, the yield of common toxic gases was significantly greater than that from the untreated foam, so that it was possible to obtain an LCt_{50} using the cup furnace. The concentrations of carbon oxides and hydrogen cyanide were sufficient to account for approximately 0.7 of the observed toxic potency, but it is possible that the remaining 0.3 represents the effects of unidentified irritants evolved due to the less efficient combustion occurring from this foam compared to an untreated foam.

Based upon available published small- and large-scale test data, it is possible to make some general observations regarding the early, well-ventilated, flaming condition. The basic finding is that the published database is very poor, there being only a few tests or none on quite common materials. The only materials for which a reasonable number of tests have been performed under flaming conditions are wood, flexible polyurethanes, and PVC. Needless to say, these involve a variety of wood species and polymer formulations. Based upon this inadequate database, the pattern that emerges is that the range of toxic potencies of common materials covers approximately a factor of 50, with LCt_{50} exposure doses of from approximately 75 to 3750 $g \cdot m^{-3} \cdot min$. As could be predicted, the least toxic materials are the cellulosics and simple hydrocarbon polymers, such as polypropylene. Flexible polyurethanes are of low to intermediate toxic potency within this range. The most toxic materials are the acrylonitriles, which release quite large amounts of

HCN even under well-ventilated flaming conditions. PVCs are generally somewhat more toxic than the cellulosic materials under these conditions, due to their relatively low combustion efficiency and high HCl yield.

Small-Scale Tests Replicating Fully Developed Fire Conditions—Especially Post-Flashover Fires

The decomposition conditions in fully developed fires depend very heavily upon the conditions in fire compartments and in particular the air supply. A general principle would be that in the common situation of a fire in a building, which would typically contain large amounts of combustible fuel, the fire growth will depend upon the rate of involvement of the fuel in the early stages, with efficient combustion and high CO_2/CO ratios (100/1 to 200/1). Then as the fire grows, combustion becomes increasingly ventilation controlled, so that fully developed fires tend to be oxygen vitiated, with low CO_2/CO ratios ($<$10/1). However, it is possible to have fully developed, well-ventilated fires with high CO_2/CO ratios (up to 100/1), as indicated in Table 2-6.27. These conditions can commonly occur during some stages of test fires in large-scale test rigs. Such large-scale tests usually have a relatively small amount of fuel (such as a single chair), and have a rig with an open side or doorway or window openings, which are, in turn, supplied freely with air from outside or from a large test facility building. Another factor that may provide high CO_2/CO ratios in the effluents from a primarily vitiated post-flashover fire is secondary combustion outside the fire compartment, where the products mix with air and are sufficiently hot to support further combustion. This effect has been observed at the DIN furnace outlet when attempting to simulate post-flashover decomposition conditions.

Accidental fires in real occupied buildings often have access to a much larger amount of fuel than test fires, and often have access to a more restricted air supply (such as air from inside the building). Thus in the Boston Fire Department study of accidental fires,[155] 50 percent had CO_2/CO ratios of less than 10/1 and a further 22 percent had ratios of approximately 10 to 20/1. Only 17 percent fell into the well-ventilated category, with ratios above 40/1. When full-scale tests are more closely related to real buildings or contents, then low ratios occur. For example, a simulation of a fire in a fully furnished hotel bedroom, opening on an open corridor with a side room attached, gave CO_2/CO ratios of 2/1 in the burn room and 3/1 in the side room at the fire peak.[138]

Once a fire has passed beyond the very early, well-ventilated stage, there are basically two paths for continued development, depending largely on the type of fire compartment. First, where the fire occurs in a room-sized compartment, and the room doors and windows are shut, the combustion becomes vitiated from a very early stage, since a typical domestic room will not support complete combustion of more than approximately 1 kg of fuel before the oxygen concentration in the room is reduced to approximately 10 percent and the fire extinguishes or dies down. Fires of this type, involved in many deaths, tend not to develop beyond a small size as long as the compartment is closed, but the CO_2/CO ratio decreases from a very early stage. An example is a burning 5-kg wood crib in a closed room. Table 2-6.32 shows the gas concentrations in the room during this fire, the atmosphere becoming progressively more vitiated and the CO_2/CO ratio decreasing as the fire progresses. The last column shows the influence this process has on the toxic potency of wood, assuming that carbon oxides are the only important toxic products (and also ignoring any toxic effects of low-oxygen hypoxia). The data show that, if a sample of wood was decomposed in a number of runs of a small-scale test under conditions giving the range of CO_2/CO ratios recorded at different stages of the full-scale fire, then the toxic potency of the wood would increase from very low levels as shown.

The other common situation is where a window or door is open, or where the compartment is large, so that there is sufficient ventilation to support a much bigger fire before the air supply becomes the controlling factor. Such fires, typically the cause of smoke deaths in locations remote from the fire, become both hot and vitiated, and constitute the post-flashover situation that chiefly needs to be simulated in small-scale tests, with a temperature of 800°C or more, and CO_2/CO ratios of less than 10/1, and as low as 2/1. The lower part of Table 2-6.32 illustrates this with data from the developed stage of larger (44 kg) wood fires run in the same rig as the 5-kg test. These fires were run

Table 2-6.32 ***Toxic Gas Concentrations and Calculated Toxic Potencies during Full-Scale Wood Fires in a Room-Corridor Test Rig***

1. Fire of 5-kg wood in a closed room—total mass loss 3.5 kg; room temperature approximately 200°C

Time (min)	CO ppm	CO_2 ppm	CO_2/CO Ratio	O_2%	LCt_{50}[a] for COx g·m^{-3}·min
6	750	45,000	60	18	3,750
8	1,500	75,000	50	13.5	3,461
10	2,500	88,500	35	11	2,857
12	4,000	95,000	24	10	2,222
20	9,000	75,000	8.3	11.5	1,034

2. Fires of 44-kg wood in open room with high and low ventilation; room temperature approximately 800°C

High vent.	10,000	150,000	15	9	1,800
Low vent.	50,000	150,000	3 to 1.5[b]	4	750

[a] LCt_{50} calculated in terms of mass loss concentration of wood, assuming carbon oxides to be only toxic products of importance.

[b] Second figure shows ratio in corridor, all other figures in room.

with high and low ventilation from the corridor, to simulate well-ventilated and oxygen-vitiated fully developed (post-flashover) fires. The results show that both fires become vitiated when fully developed, the poorly ventilated fire giving very low CO_2/CO ratios of 3/1 in the room and 1.5/1 in the corridor.

If the typical post-flashover fire is hot, and oxygen vitiated, with low CO_2/CO ratios, the next consideration is what effects these decomposition conditions have on the toxic potency of the products. The most obvious effect is that the toxic potency is increased compared to well-ventilated fires due to the higher concentrations of CO produced as the CO_2/CO ratio falls. The series of room-corridor fires performed at the Fire Research Station using 44-kg wood cribs provides a good example. When these were burned with restricted ventilation, the CO_2/CO ratio fell to the low values mentioned, of 3/1 in the room and 1.5/1 in the corridor after 3.5 min, with very high concentrations of CO (5 percent) in the room. Assuming as before that toxicity would be due solely to carbon oxides, then the theoretical LCt_{50} would be 750 g·m^{-3}·min, which is approximately 5 times more toxic than that in the well-ventilated, early flaming fire, and is similar to results obtained for pine and sipo wood in the DIN apparatus at 850°C.[20] Table 2-6.33 shows the toxic potency analysis for this fire.

A very important aspect of post-flashover fire conditions is the fate of nitrogen in materials. Under hot, vitiated conditions the yield of HCN from all nitrogen-containing materials increases dramatically. Hydrogen cyanide can, therefore, be an important toxic product in post-flashover fires where the fuel has a high nitrogen content. Another problem with such fires is the yield of organic irritants. Vitiated post-flashover fires produce large quantities of smoke, and recent experiments with some common materials decomposed under these conditions in a DIN-style tube furnace have shown that the dense smoke is rich in organic products, which are irritant to mice. With regard to inorganic irritants, such as HCl, these are produced at the same high yield as with early flaming fires, except that their effects are less prominent in the fully developed fire in comparison with the high yields of other toxic products.

Results from DIN and Other Tube Furnace Methods and Full-Scale Tests

If the database of small-scale toxicity test results on materials tested under early flaming conditions is poor, that on materials tested under post-flashover conditions is almost nonexistent. The only small-scale apparatus that can be used to replicate these conditions is the DIN tube furnace, when it is run at high temperatures. A small amount of rodent lethality data is available from tests run using this method at temperatures above 800°C. Apart from this, other data are from a number of small-scale and large-scale tests where analytical measurements were made, from which it is possible to make toxic potency as-

Table 2-6.33 ***Toxic Potency Analysis of Materials Decomposed under High-Temperature, Vitiated Conditions in Large-Scale Fires and in the DIN Apparatus***

LCt_{50} calculated	750 g·m^{-3}·min		81 g·m^{-3}·min	
LCt_{50} observed (DIN test under similar conditions)	876 g·m^{-3}·min		no data	

sessments, assuming that toxic effects were due only to carbon oxides and HCN. In such vitiated post-flashover conditions, it is to be expected that carbon monoxide and hydrogen cyanide would be the dominant toxic species, since carbon monoxide will be present at high yields in all fires and hydrogen cyanide can also be expected at high yields if the materials being burned contain nitrogen. Added to this will be an uncertain contribution from organic irritants, and a contribution from inorganic irritants if these are present. While recent work suggests that organic irritants may be more important under these conditions than was thought previously, it is considered likely that they are less important than under nonflaming conditions, and are unlikely to be the dominant factor in the toxic potency.

Table 2-6.33 shows some examples of toxic potency analyses for this fire condition. The table shows analytical data from a large-scale wood fire, compared with animal data from a DIN test on wood for which no analytical data are available, and data from a small-scale (DIN) furnace test on a nitrogen-containing material (i.e., wool). Rats were exposed in the test at an exposure dose of 18 $g \cdot m^{-3} \cdot min$, and all died. The data shown are projected gas concentrations at the calculated LCt_{50}. For the wood data, the point illustrated is that, based upon the measured carbon oxide concentrations, the toxic potency is likely to be dominated by CO, and on this basis the potency of wood is greater than under well-ventilated flaming conditions. That this projection is reasonable is supported by the results of DIN work on Scotch pine, carried out under nominally similar conditions. This work gave a rat LCt_{50} of 875 $g \cdot m^{-3} \cdot min$, which is similar to the predicted figure for wood decomposed under these general conditions. Unfortunately, no analytical data were published for the DIN test results. For the wool data, the main point illustrated is that even at 700°C, which is somewhat below what would be considered a post-flashover temperature, the toxicity is likely to be dominated by the high HCN yield, and this is also considered to be true for most other nitrogen-containing materials. The other point made strongly by these examples is the paucity of available data for this type of fire.

Based upon the available data it is estimated that the toxic potency range for common materials decomposed under vitiated post-flashover conditions covers an LCt_{50} range from approximately 21 $g \cdot m^{-3} \cdot min$ for materials with a high nitrogen content decomposed at temperatures around 1000°C, up to 3000 $g \cdot m^{-3} \cdot min$ for certain cellulosic or hydrocarbon-based polymers, a range of more than two orders of magnitude for the small sample of published data.

Adaptation of Data from Other Small-Scale Tests

It has been recognized that tests other than the DIN, such as the cone calorimeter and the U.S. radiant method, are incapable of simulating post-flashover decomposition conditions, producing the wrong yields of CO and the wrong CO_2/CO ratios. However, since it is also considered in the U.S. that this fire condition is the most important to study, suggestions have been made that a calculation method can be applied to cone and U.S. radiant data toxicity data to allow for the low CO yield in the tests, relative to those in post-flashover fires. This is obviously not a realistic suggestion, since even if a calculation factor could be used to correct the CO data, the result would still be wrong if no factor were used to correct for the differences in the yields of HCN and other nitrogen-containing products, and for the yields of the many other organic irritants. Rather, if it is wished to study the behavior of materials under vitiated, high-temperature post-flashover conditions, small-scale tests should be used that create such decomposition conditions, so that the chemistry and toxicity of the decomposition products evolved under these conditions can be studied. Since tube-furnace methods similar to the DIN are cheap and very effective means of simulating this fire condition, it is recommended that this method be used, under appropriate conditions of temperature and airflow, for this purpose. Where calculation methods are to be used, it is better to base them on the elemental composition of the material and knowledge of full-scale fire conditions rather than on small-scale tests conducted under inappropriate conditions.

General Pattern of Toxic Potency for Common Materials under Three Fire Conditions

The survey of the toxic potency data for common materials under three fire conditions, (1) non-flaming, (2) early flaming, and (3) post-flashover, has revealed an inadequate database, but it has been possible to derive approximate LCt_{50} for common materials. The results for individual materials range over approximately two orders of magnitude from 20 to 3750 $g \cdot m^{-3} \cdot min$, but when the data are reduced to basic types of materials under each decomposition condition a relatively simple pattern can be described. (See Table 2-6.4.) The table shows the approximate average lethal exposure doses (LCt_{50}) for classes of materials, the LC_{50} for 30-min exposures, and a potency factor (based upon a figure of 500 $g \cdot m^{-3} \cdot min$ for the "normal" lethal potency for combustion products). The findings are as follows.

Under nonflaming oxidative decomposition conditions at >400°C most materials have a similar potency close to 500 $g \cdot m^{-3} \cdot min$ (i.e., a potency factor of approximately 1) due mainly to the effects of carbon monoxide and irritants. The main exceptions are nitrogen-containing materials releasing significant HCN at low temperatures (e.g., polyacrylonitrile, modacrylic, and rigid polyurethane foam), which have toxic potency factors of 3 to 8.

Under early flaming conditions most non-fire-retardant materials are substantially less toxic than under nonflaming conditions. Cellulosics (e.g., wood and cotton) are the least toxic with LCt_{50} of >3000 $g \cdot m^{-3} \cdot min$ (potency factor 0.2). Plastics containing carbon, hydrogen, or oxygen are somewhat more toxic with a potency factor of 0.4 (LCt_{50} ~1200), and those containing low percentages of nitrogen (e.g., flexible polyurethanes, wool, and nylon) also fall into this area. Both PVC and fire-retardant materials have toxic potencies similar to those under nonflaming conditions of approximately 1. Rigid polyurethanes and nitrogen-containing acrylics have high potencies similar to those under nonflaming conditions.

Under post-flashover conditions the potency of all materials increases due to the increased yields of HCN or CO. More smoke and irritants are also present than under early flaming conditions, which may add somewhat to the potency, particularly of the non-nitrogen-containing materials. For cellulosic materials and hydrocarbon plastics, the potency is similar to that under nonflaming conditions (potency factor close to 1). For all nitrogen-containing materials the toxic potency is high, ranging from approximately 2.5 for flexible polyurethane foam to approximately 11 for polyacrylonitrile and modacrylic. It is suggested that PVC would have a potency of approximately 2.5 under these conditions.

The Conduct and Application of Small-Scale Tests in the Assessment of Toxicity and Toxic Hazard

Small, laboratory-scale toxicity tests are of necessity capable only of investigating materials. Investigation of toxic fire hazard associated with actual items such as furnishings can be investigated only in large-scale tests, although it may be possible to a limited extent to study some composite materials using small-scale tests. The potential usefulness of these tests is then to examine the toxicity of the decomposition products from materials. This information can be used in conjunction with other small-scale test data on such characteristics of materials as ease of ignition, rate of flame spread, heat release, and smoke production to judge the suitability of one material versus another for a particular application, and ideally as a prelude to large-scale fire tests. From these it should be possible to draw some conclusions as to likely fire scenarios as well as the toxic and general fire hazards involved. A sensible approach to the use and application of such toxicity tests should involve the following steps:

1. Decide what kinds of fire scenarios are of interest and likely to involve the material under investigation, and what types of fire conditions it may be subjected to—smoldering/overheat, small flaming fire, or fully developed/post flashover.
2. Choose a small-scale test method or methods capable of simulating these conditions.
3. Run the test without animals and measure as many as possible of the common fire products important with respect to toxicity. A minimum that should be measured include CO, CO_2, O_2, HCN (if nitrogen present in material), HCl (or other appropriate acid gases if likely to be present), smoke optical density, and particulate concentration. All tests should be characterized in terms of NAC mass charge, NAC mass loss, decomposition temperature, and whether the decomposition is flaming or nonflaming. Calculate an approximate LCt_{50} at this point for use in hazard modeling. If more information is required, proceed to carry out animal experiments.
4. Set up a test atmosphere at a concentration that should be just sublethal for the known toxic atmosphere constituents (in most cases the determining factor will be the CO concentration). Then, expose a group of animals and measure the toxic effects in terms of type (asphyxiant or irritant), time of onset, severity, and duration, noting in particular the degree of incapacitation and the occurrence of any deaths. In the first instance this should involve a 30-min exposure followed by a 14-day observation period.
5. Decide from this whether the observed effects are consistent with the toxicity due to common fire products, or whether there were any unusual or severe toxic effects. If the toxicity can be interpreted in terms of the common asphyxiant products CO and HCN, then it should be possible to attempt modeling of toxic hazard on the large scale. However, if the products are irritant, as in most cases they will be, or if some unexpected toxic effect should occur, then further investigations are indicated.
6. If some unexpected toxic effect should occur, attempt to identify the toxic product or products responsible, and the conditions under which they are likely to be formed. The minimum necessary is to establish the 30-min exposure LC_{50} concentration to give some indication of the possible toxic potency of the material when decomposed in a fire. However, if the identity of the toxic product and the conditions of its formation are not understood, it is unwise to assume that small-scale tests will adequately predict of what might happen in a large-scale fire. A good example is PTFE (teflon). In one small-scale test method (the NBS method), PTFE decomposes to form a highly toxic lung irritant which causes death at concentrations of two to three orders of magnitude less than that of other polymeric materials.[9] In the Pittsburgh method the material is approximately 20 percent less toxic,[156] and in a tube furnace method similar to the DIN method a further three times less toxic,[157] although still somewhat more toxic than most other materials. However, when decomposed in a way different from any of these tests, the high toxic potency is lost,[158] and it is possible that under real fire conditions the products may not be significantly more toxic than those of other materials, although this is yet to be established.
7. Assess the irritancy potential of a material by measuring the effects of its thermal decomposition and combustion products in animals. With regard to the assessment of irritancy, although many known irritants have been identified in combustion product atmospheres, it is still not possible to predict the irritancy of an atmosphere from an analysis of its composition. The potential for causing upper respiratory tract and eye irritation (sensory irritancy) should be assessed by measuring the mouse RD_{50} concentration of the material. The potential for causing lung irritation with serious or lethal lung inflammation should be assessed by examining postexposure lethality in rats or mice. Thus if carbon monoxide concentrations are relatively low in relation to irritant products, a concentration of decomposition products may occur when the animals die either during, or in most cases after, exposure due to lung inflammation. An LC_{50} concentration for these nonasphyxiant deaths should then be determined to indicate the potency of the material in terms

of causing lung inflammation under specific decomposition conditions. If it is not possible to identify the product or products responsible for these irritant effects, it will be necessary to use the material RD_{50} and LC_{50} data in an attempt to predict likely large-scale toxic hazard. Although this measurement is only approximate, there are indications that both the RD_{50} and LC_{50} levels of most materials fall into relatively narrow bands, each effect spanning approximately one order of magnitude, with one to two orders of magnitude between the effects, at least under nonflaming conditions. Under nonflaming conditions it is likely that most materials may cause potentially serious lung inflammation following a 30-min exposure at an NAC mass loss of approximately 10 mg/L, and severe sensory irritation at somewhat lower concentrations, possibly around 1 mg/L, although tenability limits for humans are difficult to estimate. Under flaming conditions the degree of irritancy is likely to be less, sometimes considerably so, depending upon the efficiency of combustion.

8. Having evaluated the toxicity of the combustion products from the material in this way, it should be possible to use the data in conjunction with other information from small- and large-scale fire tests, or mathematical models, to assess potential toxic hazard for the material or materials in question in their end use configuration.

Misuse of Toxicity Test Data

Another way of using toxicity test results is to rank materials in order of toxicity and choose the least "toxic" material, as if toxic hazard were an inherent property of the material. This is not a realistic approach, since the toxic hazard associated with any material is not an inherent property but depends upon how the material is used and how it may be decomposed in a real fire scenario. Indeed, it is very easy to alter the toxicity of a material in a small-scale fire test simply by altering the test conditions, particularly with respect to CO and HCN yields. Thus, when wood or most other hydrocarbon polymers are decomposed under flaming conditions with restricted oxygen, the CO_2 to CO ratio in the products can be lowered (to around a value of 4)[16,17] and the toxic potency is high. However, under well-oxygenated efficient combustion conditions, the CO_2 to CO ratios in a fire may be as high as 1000, and under such conditions the toxic potency of the products is very low. Although such anomalies can be overcome to some extent by careful control of the small-scale decomposition conditions and by relating them to conditions known to occur in large-scale fires, it is still difficult to predict the CO concentration profile, and hence the toxic hazard, for a large-scale fire from the small-scale fire model in a toxicity test. For this reason, ranking materials in order of their performance in small-scale toxicity tests does not have much meaning or usefulness. The best use of small-scale toxicity tests is to identify the products responsible for the major toxic effects so that the concentration/time profiles of these products in large-scale fires can be measured or modeled, and the likely toxic hazard can be assessed.

Summary of Toxic and Physical Hazard Assessment Model

Having identified the main toxic products evolved in particular fire scenarios in terms of the main types of fire conditions—smoldering/nonflaming, early flaming, and fully developed/post flashover—estimates of potential toxic hazard can be made by a consideration of two sets of information.

1. The concentration/time profiles of the major toxic products in the full-scale fire
2. The time/concentration/toxicity relationships for these toxic products when they occur individually and in combination

From these two data sets, it is possible to construct a model to predict probable time to incapacitation or death due to toxicity for a victim exposed in such a fire.

The first data set, the large-scale fire profile, may be determined by a combination of small- and large-scale fire tests and mathematical modeling. A guide to the general characteristics of fires is shown in Table 2-6.15, and an example of a fire profile in Figure 2-6.15.

The fire profile should be characterized in terms of the following minimum range of parameters, measured or estimated at the breathing zone of a potential victim:

1. Mass loss of material divided by the volume of air into which the material is dispersed
2. Carbon monoxide concentration
3. Hydrogen cyanide concentration (if materials containing nitrogen are present)
4. Carbon dioxide concentration
5. Oxygen concentration
6. Radiant heat flux
7. Air temperature
8. Smoke optical density

Ideally, some measure should also be made of

9. Mass charge concentration of material divided by the volume of air into which the products are dispersed
10. Acid gas concentrations (HF, HCl, HBr, SO_2, or NO_2)
11. Organic product profile, particularly oxidized organic species (especially acrolein, formaldehyde, and crotonaldehyde)

Any properly conducted large-scale fire test or practical fire model should be able to provide concentration (or intensity)/time profiles for all of the first eight parameters. These can then be used as input data for the toxic and physical hazard assessment model.

The aim of the hazard assessment model is to determine the point in time during exposure when potential victims are predicted to become incapacitated, such that they would be unable to escape or their ability to escape would be severely compromised. The model also determines the point where the exposure would be sufficient to cause death either during the fire or later, as a result of the injuries sustained. The hazard assessment is based on a "step through" approach whereby the degree of hazard is calculated for each successive minute (or other appropriate time interval) during the fire, until a point is reached when incapacitation or death is predicted.

For some fire parameters the occurrence of incapacitation (or death) is related primarily to the concentration or intensity of the agent to which the victim is exposed (e.g., radiant heat, smoke optical density, or sensory irritation). Tenability limits have been set for these parameters, and incapacitation is predicted to occur rapidly at the point where the limits are met.

For other parameters (e.g., carbon monoxide, hydrogen cyanide, carbon dioxide, low-oxygen hypoxia, convected heat, and lung irritants) a dose accumulated over a period of time is the primary concern. For these parameters, the fraction of an incapacitating dose acquired each minute is calculated, and the fractions added for each successive minute until the fractional dose reaches unity, when incapacitation is predicted.

Preliminary Rough Estimate of Toxic Hazard

Although it is strongly recommended that a hazard assessment for any particular fire scenario be based on all of the eight major parameters previously listed, it is possible to make a very crude assessment of the existence of a serious toxic hazard by reference to a single parameter, the mass loss/volume dispersed profile. The three items of data needed for such an assessment are

1. The basic fire condition (smoldering, early flaming, or fully developed)
2. The mass loss/dispersal volume time curve for the fire
3. The rodent LC_{50} concentrations for the materials involved in the fire in terms of NAC mass loss, determined from small-scale tests performed under the same decomposition conditions as those in the fire

The dose of products available in the fire per minute in terms of mg min/L of mass loss is expressed as a fraction of the rodent LC_{50} dose in mg·min/L. The fractions of a lethal dose available each minute are added until the fraction reaches unity, when it is predicted that a human fire victim would probably have inhaled a lethal dose of toxic products.

Since the toxic potencies of combustion products from most materials fall into a relatively narrow range of approximately one order of magnitude,[9,42,156] (Table 2-6.2) it is possible to use a single toxic potency figure in simple hazard models. The range of LC_{50} for the preceding references quoted was 5 to 61 mg/L NAC mass loss for a 30-min exposure, which is equivalent to a dose range of approximately 150 to 1800 mg·min/L, with an average value of approximately 30 mg·min/L. Allowing for a margin of safety and for the possibility (derived from primate data)[80] that humans may be more sensitive than rodents to lung damage from fire products, it is recommended that a figure of 300 mg·min/L should be used as a probable lethal dose of combustion products in man for preliminary modeling purposes.

Main Toxic and Physical Hazard Assessment Model

Asphyxiation: The first task is to assess the point at which a victim is likely to become incapacitated by loss of consciousness due to the effects of asphyxiant (narcotic) gases. For this assessment, it is necessary to calculate the fractional incapacitating doses of each asphyxiant gas (CO, HCN, O_2, and CO_2) individually, and interactions between them, for each successive minute of the fire.

Carbon monoxide: The most important toxic fire product is CO. Toxic effects occur when a certain dose in the form of carboxyhemoglobin (COHb) has been inhaled. Time to achieve a COHb concentration causing incapacitation (unconsciousness) for a 70-kg human engaged in three levels of activity is shown in Figure 2-6.14 and calculated from primate incapacitation data and the Coburn-Forster-Kane equation.

For short exposures to high concentrations of CO, COHb concentration can be calculated approximately using the Stewart equation (Equation 6)

$$\%\text{COHb} = (3.317 \times 10^{-5})(\text{ppm CO})^{1.036}(\text{RMV})(t) \quad (6)$$

where

CO = CO concentration (ppm)
RMV = volume of air breathed (L/min)
t = exposure time (min)

From this equation, the expression for the fractional incapacitating dose each minute for a 70-kg human engaged in light activity over periods of up to one hour is derived

$$F_{I\text{co}} = \frac{K(\text{ppm CO}^{1.036})(t)}{D} \quad (7)$$

where

$F_{I_{\text{CO}}}$ = fraction of incapacitating dose
t = exposure time (min)
$K = 8.2925 \times 10^{-4}$ for 25 L/min RMV (light activity)
D = COHb concentration at incapacitation (30 percent for light activity)

For a 70-kg human engaged in light work, an RMV of approximately 25 L/min can be expected with loss of consciousness at around 30 percent COHb. Therefore, this equation predicts incapacitation after approximately 5.3 minutes at a concentration of 5000 ppm CO. For a subject at rest, the RMV will be approximately 8.5 L/min giving a value for K of 2.8195×10^{-4}, and incapacitation is likely at approximately 40 percent COHb. Thus, at 5000 ppm, time to incapacitation will be approximately 21 min.

For smaller adults and especially for children, or for CO concentrations below approximately 2000 ppm and exposure durations above one hour, or also for estimating time to death (at approximately 50 percent COHb), the rate of uptake departs significantly from the Stewart equation and predictions should be based on the CFK equation. (See Appendix 2-6A.) Time to incapacitation and death for small children may be one-half that for adults.

Hydrogen cyanide: Hydrogen cyanide is the next most important toxic gas causing incapacitation by asphyxia in fires. Time to incapacitation depends partly on rate of uptake and partly on dose. (See Figure 2-6.6.) Below a threshold of approximately 80 ppm HCN only minor ef-

fects should occur over periods of up to one hour. From 80 to 180 ppm, time to incapacitation $t_{I_{CO}}$ (loss of consciousness) will be between 2 and 30 min approximately according to the relationship (Equation 8).

$$(t_{I_{CN}})(\text{min}) = \frac{(185 - \text{ppm HCN})}{4.4} \quad (8)$$

For concentrations above approximately 180 ppm, incapacitation will occur rapidly (0 to 2 min).

Deriving an exponential expression for the data gives

$$(t_{I_{CN}})(\text{min}) = \exp\,(5.396 - 0.023 \times \text{ppm HCN}) \quad (9)$$

From Equation 8, the fractional incapacitating dose per minute equation for HCN is derived

$$F'_{I_{CN}} = \frac{1}{\exp\,(5.396 - 0.023 \times \text{ppm HCN})}$$

This has been simplified to

$$F'_{I_{CN}} = \frac{\exp\,([CN]/43))}{220} \quad (11)$$

where [*CN*] represents the concentration of cyanide corrected for the presence of other nitriles besides HCN and for the protective effect of NO_2. [*CN*] can be calculated as [*CN*] = [HCN] + [total organic nitriles] – [NO_2].

Low-oxygen hypoxia: The effects of low-oxygen hypoxia are partly concentration-related and partly dose-related. When a subject reaches equilibrium with respect to different oxygen concentrations, the effects are approximately as follows:

20.9–14.4 percent—no significant effects, slight loss of exercise tolerance
14.4–11.8 percent—slight effects on memory and mental task performance, reduced exercise tolerance
11.8–9.6 percent—severe incapacitation, lethargy, euphoria, loss of consciousness
9.6–7.8 percent—loss of consciousness, death

The time taken to achieve a blood oxygen concentration causing incapacitation depends on the dose of hypoxia acquired over that period. For input into the model, time to loss of consciousness is given by

$$(t_{I_O})\text{min} = \exp\,[8.13 - 0.54(20.9 - \%O_2)] \quad (12)$$

where 20.9 – $\%O_2$ = $\%O_2$ Vit (percent oxygen vitiation)

From this the expression for fractional incapacitating dose per minute is derived

$$F'_{I_O} = \frac{1}{\exp\,[8.13 - 0.54(20.9 - \%O_2)]} \quad (13)$$

Carbon dioxide: As with hypoxia, the effects of carbon dioxide are partly concentration-related, but it is also possible to calculate the time taken to acquire a dose capable of causing loss of consciousness. The concentration-related effects of carbon dioxide are approximately

3–6 percent—respiratory distress, increasing with concentration
6–7 percent—severe respiratory distress, dizziness, bordering on loss of consciousness
7–10 percent—loss of consciousness

There are, therefore, two important considerations with respect to carbon dioxide: (1) it greatly increases the RMV, which will increase the rate of uptake of other toxic gases, and (2) it is itself a asphyxiant.

It is therefore necessary to calculate a multiplication factor ($V\text{CO}_2$) to allow for the effect of the increased RMV caused by carbon dioxide on the rate of uptake of other toxic gases. The expression for this is

$$\text{VCO2} = \exp\left(\frac{[CO_2]}{5}\right) \quad (18)$$

It is also necessary to calculate the fractional incapacitating dose of carbon dioxide. Time to unconsciousness by carbon dioxide is given by

$$t_{I_{CO_2}} = \exp[6.1623 - 0.5189 \times \%CO_2) \quad (19)$$

From this the fractional incapacitating dose per minute expression is derived

$$F'_{I_{CO_2}} = \frac{1}{\exp\,(6.1623 - 0.5189 \times \%CO_2)} \quad (15)$$

Interactions between asphyxiant gases: For the purposes of the hazard model, the following interaction factors are used:

1. CO and HCN are considered to be directly additive.
2. CO_2 increases the rate of uptake of CO and HCN in proportion to its effect on the RMV.
3. The asphyxiant effect of low oxygen hypoxia is considered to be directly additive to the combined effects of CO and HCN.
4. The asphyxiant effect of CO_2 is considered to act independently of the effect of the other gases.

On this basis, it is possible to derive a fractional incapacitating dose equation for asphyxia (Equation 21)

$$F_{in} = [(F_{I_{CO}} + F_{I_{CN}} + \text{FLD}_{\text{irr}}) \times V\text{CO}_2 + \text{FED}_{I_O}] \text{ or } F_{I_{CO_2}} \quad (21)$$

where

F_{in} = fraction of an incapacitating dose of all asphyxiant gases
$F_{I_{CO}}$ = fraction of an incapacitating dose of CO
$F_{I_{CN}}$ = fraction of an incapacitating dose of HCN (and nitriles, corrected for NO_2)
FLD_{irr} = fraction of an irritant dose contributing to hypoxia
$V\text{CO}_2$ = multiplication factor for CO_2-induced hyperventilation
F_{I_O} = fraction of an incapacitating dose of low oxygen hypoxia
$F_{I_{CO_2}}$ = fraction of an incapacitating dose of CO_2

for a 1-min exposure to each gas concentration, C,

$$F_{I_{CO}} = \frac{(8.2925 \times 10^{-4} \times \text{ppm CO}^{1.036})}{30}$$

$$F_{I_{CN}} = \frac{(\exp([CN]/43))}{220}$$

where [CN] represents the concentration of cyanide corrected for the presence of other nitriles besides HCN and for the protective effect of NO_2. [CN] can be calculated as [CN] = [HCN] + [total organic nitriles] – [NO_2].

$$\begin{aligned} \text{FLD}_{\text{irr}} = {} & \text{FLD}_{\text{HCl}} + \text{FLD}_{\text{HBr}} + \text{FLD}_{\text{HF}} + \text{FLD}_{\text{SO}_2} \\ & + \text{FLD}_{\text{NO}_2} + \text{FLD}_{\text{CH}_2\text{CHO}} + \text{FLD}_{\text{HCHO}} + \Sigma\text{FLD}_x \end{aligned} \quad (22)$$

$$V\text{CO}_2 = \exp\left(\frac{[\text{CO}_2]}{5}\right)$$

$$F_{I_O} = \frac{1}{\exp[8.13 - 0.54(20.9 - \%\text{O}_2)]}$$

$$F_{I_{CO_2}} = \frac{1}{\exp(6.1623 - 0.5189 \times \%\text{CO}_2)}$$

An example using data obtained from a large-scale fire test (the single armchair room burn shown in Figures 2-6.15 and 2-6.19) is given in Table 2-6.6. The histograms in Figure 2-6.19 show the average concentrations of asphyxiant gases each minute for the first six minutes of the fire, which are shown numerically in Table 2-6.6. Using the equations given above, the fractional incapacitating dose for each asphyxiant gas is calculated for each minute and these data are shown in Table 2-6.7. The first two rows give the fractional doses for CO and HCN, which are added together and multiplied by the carbon dioxide hyperventilation factor $V\text{CO}_2$. The fractional dose of low-oxygen hypoxia is added to give a total fractional dose for asphyxia for each minute. The running total summed each minute exceeds unity during the fifth minute, giving a figure of 1.199, and indicating the onset of incapacitation (loss of consciousness). Alternatively, asphyxia may occur due to the effects of carbon dioxide, but the cumulative dose of this gas is only 0.065 during the fifth minute, which is insufficient to have any asphyxiant effect.

Physical factors and irritancy: Having calculated the effects of asphyxiant gases the next steps are to assess the effects of radiant and convected heat, smoke obscuration, sensory irritation, and lung irritation.

Radiant heat: As shown in Figure 2-6.28, there is a fairly obvious intensity limit for tolerance of radiant heat at 0.25 W/cm² (2.5 kW/m²). Below this intensity, radiant heat can be tolerated for at least several minutes, but above this intensity for a few seconds only. The curves of radiant heat flux and of the other physical parameters for the first ten minutes of the armchair fire are shown in Figure 2-6.29. The tenability limit is exceeded for approximately one minute during the sixth minute of the fire, and it is predicted that some degree of pain and skin burns might be sustained during that minute due solely to the effects of radiant heat.

The tenability limit for exposure of skin to radiant heat is approximately 2.5 kW/m², below which exposure can be tolerated for at least several minutes. Radiant heat at this level and above causes skin pain followed by burns within a few seconds, but lower fluxes can be tolerated for more than 5 min. For situations where occupants are required to pass under a hot smoke layer in order to escape, this radiant flux corresponds approximately to a hot layer temperature of 200°C. Above this threshold, time (seconds) to incapacitation due to radiant heat $t_{I\text{rad}}$, at a radiant flux of q kW/m² is given by Equation 26 (see Hockey and Rev[132] and Purser[157]).

$$t_{I\text{rad}} = \frac{80}{q^{1.33}} \quad (26)$$

Radiant heat tends to be directional in fires, so that the main problem tends to be local heating of particular areas of skin. The air temperature, and hence that of the air breathed and that in contact with other parts of the body, may be relatively low, even when the radiant flux is high. For this reason the main hazard is pain and burns to the skin, rather than hyperthermia. Skin temperature depends upon the relationship between the rate of heat supply to the skin surface and the removal of heat from inner layers by the blood. There is, therefore, a threshold radiant flux below which significant heating of the skin is prevented, but above which rapid heating of the skin occurs.

Convected heat: For exposures of up to one hour to convected heat from air containing less than 10 percent by volume of water vapor, the time (min) to incapacitation, $t_{I\text{conv}}$ at a temperature T (°C) is calculated from Equation 27:

$$t_{I\text{conv}} = 5 \times 10^7 T^{-3.4} \quad (27)$$

As with toxic gases, the body of a fire victim may be regarded as acquiring a "dose" of heat over a period of time during exposure, with short exposure to a high radiant flux or temperature being more incapacitating than a longer exposure to a lower temperature or flux. The same fractional incapacitating dose model as with the toxic gases may be applied and, providing that the temperature in the fire is stable or increasing, the fractional dose of heat acquired during exposure can be calculated by summing the radiant and convected fractions using Equation 28.

$$\text{FED} = \sum_{t_1}^{t_2} \left(\frac{1}{t_{I\text{rad}}} + \frac{1}{t_{I\text{conv}}}\right)\Delta t \quad (28)$$

Note: $t_{I\text{rad}}$ will tend to zero as q tends to <2.5 kW/m².

Thermal tolerance data for unprotected skin of humans suggest a limit of about 120°C for convected heat, above which considerable pain is quickly incurred along with the production of burns within a few minutes. Depending upon the length of exposure, convective heat below this temperature may still result in incapacitation due to hyperthermia. Examples of tolerance times to different radiant fluxes and air temperatures are shown in Table 2-6.19.

Conducted heat is physiologically important only when skin is in contact with hot surfaces, such as door handles. A 1-s contact with metal at 60°C can cause burns.

The average temperature each minute during the fire and the fractional incapacitating dose of heat are shown in Table 2-6.20. The cumulative fractional dose exceeds unity during the fourth minute (2.273) as the temperature exceeds 220°C, and then continues to increase dramatically during the fifth and sixth minutes. There will also be some degree of added effect from the radiant heat which would further increase the fractional dose. Incapacitation due to skin pain and burns is therefore predicted during the fourth minute, with severe and probably fatal burns of the skin and upper respiratory tract being a strong possibility, particularly after the fourth minute.

Smoke: Visual obscuration by smoke is obviously concentration-related, and a tenability limit of extinction coefficient 1.2/m (OD/m = 0.5) has been set. As Figure 2-6.29 shows, this limit is exceeded during the second minute of the armchair fire, and an extinction coefficient 2.4/m (OD/m = 1.0), or approximately 1 m visibility, is exceeded at the beginning of the third minute, at which point the smoke curve rises very steeply.

The FEC for smoke is given by

$$\text{FEC}_{\text{smoke}} = [\text{OD/m}]/\,0.2 \text{ for small enclosures or } [\text{OD/m}]/0.08 \text{ for large enclosures} \quad (23)$$

Sensory and lung irritancy: As stated in the section on irritancy, there are two factors to consider: (1) the immediate incapacitation due to the painful effects of sensory irritation of the eyes and respiratory tract, adding to the obscurational effects of smoke and disrupting escape behavior, and (2) the later inflammatory effects on the lung which may cause death after exposure.

The FIC for sensory irritatancy is given by

$$\text{FIC} = \text{FIC}_{\text{HCl}} + \text{FIC}_{\text{HBr}} + \text{FIC}_{\text{HF}} + \text{FIC}_{\text{SO}_2} + \text{FIC}_{\text{NO}_2} + \text{FIC}_{\text{CH}_2\text{CHO}} + \text{FIC}_{\text{CH}_2\text{O}} + \Sigma\text{FIC}_x \quad (24)$$

where ΣFIC_x = FICs for any other irritants present.

The FLD for lung inflammation is given by

$$\text{FLD}_{\text{irr}} = \text{FLD}_{\text{HCl}} + \text{FLD}_{\text{HBr}} + \text{FLD}_{\text{HF}} + \text{FLD}_{\text{SO}_2} + \text{FLD}_{\text{NO}_2} + \text{FLD}_{\text{CH}_2\text{CHO}} + \text{FLD}_{\text{HCHO}} + \Sigma\text{FLD}x \quad (25)$$

where ΣFLD_x = FLDs for any other irritants present.

Alternatively the sensory irritancy can be assessed in terms of the RD_{50} of a fire effluent mixture evolved from a material under defined decomposition conditions in a small-scale combustion toxicity test. Lung inflammation can be assessed in terms of late rodent death (postexposure) in a small-scale combustion toxicity test.

With regard to the worked example, the first consideration is whether the victim would be able to escape from the fire. In this context sensory irritation is most important. This is concentration-related, and in order to predict the irritancy of the smoke, it is necessary to know the RD_{50} concentration of the atmosphere produced by the materials involved under the particular decomposition conditions existing in the fire. Most importantly, it is necessary to know the concentration/time profile of the fire products in terms of mass loss per liter of air (NAC mass loss). Although the mass loss curve for the armchair is shown in Figure 2-6.29, there are no data on the volume of air into which this mass was dispersed during the fire. For the purposes of this example it will be necessary to make an estimate of possible mass loss concentration. Also, since the RD_{50} of the polyurethane and polystyrene components of the chair under flaming conditions are unknown, it will be necessary to use estimated values.

In the section on irritancy, a general tenability limit for severe sensory irritation was set at a concentration of 1 mg/L NAC mass loss, and an incapacitating dose for serious postexposure lung inflammation was set at 10 mg/L NAC mass loss for 30 min (a *Ct* product of 300 mg·min/L). From the general conditions, the smoke curve, and the CO concentration curve, it is estimated that the tenability limit for sensory irritancy would be exceeded during the third minute, greatly adding to the deleterious effects of smoke on vision and escape behavior.

With regard to lung irritation, it is estimated that the average mass loss concentration over the first five minutes of the fire would be approximately 10 mg/L. If so, this would represent a fractional incapacitating dose of 50 mg·min/L, which would probably be insufficient compared with the more serious effects of heat exposure, to cause significant lung damage after exposure. However, if the average mass loss concentration over the first five minutes should reach 60 mg/L, then serious effects on the lung would likely occur after, and probably during, exposure.

Interactions: In terms of physiological effects, it is likely that there would be some degree of interaction between asphyxia and several of these physical factors, but it is likely that most would be relatively minor during the fire, and a reasonable model can be used in which asphyxia, sensory irritancy, and the effects of heat and visual obscuration can be treated separately (with the possible exception of the effects of CO_2-induced hyperventilation on the uptake of irritants). At the behavioral level, interactions may be more important. The interaction between sensory irritation and visual obscuration has been mentioned and there is some experimental evidence for such an interaction in humans.[86] After exposure, as mentioned in the section of this chapter on heat, the effects of skin burns, respiratory tract burns, and chemical irritation (and even possibly CO asphyxia) all combine to increase the probability of fatal pulmonary edema and inflammation.

Summary of Model Predictions for Armchair Fire

From the analysis, the effects on a victim exposed to the conditions in the armchair room burn (Figure 2-6.15) are predicted as follows:

1. Toward the end of the second minute and the beginning of the third minute, the smoke optical density and mass loss/liter would exceed the tenability limits for

visual obscuration and sensory irritancy sufficiently to severely inhibit escape from the room.
2. During the fourth minute, the average temperature is 220°C, and sufficient heat would be accumulated in the skin surface to cause skin burns resulting in incapacitation.
3. During the fifth minute, a victim is likely to lose consciousness due to the combined effects of the accumulated doses of asphyxiant gases.
4. It is predicted that a victim escaping or rescued after the fourth minute would suffer severe postexposure effects due to skin burns, possible laryngeal burns with accompanying edema and danger of obstructive asphyxia, and also pulmonary edema and inflammation which might well be fatal (due to the combined effects of inhaled hot gases, chemical irritants, and the pulmonary secondary effects of skin burns). After the sixth minute, it is likely that a victim would die at some time between a few minutes and one hour due to the effects of asphyxia, circulatory shock, and possibly hyperthermia.

It is unlikely that an otherwise healthy adult would be able to escape from a fire such as this if he or she remained longer than three minutes after ignition. Three minutes is a long time in which to leave a room, however, so providing the victim is awake and aware of the fire, is not otherwise incapacitated, and does not stay after two minutes in an attempt to fight the fire or rescue belongings, it is likely that he or she would be able to escape without serious injury. Tenability limits for some 5- and 30-minute exposures to common toxic fire products in terms of time to incapacitation and death are shown in Appendix 2-6B.

Appendix 2-6A

Coburn-Forster-Kane Equation for the Uptake of Carbon Monoxide in Man

The Coburn-Forster-Kane (CFK) equation[22] provides an accurate method for predicting the blood carboxyhemoglobin concentration in humans (or various animal species) resulting from exposure to a given concentration of carbon monoxide. The theoretical predictions of the equation have been validated for humans by experimental human exposures to carbon monoxide.[23,54] The strength of the equation is that it is based upon numerical values for all the main constants and variables that determine the uptake of CO into the blood; it is therefore not based on a simple empirical fit to observed uptake data in individuals, as are other CO uptake equations.[19,27] The result is a powerful equation that can be used to predict CO uptake over wide ranges of concentrations and time scales, and can accommodate variables such as the degree of activity of the subject, body size (for men, women, or children), blood volume, hemoglobin concentration, and lung function status, all of which can affect CO uptake and therefore time to incapacitation or death for a given subject. The equation should be equally applicable to animals, providing of course that data for the various constants and variables are available. The disadvantage of the CFK equation is its complexity. In particular, several of the variables need to be calculated from other equations, which in turn contain variables which must be calculated from further equations. The data in the text and figures in this chapter are all based on CO uptake for a 70-kg human, either at rest [RMV approximately 8.5 L/min, engaged in light work (e.g., walking 6.4 km/h—RMV approximately 25 L/min)] or engaged in heavy work (e.g., slow running 8.5 km/h or walking 5.6 km/h up a 17 percent gradient—RMV approximately 50 L/min).[55] In this Appendix, data for necessary constants and equations for the derivation of all variables, with their sources, have been provided to enable uptake calculations to be made for any particular situation.

The basic form of the CFK equation[22] is as follows:

$$\frac{A[\mathrm{HbCO}]_t - BV_{\mathrm{CO}} - PI_{\mathrm{CO}}}{A[\mathrm{HbCO}]_0 - BV_{\mathrm{CO}} - PI_{\mathrm{CO}}} = e^{-tAV_bB}$$

where

$$A = \frac{\overline{P}_{\mathrm{C,O_2}}}{M[\mathrm{HbO_2}]}$$

$$\overline{P}_{\mathrm{C,O_2}} = PI_{\mathrm{O_2}} - 49$$

$$PI_{\mathrm{O_2}} = 148.304 - 0.0208 \times PI_{\mathrm{CO}}$$

$$M = 218$$

$$[\mathrm{HBO_2}] = 0.22 - [\mathrm{HbCO}]_t$$

$$[\mathrm{HbCO}]_t = [\mathrm{COHb\%}t] \times 0.0022$$

$$B = 1/DL_{\mathrm{CO}} + PL/VA$$

$$DL_{\mathrm{CO}} = 35V\mathrm{O_2} \times e^{0.33} \quad \text{Reference 159}$$

$$V\mathrm{O_2} = \frac{\mathrm{RMV}}{22.274} - 0.0309 \quad \text{Reference 55}$$

$$PL = 713$$

$$V_A = 0.933V_E - 132f$$

$$f = \exp\,[0.0165 \times \mathrm{RMV} + 2.3293] \quad \text{Reference 159}$$

where

$[\mathrm{HbO_2}]$ = mL of O_2 per mL of blood

$[\mathrm{HbCO}]_t$ = mL of CO per mL of blood at time of t

$[\mathrm{HbCO}]_0$ = mL of CO/mL blood at the beginning of the exposure. Can be taken as 0.8 percent COHb = 0.00176 mL CO/mL blood for a nonsmoker[21]

M = ratio of the affinity of blood for CO to that for O_2

$P_{\mathrm{C,O_2}}$ = average partial pressure of oxygen in lung capillaries, mmHg

$\dot{V}_{\mathrm{CO}}$ = rate of endogenous CO production, mL/min very small set at 0.007 mL/min[23]

DL_{CO} = diffusivity of the lung for CO, mL/min·mmHg

PL = barometric pressure minus the vapor pressure of water at body temperature, mmHg

V_b = blood volume, mL; 74 mL/kg body weight (approximately 5,500 mL for a 70 kg human)[23]

PI_{CO} = partial pressure of CO in inhaled air, mmHg
V_A = alveolar ventilation rate, mL/min
t = exposure duration, min
e = 2.7182
PI_{O_2} = partial pressure of oxygen in inspired air
COHb%t = percent carboxyhemoglobin at time of t
V_{O_2} = oxygen consumption, L/min
RMV = respiratory minute volume (volume of air breathed/min, liters)
V_E = RMV, mL
f = respiratory frequency, breaths/min

Appendix 2-6B

Tenability Limits

Asphyxiants: Concentrations at which there would be danger of incapacitation (loss of consciousness) and death after approximately 5 and 30 minutes exposure in a person engaged in light activity are shown in Table 2-6B(a).

Irritants: The initial painful effects of irritants (sensory irritation) are mainly upon the eyes and upper respiratory tract. These effects do not worsen with prolonged exposure and may even lessen. The toxic effects on the lungs increase with prolonged exposure, are often most serious some hours after exposure, and may cause death.

For sensory irritation two levels are presented: level a represents unpleasant and quite severely disturbing eye and upper respiratory tract irritation; and level b represents severe eye and upper respiratory tract irritation with severe pain, blepharospasm, copious lacrymation, and mucus secretion accompanied by chest pain. For deaths, the levels represent concentrations at which there is danger of death occurring during or immediately after exposure.

In general, smokes are irritating when they contain oxidized organic products.[16] The most irritating of these substances known to occur commonly in smokes from a number of different materials is acrolein. Another well-known irritant is the acid gas hydrogen chloride, which is evolved during the thermal decomposition of polyvinyl chloride (PVC). Data on these two products are presented in Table 2-6B(b) as examples of irritant effects.

Appendix 2-6C

Glossary of Terms

Acidosis: A condition in which the pH of the blood is lowered (i.e., becomes more acidic). Respiratory acidosis in fire exposures results from excess carbon dioxide uptake. Metabolic acidosis results from impaired tissue respiration (due to tissue hypoxia) caused by burns or asphyxia. (See alkalosis.)

Addition: Two or more toxic substances are considered to exert an additive effect when they act in concert, such that the effect in combination is greater than the effect of either substance acting alone, but not greater than the sum of the effects of either substance acting alone (when they may be said to be directly additive). (See also synergism.)

Aerodynamic diameter: The aerodynamic diameter of a particle is an expression of particle size, and represents the diameter of a spherical particle of unit density with the same aerodynamic properties as the particle under consideration.

Aerosol: Solid or liquid particles dispersed in air.

Alkalosis: Respiratory alkalosis occurs when the pH of the blood is increased (i.e., becomes more alkaline). It is caused by excess removal of carbon dioxide from the blood via the lungs during hyperventilation, and may cause a loss of consciousness.

Asphyxia: Suffocation, decrease in the oxygen content, and increase in the carbon dioxide content of the blood. This may occur due to laryngeal spasm caused by burns or irritant gases, or to impairment of breathing or gas exchange in the lung. The term has been extended to include all causes of tissue hypoxia, including exposure to asphyxiant gases (low oxygen concentration due to the excess of any other gas, or exposure to the asphyxiant gases carbon monoxide and hydrogen cyanide, which produce asphyxia chemically).

Atmosphere (Fire atmosphere or Test atmosphere): The total airborne medium to which a victim or experimental animal is exposed, consisting of solid and liquid particles and vapors dispersed in air.

Behavioral effects/incapacitation: The extent to which exposure to fire products affects the ability or willingness of a subject or experimental animal to perform coordinated movements or tasks, particularly movements or

Table 2-6B(a) ***Tenability Limits for Incapacitation or Death from Exposures to Common Asphyxiant Products of Combustion***

	5 min		30 min	
	Incapacitation	Death	Incapacitation	Death
CO	6000–8000 ppm	12,000–16,000 ppm	1400–1700 ppm	2500–4000 ppm[44,45]
HCN	150–200 ppm	250–400 ppm	90–120 ppm	170–230 ppm[45,59]
Low O_2	10–13%	<5%	<12%	6–7%[21,25,45]
CO_2	7–8%	>10%	6–7%	>9%[21,25,45]

Table 2-6B(b) ***Tenability Limits for Sensory Irritation or Death from Irritant Substances***

	Sensory irritation		Death (minutes)		
	a	b	5	10	30
Acrolein (ppm)	1–5[21,84]	5–95[84,85]	500–1000[85]	150–690[84,91]	50–135[84,91]
HCl (ppm)	75–300[21]	300–11,000[84,85]	12,000–16,000[84,85]	10,000[84]	2000–4000[21]

tasks similar to those required to escape from a fire. (See incapacitation.)

Bioassay: Originally a term reserved for the use of a biological system to detect or measure the amount of a biologically active material. In the fire context, it refers to the use of animal exposures rather than chemical analysis to determine the toxicity of a combustion product atmosphere.

Blepharospasm: Involuntary and sustained closure (spasm) of the eyelids. In fires this is due to the painful stimulation of the cornea by combustion products that are sensory irritants.

Bronchoconstriction: Constriction of the conducting airways in the lung due to the contraction of smooth muscle in the airway walls in response to an agonist or to stimulation of irritant receptors acting through the vagus nerve.

Burn: Tissue lesion caused by heat or chemicals. For description of burn types and degrees, see text.

Carboxyhemoglobin (COHb): Combination of carbon monoxide with hemoglobin in the blood, which limits the combination of hemoglobin with oxygen (oxyhemoglobin), and therefore the carriage of oxygen in the blood.

Cerebral depression: Condition in which the electrical activity of the cerebral cortex as revealed in the electroencephalogram consists mainly of slow wave (or delta wave) activity. This is typical of a semiconscious or unconscious state.

Combustion products: Strictly speaking, this means the products of flaming decomposition, and is used in this sense when contrasted with thermal decomposition products. However, in general usage, the term "combustion products" may be taken to include all fire products, whether produced by flaming or nonflaming thermal decomposition.

Concentration: The amount of a contaminant in the atmosphere per unit volume of the atmosphere, usually quoted as mass/volume (mg/L or mg/m^3) or volume/volume (ppm or percent). (See nominal atmosphere concentration.)

Dose: The amount of a toxicant to which a fire victim or test animal is exposed. The simplest estimation of dose for inhalation toxicology is to multiply the atmosphere concentration by the duration of exposure (Ct product). A lethal dose may be expressed in terms of the LCt_{50}. However, other factors may affect the amount of toxicant actually entering the body, and for fires it may be necessary to express dose in terms of the material in the fire. (See nominal atmosphere concentration.)

Edema: Accumulation of an excessive amount of fluid in cells, tissues, or body cavities. Pulmonary edema occurs when a fluid exudate leaks out of blood vessels as a result of inflammation or circulatory insufficiency, and the lung tissues become swollen and waterlogged. Further development results in a fluid exuded within the alveolar spaces. This fluid accumulation seriously affects gas exchange in the lung and may be fatal.

Electroencephalogram: Waves of electrical activity in the cerebral cortex recorded from the surface of the head, which give an indication of the physiological state of the brain and the degree of alertness of the subject. A preponderance of fast (beta and alpha) activity indicates a conscious and normal state, whereas a preponderance of slow (theta and delta) activity signifies a physiologically depressed or unconscious state.

Erythema: Reddening of the skin in response to heat. This change coincides with pain and just precedes a skin burn.

Fire profile: Record of the changes with time of the concentrations of important fire products and intensities of physical parameters during the course of a fire.

Flaming fire: In the context of this chapter, this refers to the early stages of fire growth (pre flashover), when the fire is still confined to burning items within a well-defined area.

Flashover: Point in growth of a flaming fire where the flames are no longer confined to burning items, but also occur within the fire effluent, remote from the seat of the fire.

Fractional incapacitating dose: The dose of a toxic product acquired during a short period of time, expressed as a fraction of the dose required to cause incapacitation at the average exposure concentration during that time interval. The fractional incapacitating doses acquired during each short time period are summed throughout the exposure, incapacitation occurring when the fraction reaches unity.

Fully developed fire: A fire that has reached its maximum extent of growth, usually extending throughout the fire compartment.

Haber's rule: Principle that toxicity in inhalation toxicology depends on the dose available and that the product of concentration and exposure time is a constant.

Hazard: A toxic fire hazard exists when a toxic product is present at a sufficient concentration and over a sufficient period of time to cause a toxic effect. A physical fire hazard exists when a physical fire parameter (heat or

smoke), is present at an intensity and over a period sufficient to cause injury or seriously inhibit the ability to escape from a fire.

Hypercapnia: Increased blood carbon dioxide concentration.

Hyperthermia (heat stroke): An increase in body temperature above 37°C. Hyperthermia is life-threatening if the body core temperature, or temperature of the blood entering the heart, exceeds 42.5°C.

Hyperventilation: Increased rate and depth of breathing (increased respiratory minute volume, or RMV), in response to increased carbon dioxide, hypoxic hypoxia, hydrogen cyanide, exercise, heat, or stimulation of pulmonary irritant receptors.

Hypoxia: A reduction in the amount of oxygen available for tissue respiration. This can occur in the following four ways:

Anemic hypoxia: The arterial PO_2 is normal, but the amount of hemoglobin available to carry oxygen is reduced and the ability to release oxygen to the tissues is impaired. For fire exposures this results mainly from the formation of carboxyhemoglobin following exposure to CO, but an anemic subject would be at increased risk.

Histotoxic hypoxia: The amount of oxygen delivered to the tissues is adequate, but due to the action of a toxic agent such as HCN, the tissue cells cannot make use of the oxygen supplied to them.

Hypoxia hypoxia (low-oxygen hypoxia): The PO_2 of the arterial blood is reduced as a result of a low atmospheric oxygen concentration or impairment of gas exchange in the lung, due to bronchoconstriction or respiratory tract damage or disease.

Ischemic hypoxia: Blood flow to a tissue is so low that adequate oxygen is not delivered to it despite a normal PO_2 and hemoglobin concentration. This occurs during shock following burns and in cerebral tissue due to alkalosis, or briefly during postural hypotension.

Incapacitation: An inability to perform a task (related to escape from a fire) caused by exposure to a toxic substance or physical agent in a fire. A distinction is sometimes made between severe physiological incapacitation, in which the subject is unable to move normally, such as might occur in an unconscious or badly burned victim, and the more behavioral incapacitation, such as that caused by visual obscuration or eye irritation from smoke, in which the victim is more or less intact, but still unable to escape from the fire.

Inflammation: A complex of reactions occurring in blood vessels and adjacent tissues around the site of an injury. The initial reaction is congestion (engorgement of local blood vessels), exudation of fluid into the tissues (edema), and pain. This is followed by a phase of destruction and removal of injured tissue by inflammatory cells, and then a phase of repair.

Intensity: Level of a harmful physical fire parameter (such as radiant heat flux, air temperature, or smoke optical density).

Intoxication: A state in which a subject is adversely affected by a toxic substance. Specifically, the time at which a subject has taken up sufficient of an asphyxiant (narcotic) gas that he or she behaves like someone severely affected by alcohol.

Irritation and irritancy: Irritation is the action of an irritant substance, irritancy is the response. This response takes the following two forms:

Pulmonary (lung) irritant: Response occurs when an irritant penetrates into the lower respiratory tract. This may result in breathing discomfort (dyspnea), bronchoconstriction, and an increase in respiratory rate during the fire exposure. In severe cases it is followed after a period (usually of a few hours) by pulmonary inflammation and edema, which may be fatal.

Sensory irritant: Response occurs when an irritant substance comes in contact with the eyes and upper respiratory tract (and sometimes the skin), causing a painful sensation accompanied by inflammation with lacrimation or mucus secretion. At low concentrations, this adds to the visual obscuration caused by smoke, but at high concentrations the severe effects may cause behavioral, and to some extent physiological, incapacitation. Sensory irritation causes a decrease in respiratory rate which is transient in humans, but continuous in rodents.

Lacrimation: The production of tears in response to sensory irritation of the eyes.

LC_{50}: Lethal concentration—50 percent. The concentration statistically calculated to cause the deaths of one half of the animals exposed to a toxicant for a specified time. It may be expressed as volume/volume (ppm, percent) or mass/volume (mg/L). Care must be taken in comparing LC_{50}s of both the exposure duration and the postexposure period over which deaths were scored. In combustion toxicology, the LC_{50} may be related to the test material rather than its products, and expressed in terms of the nominal atmosphere concentration of material either of mass charge or mass loss. (See nominal atmosphere concentration.)

LCt_{50}: The product of exposure concentration and duration causing the deaths of 50 percent of animals.

Narcosis: Literally "sleep induction," but used in combustion toxicology to describe central nervous system depression causing reduced awareness, intoxication, and reduced escape capability, leading to loss of consciousness and death in extreme cases. The asphyxiant gases CO, HCN, and CO_2 cause asphyxia, as does lack of oxygen due to the inhalation of an atmosphere low in oxygen, an impairment of breathing, or an impairment of gas exchange in the lung. The terms "narcosis" and "narcotic gases" are used synonymously with the terms "asphxia" and "asphyxiant gases."

Nominal Atmosphere Concentration (NAC): The theoretical concentration of test substance in a test atmosphere, calculated from the mass of test substance produced from the atmosphere generation system each minute divided by the air volume into which it is generated. This concept is not directly applicable to combustion toxicology since

the test material is decomposed in the fire or furnace system, but two derivative concepts are used to relate the test material to the degree of toxicity as follows:

Nominal Atmosphere Concentration mass charge (NAC mass charge): The mass of material placed in the furnace system per volume of air into which it is dispersed (mg material/liter).

Nominal Atmosphere Concentration mass loss (NAC mass loss): The mass loss of material during decomposition per volume of air into which it is dispersed (mg material/liter).

Physiological effects: Effects of chemical fire products or physical fire parameters on the functioning of the body, as opposed to parameters affecting the mind. Thus, a physiological effect of smoke is that it obscures vision, which might have a psychological effect on the willingness of a victim to enter a smoke-filled corridor.

Pneumonia (Pneumonitis): Inflammation of the lungs, in fire victims due to the direct effects of inhaled chemicals or hot gases, or secondarily to skin burns. The initial inflammatory phase may be followed by infection. As it passes through different phases, pneumonia may be life-threatening at any time from one hour after exposure in a fire to several weeks after exposure.

Potency: The toxic potency is a measure of the amount of a toxic substance required to elicit a specific toxic effect—the smaller the amount required, the greater the potency.

Psychological effects: Psychological effects of exposure to fire scenarios are on the mind of the victim, and may result in a variety of behavioral effects. These are distinct from physiological effects on body function (see above). A fire victim is likely to suffer both types of effects at various stages of a fire, and interactions between psychological and physiological effects are likely.

Psychomotor: Psychomotor skills are required to perform behavioral tasks involving a series of coordinated movements of the type required to escape from a fire in a compartment (such as a building).

Pyrolysis: In this chapter, the term "pyrolysis" is restricted to the thermal decomposition of materials without oxidation. In small-scale tests pyrolysis may be achieved by heating the material in a stream of nitrogen.

RD_{50}: Respiratory depression 50 percent—statistically calculated concentration of a sensory irritant required to reduce the breathing rate of laboratory rodents (usually mice) by 50 percent.

Respiratory Minute Volume (RMV): Volume of air breathed each minute (liters/minute). RMV = TV × RR.

Respiratory Rate (RR): Respiratory frequency (i.e., number of breaths per minute).

Respiratory tract: The nose, pharynx, larynx, trachea, and large bronchi are termed the upper respiratory tract, and the bronchioli, alveolar ducts, and alveoli are termed the lower respiratory tract.

Shock: A reduction in the circulating blood volume with a fall in blood pressure.

Smoke: Total fire effluents, consisting of solid and liquid particles and vapors.

Smoldering/Nonflaming Oxidative Decomposition: Thermal decomposition in which there is partial oxidation of the pyrolysis products, but no flame. This may result from overheating of materials by means of an external heat source, or from self-sustained smoldering.

Specific toxicity: A particular adverse effect caused by a toxicant (e.g., asphyxia, irritancy).

Supertoxicant: A term used to describe a toxicant with an unusual specific toxicity not usually associated with fire effluents, often with a high potency.

Synergism: Situation where the toxic potency of two or more substances acting in concert is greater than the sum of the potencies of each substance acting alone.

Tenability limit: Maximum concentration of a toxic fire product or intensity of a physical fire parameter that can be tolerated without causing incapacitation.

Thermal decomposition: Chemical breakdown of a material induced by the application of heat.

Tidal Volume (TV): Volume of air exhaled in each breath.

Toxicity: The nature and extent of adverse effects of a substance upon a living organism.

Ventilation (lung): The volume of air breathed each minute (synonymous with respiratory minute volume).

CHAPTER 7

Flammability Limits of Premixed and Diffusion Flames

Craig Beyler

Introduction

It is well known that not all fuel/oxidant/diluent mixtures can propagate flame. There exist limits definable in terms of fuel/oxidant/diluent composition outside which normal flame-type combustion cannot be sustained. Definition of these limits has received a great deal of attention in premixed combustion conditions, that is in systems where the fuel and oxidant are mixed prior to combustion. Despite scientific interest in the subject dating back to the nineteenth century, the mechanism responsible for flammable limits is not yet understood. Nonetheless, a great deal has been learned that has practical application.

Much less investigation into the nature and cause of limits in diffusion flames has been undertaken. Empirically, clear parallels exist between diffusion and premixed limits, and these will be explored in the latter portion of this chapter.

Premixed Combustion

Premixed flame fronts can only propagate within a range of compositions of fuel and oxidant. The composition limits within which a flame can propagate are known as the upper and lower flammable limits, and are expressed as concentrations of the fuel in a specified oxidant/diluent mixture at a specified temperature and pressure. For instance, the lower flammable limit (LFL) of methane in air at normal temperature and pressure is 5 percent by volume, and the upper flammable limit (UFL) is 15 percent by volume. As such, only methane/air mixtures with methane concentrations between 5 and 15 percent methane will support propagation of flame. For most simple hydrocarbons, the lower and upper flammable limits in air correspond to an equivalence ratio of approximately 0.5 and 3, respectively. The lower flammable limit concentrations for these fuels is approximately 48 g/m^3. (See Figure 2-7.1[1])

The most widely used method of measuring flammable limits was developed by the U.S. Bureau of Mines.[2] The apparatus consists of a 1.5 m-long, 0.05 m-diameter vertical tube which is filled with the fuel/oxidant/diluent mixture to be tested. The top of the tube is closed, and the base of the tube can be closed until the start of the test to prevent diffusion of the mixture from the tube. With the base of the tube open, the mixture is ignited by a spark or small pilot flame at the base of the tube, and the travel of the flame front up the tube is observed. The mixture is deemed to be within the flammable limits if the flame can propagate halfway up the 1.5 m tube. The test is designed

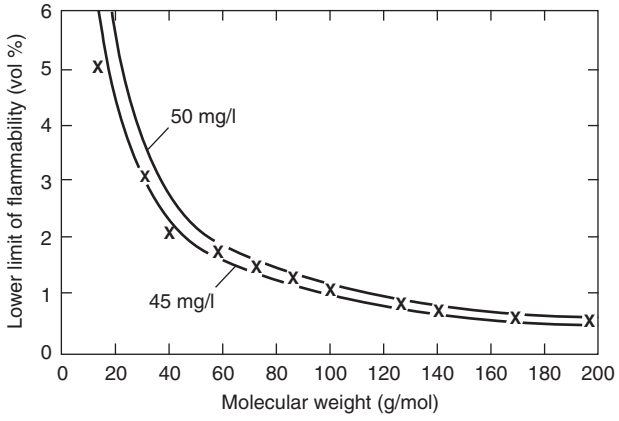

Figure 2-7.1. ***Effect of molecular weight on lower limits of flammability of alkanes at 25°C.[1]***

Dr. Craig Beyler earned a Ph.D. in engineering science at Harvard University under the direction of Professor Howard Emmons and served on the faculty of Worcester Polytechnic Institute's Center for Firesafety Studies. Dr. Beyler is currently technical director of Hughes Associates, Inc., Fire Science and Engineering.

to identify the range of mixture compositions capable of flame propagation remote from the ignition source.

The apparatus can be used with ignition at the top of the tube, but the flammable limits determined for downward propagation are narrower than for upward propagation. The 0.05-m diameter of the tube was chosen as the smallest diameter at which the heat losses from the flame to the tube wall had minimal effect on the flammable limits determined. (See Figure 2-7.2[3]) Several other methods for determining flammable limits are available.[4–7] While some methods are designed for use in special conditions, others simply reflect national differences. While each method gives substantially similar results, some variations in results do exist (see, for example, References 8 and 9).

Mixtures are capable of combustion outside the flammable limits, but external energy must be provided throughout the mixture volume in order to allow propagation of a flame.[10] An example of this behavior is shown in Figure 2-7.3. A small hydrogen diffusion flame is used as a pilot source in a lean methane/air mixture. At methane concentrations less than 5 percent, combustion occurs only in the wake of the pilot flame. Above 5 percent, the flame can propagate away from the pilot flame, regardless of the orientation of the pilot flame.

Flammable limits are a function of the oxygen and inert concentrations, as well as the mixture temperature and pressure. As the concentration of inerts is reduced and the

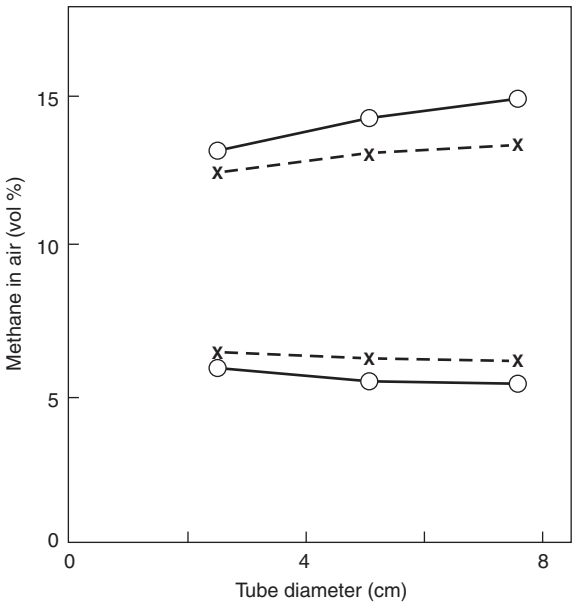

Figure 2-7.2. ***Upper and lower flammable limits of methane as determined in a vertical tube apparatus for upward propagation (circles), and for downward propagation (crosses).[3]***

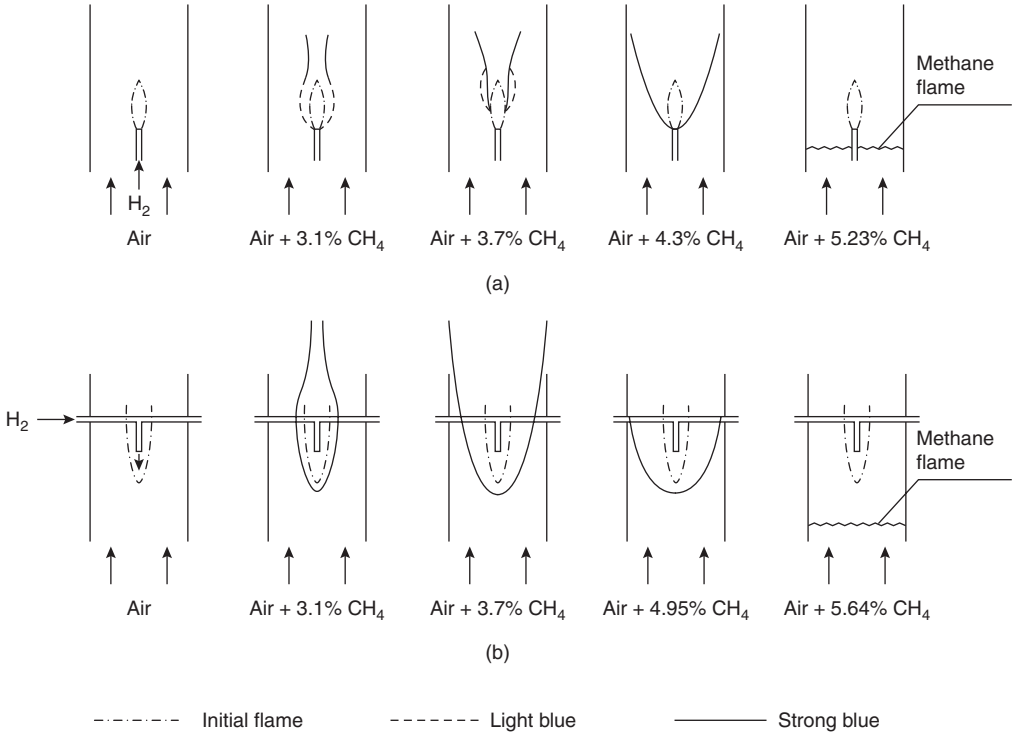

Figure 2-7.3. ***A small jet diffusion flame in a coflowing (a) and contraflowing (b) stream as the concentration of the fuel in the stream is gradually increased up to ignition. The stream velocity is 0.222 m/s, and the hydrogen jet diameter is 1.52 mm.[10]***

oxygen concentration is increased, the upper flammable limit is increased, while the lower limit is relatively unchanged. This result can be understood by observing that at the lower flammable limit there is always more than enough oxygen present for complete combustion, while at the upper limit less than the stoichiometrically required oxygen is present. Hence, at the upper limit the additional oxygen participates in the combustion process, while at the lower limit the additional oxygen simply replaces inert gas.

The lower flammable limit is also insensitive to the pressure, except at pressures well below atmospheric. The upper limit shares this insensitivity at subatmospheric pressures, but the upper limit increases with increasing pressure above atmospheric. (See Figure 2-7.4.)[1]

The flammable limits widen with increases in mixture temperature as illustrated in Figure 2-7.5;[1] this aspect will be discussed further later in this chapter. Figure 2-7.5 also relates flammable limits with the saturation vapor curve and the autoignition temperature (AIT). The flashpoint of a liquid is given in the figure as T_L. At that temperature, the vapor pressure at the liquid surface is at the lower flammable limit. The corresponding upper limit temperature is given as T_U. If a liquid is contained within a closed vessel and the vapors are allowed to come into equilibrium at temperatures above the upper limit temperature, the vapors in the vessel will be above the upper flammable limit. This result typically occurs in an automobile gas tank. If the liquid is not enclosed fully, there will be a location above from the surface of the liquid where the fuel/air mixture will be diluted below the upper flammable limit and will ignite if an ignition source is present.

Predicting Lower Flammable Limits of Mixtures of Flammable Gases (Le Chatelier's Rule)

Based on an empirical rule developed by Le Chatelier in the late nineteenth century, the lower flammable limit

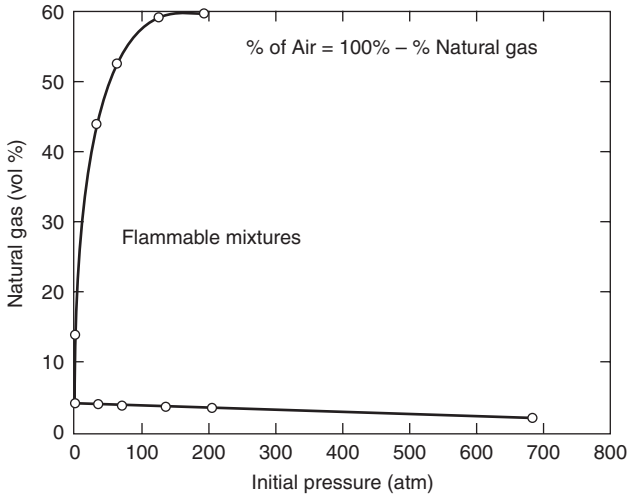

Figure 2-7.4. ***Effect of pressure on the limits of flammability of natural gas in air at 28°C.[1]***

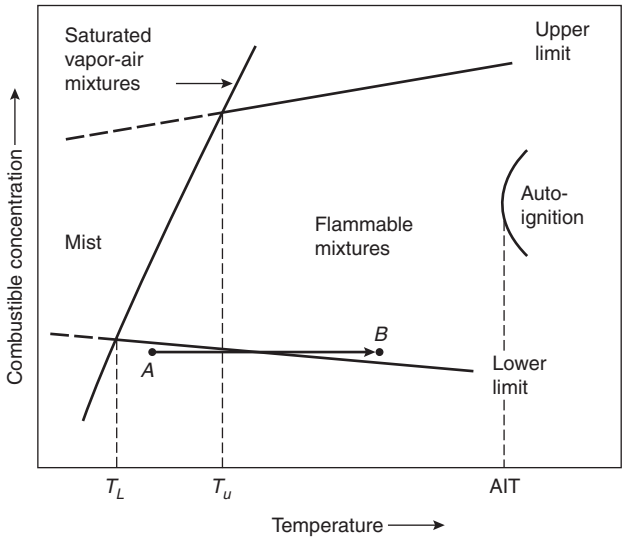

Figure 2-7.5. ***Effect of temperature on limits of flammability of a combustible vapor in air at constant initial pressure.[1]***

of mixtures of multiple flammable gases in air can be determined. A generalization of Le Chatelier's rule was given by Coward et al.[11]

$$\sum_{i=1}^{n} \frac{C_i}{\mathrm{LFL}_i} \geq 1 \tag{1}$$

where C_i is the volume percent of fuel gas, i, in the fuel/air mixture, and LFL_i is the volume percent of fuel gas, i, at its lower flammable limit in air alone. If the indicated sum is greater than unity, the mixture is above the lower flammable limit. This relationship can be restated in terms of the lower flammable limit concentration of the fuel mixture, LFL_m, as follows:

$$\mathrm{LFL}_m = \frac{100}{\sum_{i=1}^{n} (C_{f_i}/\mathrm{LFL}_i)} \tag{2}$$

where C_{f_i} is the volume percent of fuel gas i in the fuel gas mixture.

EXAMPLE 1:

A mixture of 50 percent methane, 25 percent carbon monoxide, and 25 percent hydrogen is mixed with air. Calculate the lower flammmable limit of this fuel gas mixture.

SOLUTION:

Referring to Table 2-7.1, LFLs of methane, carbon monoxide, and hydrogen are 5.0 percent, 12.5 percent, and 4.0 percent by volume, respectively. Using Equation 2 we find

$$\mathrm{LFL}_m = \frac{100}{50/5 + 25/12.5 + 25/4} = 5.48\%$$

The composition of the lower flammable limit fuel/air mixture is 2.74 percent methane, 1.37 percent carbon monoxide, 1.37 percent hydrogen, and 94.5 percent air.

Critical Adiabatic Flame Temperature at the Lower Flammable Limit

As early as 1911, Burgess and Wheeler[12] noted the constancy of the potential heat release rate per unit volume of normal alkane/air lower flammable mixtures at room temperature. Since the heat capacity of the products of complete combustion are nearly the same for all hydrocarbons, their observation also implies that the adiabatic flame temperature at the lower flammable limit is a constant. Examination of a wide range of C,H,O-containing fuels indicates that the adiabatic flame temperature at the LFL is approximately 1600 K (±150K) for most C,H,O-containing fuels, with the following notable exceptions: hydrogen, 980 K; carbon monoxide, 1300 K; and acetylene, 1280 K. This result indicates that the adiabatic flame temperature at the lower flammable limit is an indication of the reactivity of the fuel. The lower the adiabatic flame temperature, the more reactive the fuel.

The utility of the concept of a critical adiabatic flame temperature at the lower flammable limit goes beyond that outlined above. It has been demonstrated that the adiabatic flame temperature at the lower flammable limit is relatively insensitive (±100 K) to the diluent used and to the initial temperature of the mixture.[13–15]

The adiabatic flame temperature at the limit is insensitive to initial temperature only so long as significant preflame combustion reactions do not occur. As such, for a mixture near or above its autoignition temperature (AIT) for a significant length of time, the adiabatic flame temperature at the limit is not expected to be constant. Weinberg[15] has shown that a mixture of 1 percent methane (LFL = 5 percent at 293 K) in air can burn if it is preheated to 1270 K, even though the flame only increases that temperature by about 250 K, in accordance with the expected adiabatic flame temperature. This result was achieved by mixing the methane and air just before the flame so that preflame reactions were not allowed to proceed significantly.

Due to the constancy of the adiabatic flame temperature at the lower limit, the concept can be utilized to predict the effect of variable mixture temperature and diluents on the flammable limits of a mixture. Coward and Jones[2] have examined variable oxygen/diluent ratios, using nitrogen, carbon dioxide, water, argon, and helium as diluents. Their work shows that the limit temperature is insensitive to the oxygen/diluent ratio. Figure 2-7.6, adapted from Reference 16, illustrates the change in adiabatic flame temperature at the lower flammable limit as additional nitrogen is added to decrease the oxygen/nitrogen ratio. The figure shows an increase in the adiabatic flame temperature at the lower flammable limit from 1550 K to over 1700 K as we move from normal air to the stoichiometric limit. Beyond the stoichiometric limit, no fuel-lean mixture can burn. The region beyond the stoichiometric limit can be best understood in the context of flammability diagrams and upper flammable limits. We will examine these later in the chapter.

The insensitivity of the limit temperature to the chemical structure of C,H,O-containing fuels contributes significantly to the utility of the concept of a critical adiabatic flame temperature at the lower flammable limit. No systematic evaluation of the limit temperature concept for fuels containing sulfur, nitrogen, or halogens has been undertaken. Existing data indicates that halogen-containing fuels have limit temperatures several hundred degrees higher than C,H,O fuels. Since halogens are combustion inhibitors, this conclusion is consistent with the idea that the adiabatic flame temperature at the lower flammable limit is indicative of the reactivity of the fuel. Thus, possible exceptions to the generalization that the adiabatic flame temperature at the lower flammable limit is approximately 1600 K may be identifiable by considering the reactivity of the fuel gas.

Egerton and Powling[17] have shown that the limit temperatures at the upper flammable limit for hydrogen and carbon monoxide are equal to their limit temperatures at the lower flammable limit. Stull[18] has reported the same result for methane. However, it is not generally possible to calculate the adiabatic flame temperature for other fuels, since the products of combustion under fuel-rich conditions include a mixture of products of combustion and pyrolysis, which cannot be predicted by assuming chemical equilibrium is achieved or by detailed chemical kinetics calculations. Equilibrium calculations indicate that the only carbon-containing species that should be produced are CO, CO_2, CH_4, and solid carbon. This conclusion is not generally a good approximation under fuel-rich conditions.

EXAMPLE 2:

The lower flammable limit of propane at 20°C is 2.1 percent by volume. Find the lower flammable limit at 200°C.

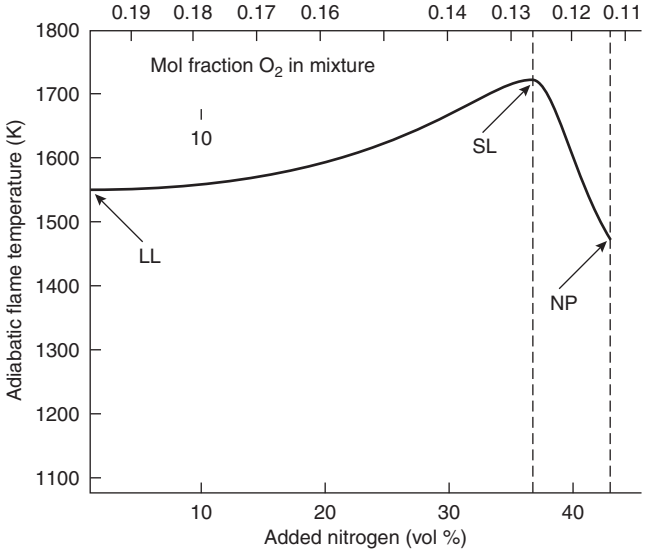

Figure 2-7.6. ***Computed adiabatic flame temperature along the lower branch of the flammability limits of propane (adapted from Reference 16). SL and NP are defined in Figure 2-7.9.***

SOLUTION:

For adiabatic combustion, all the heat released is absorbed by the products of combustion:

$$\left(\frac{\text{LFL}}{100}\right)\Delta H_c = \int_{T_0}^{T_{f,\text{LFL}}} nC_p dT \tag{3}$$

where

ΔH_c = heat of combustion of the fuel
LFL/100 = mole fraction of fuel
n = number of moles of products of combustion per mol of fuel/air mixture
C_p = heat capacity of the products of combustion
T_0 = initial temperature of the fuel/air mixture
$T_{f,\text{LFL}}$ = adiabatic flame temperature of a lower flammable limit mixture

This equation is a utilization of concepts developed in the chapter on thermochemistry. For the present purposes, it is suitable to use an average value of the heat capacity. This adjustment reduces Equation 3 to

$$\left(\frac{\text{LFL}}{100}\right)\Delta H_c = nC_p(T_{f,\text{LFL}} - T_0) \tag{4}$$

We know that $T_{f,\text{LFL}} = 1600$ K, and for $T_0 = 20$°C, we also know that LFL = 2.1 percent. Rearranging Equation 4 yields

$$\frac{\Delta H_c}{nC_p} = \frac{(T_{F,\text{LFL}} - T_0)}{\text{LFL}/100}$$
$$= \frac{1600\text{ K} - 293\text{ K}}{2.1/100}$$
$$= 6.22 \times 10^4\text{ K}$$

Both the heat of combustion and the heat capacity are weak functions of temperature, and these effects will be ignored. As such we can use the above expression to predict the lower flammable limit for an initial temperature of 200°C.

$$\frac{T_{F,\text{LFL}} - T_0}{\text{LFL}/100} = \frac{1600\text{ K} - 473\text{ K}}{\text{LFL}/100}$$
$$= 6.22 \times 10^4\text{ K}$$
$$\text{LFL} = 1.8\text{ percent}$$

Flammability Diagrams

While the flammable limits of a fuel in air can be characterized by the lower and upper flammable limits, it is necessary to represent flammable limits of more general fuel/oxidant/inert mixtures, using flammability diagrams. Examples of flammability diagrams for methane/oxygen/nitrogen mixtures are shown in Figures 2-7.7(a) and (b). Based on an extensive series of tests with a range of mixture compositions, a flammability diagram can be constructed indicating the regions of mixture compositions within the flammable limits.

Two types of flammability diagrams are often used: (1) diagram utilizes three axes in which each of the three constituent gases is explicitly represented, and (2) diagram utilizes only two axes in which the third gas concentration is determined by the difference between the sum of the other two gases and 100 percent. Both types give the same information.

Shown in Figures 2-7.7(a) and (b) are the air and limit lines. Anywhere along the air line the ratio of oxygen to

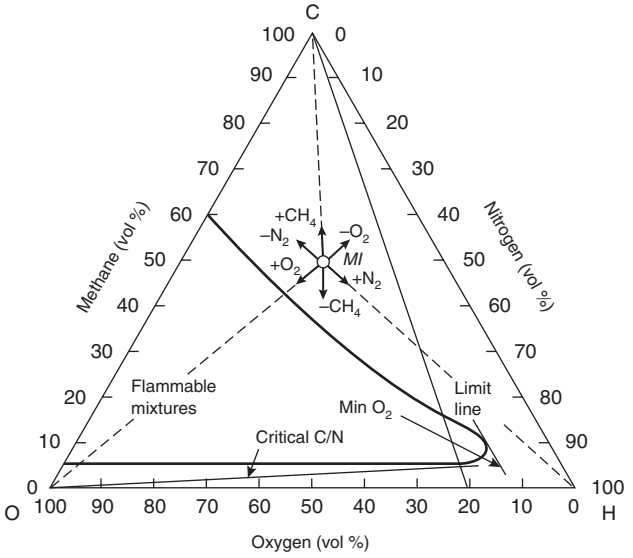

Figure 2-7.7a. ***Three-axis flammability diagram for the system methane/oxygen/nitrogen at atmospheric pressure and 26°C.[1]***

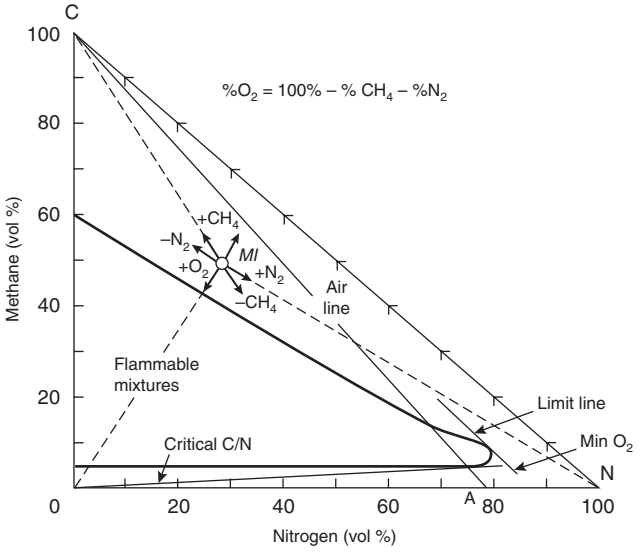

Figure 2-7.7b. ***Two-axis flammability diagram for the system methane/oxygen/nitrogen at atmospheric pressure and 26°C.[1]***

nitrogen is the same as in air. The limit line represents a range of mixtures with a fixed oxygen-to-nitrogen ratio which is tangent to the flammable region. Any oxygen/nitrogen mixture with an oxygen-to-nitrogen ratio less than that of the limit line will not support flame propagation when mixed with any amount of methane. This condition is known as the limiting oxygen concentration (LOC).

The LOC is an important concept in inerting. If the oxygen concentration can be maintained below the LOC, then premixed burning can be prevented. The LOC is a function of the temperature, pressure, fuel, and inert gas. Table 2-7.2 shows the LOC[19–23] of a wide range of fuels with nitrogen and carbon dioxide as the inert diluents. The tabulated values apply to diluted air/fuel mixtures at normal temperature and pressure. Like flammable limits, the dynamics of the LOC can generally be understood using the AFT concepts.

As can be seen in Table 2-7.2 with nitrogen diluent, the LOC is generally in the 10 to 12 percent range. Fuels like carbon monoxide and hydrogen have lower LOCs, and chlorinated fuels have higher values. These trends are expected based on AFT concepts at the LFL. For carbon dioxide as a diluent, the LOCs are generally 2 to 3 percent higher than for nitrogen diluent. Again this is expected based on AFT concepts due to the higher molar heat capacity of carbon dioxide.

Figure 2-7.8 is yet another representation of the flammable limits of fuel/oxidant/inert mixtures. The dilution of a fuel/air mixture is given by the percent of inert gas in excess of the nitrogen present in air. Figure 2-7.8 includes only mixtures that lie to the right of the air line, and as such is a magnification of a portion of the region included in Figures 2-7.7(a) and (b). Also shown in Figure 2-7.8 are several lines and points of specific interest. The highest concentration of nitrogen that will allow propagation of a flame is known as the nitrogen point (NP). Of course, this concept can be generalized to any inert (IP). If the concentration of the inert is greater than that at the inert point, no mixture of fuel and oxidant will propagate a flame remote from the ignition source.

As shown in Figure 2-7.8, the stoichiometric line passes through the flammable region. The point at which the stoichiometric line intersects the boundary of the flammable region is known as the stoichiometric limit (SL). The SL limit is the most dilute stoichiometric mixture that will propagate a flame remote from the ignition source. In the case of methane, the peak of the flammable region occurs near the stoichiometric limit. (See Figure 2-7.9.) For longer chain alkanes, the peak shifts to the rich side of the stoichiometric line. (See Figure 2-7.8.) For C_5 and higher hydrocarbons, the peak of the flammable region is bisected by the stoichiometric line defined by combustion to CO rather than to products of complete combustion. This shift has been attributed to incomplete combustion[16] and to preferential diffusion of reactants.[24] A similar shift of the maximum burning velocity to the rich side of stoichiometry is also observed. In this case, preferential diffusion of reactants has been shown to be the responsible factor.

Flammability diagrams are useful not only in determining the flammability of a given mixture, but also in

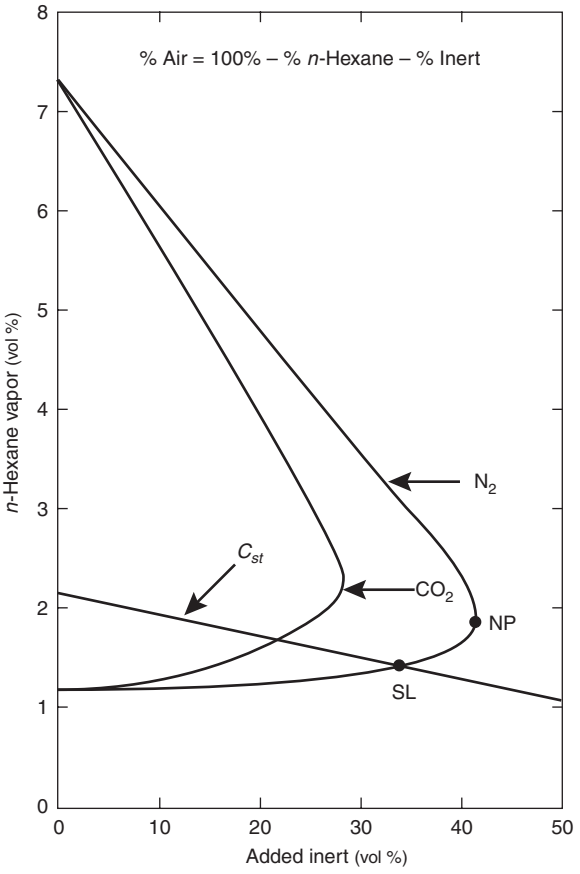

Figure 2-7.8. ***Limits of flammability of various n-hexane/inert gas/air mixtures at 25°C and atmospheric pressure.[1]***

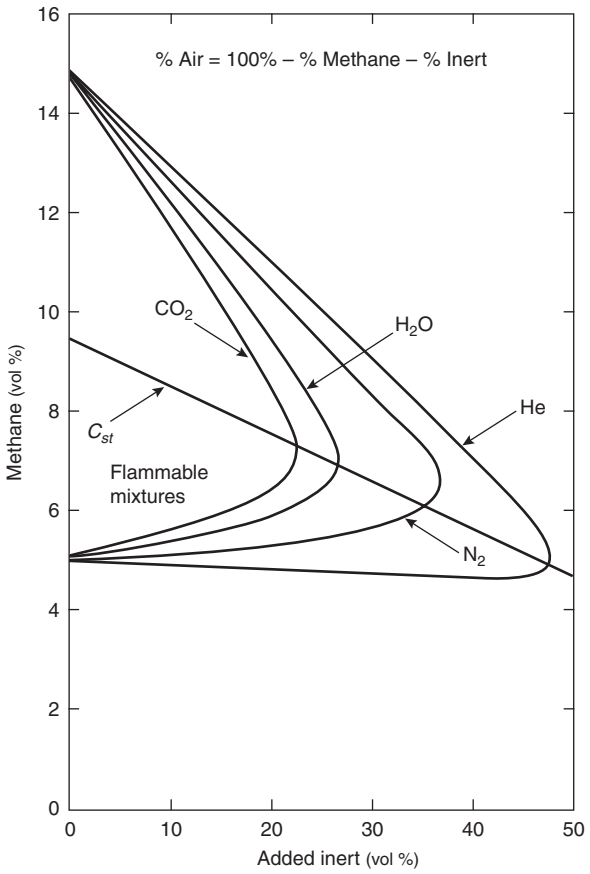

Figure 2-7.9. ***Limits of flammability of various methane/inert gas/air mixtures at 25°C and atmospheric pressure.[1]***

developing strategies for avoiding flammable mixtures while diluting fuel-rich mixtures. In order to make use of the diagrams in this fashion, we must examine the change in position on the diagram when fuel, oxygen, or inert gas is added to the mixture. Consider a mixture given by point *MI* in the three-axis diagram, Figure 2-7.7(a). The arrows indicate the change in the mixture composition with the addition or removal of each gas species. In the three-axis diagram, moving toward the vertex corresponding to 100 percent of any one of the gases corresponds to the addition of that gas, since adding an infinite amount of a single gas will reduce the concentrations of the other gases to zero. Adding air corresponds to moving toward the point on the air line at which there is no fuel. Clearly, following these examples, the effect of adding any gas or gas mixture can be plotted in the three-axis diagram. In the two-axis diagram, moving toward the vertex with 0 percent inert, 0 percent fuel corresponds to the addition of oxygen. In Figure 2-7.8 moving toward the 0 percent inert, 0 percent fuel vertex corresponds to adding air.

Figure 2-7.9 shows the effect of various inert diluents on the flammable region. As indicated by the critical adiabatic flame temperature concept, the lower flammable limit is increased in proportion to the heat capacity of the diluent. (See Section 1, Chapter 5.)

EXAMPLE 3:

A methane leak fills a 200 m^3 room until the methane concentration is 30 percent by volume. Calculate how much nitrogen must be added to the room before air can be allowed in the space.

SOLUTION:

The initial mixture in the room is given by the point B in Figure 2-7.10. Adding nitrogen moves along the line toward pure nitrogen (the N point). Drawing the line from the air point, A, tangent to the flammable region defines the mixture C: the mixture with the least nitrogen added that, on mixing with air, will not form a flammable mixture. Referring to Figure 2-7.10 we see that point C corresponds to a methane concentration of 13 percent. In order to reduce the methane concentration from 30 percent to 13 percent, an as yet unknown amount of nitrogen must be added. If we could remove only the initial mixture and replace it with nitrogen, the amount of nitrogen would simply be

$$\frac{30 - 13}{30} \times 200 \text{ m}^3 = 113 \text{ m}^3$$

However, there is generally no way to prevent mixing of the initial mixture to be exhausted and the nitrogen being

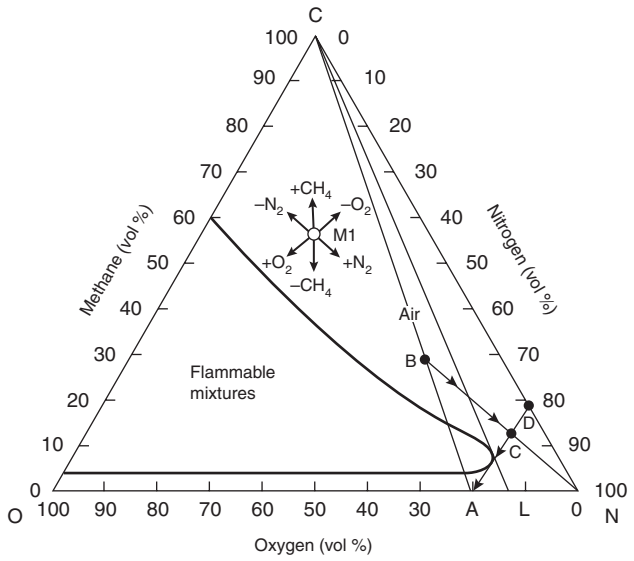

Figure 2-7.10. ***Graphic solution of Example 3 (adapted from Reference 1).***

introduced to replace it. As such, inerting nitrogen is also lost. We can model this occurrence by assuming that the room is well mixed during nitrogen injection so that the concentrations are uniform everywhere. Under these conditions the methane concentration, C, is given by

$$C = C_0 \exp\left(\frac{-V_N}{V}\right)$$

where

C_0 = initial methane concentration
V_N = volume of nitrogen added
V = volume of the room

Rearranging this equation we find

$$V_N = -V \ln\left(\frac{C}{C_0}\right) = -200\ \text{m}^3 \ln\left(\frac{13}{30}\right) = 167\ \text{m}^3$$

Of course, the flow of gases out of the room contains methane and may burn on mixing with air. Mixing air and the initial gases in the room results in mixtures along the line AB (see Figure 2-7.10), some of which are clearly flammable. As such, ignition sources must be excluded near the room exhaust, or the exhaust also needs to be inerted.

EXAMPLE 4:

A 1 kg/s flow of methane is being dumped into the atmosphere. How much nitrogen must be mixed with methane to avoid a flammable mixture in the open?

SOLUTION:

In order to make the methane nonflammable, it needs to be diluted with enough nitrogen so that on further addition of air the flammable region is missed. Such a mixture of methane and nitrogen is given by extrapolating the line AC back to zero oxygen; that is, point D on Figure 2-7.10, where the mixture is 82 percent nitrogen, 18 percent methane. The ratio of the flow rates of nitrogen to methane must equal the ratio of the concentrations of nitrogen and methane. Since concentrations expressed as volume percent are directly related to mole fractions, the flow rates of nitrogen and methane must be expressed as molar flow rates, $\dot{n}$,

$$\frac{\dot{n}_{N_2}}{\dot{n}_{CH_4}} = \frac{C_{N_2}}{C_{CH_4}}$$

The molar flow rate of methane is given by

$$\dot{n}_{CH_4} = \frac{\dot{m}_{CH_4}}{MW_{CH_4}}$$

where MW is the molecular weight and $\dot{m}$ is the mass flow rate.

$$\begin{aligned}
\dot{n}_{N_2} &= \left(\frac{\dot{m}_{CH_4}}{MW_{CH_4}}\right)\left(\frac{C_{N_2}}{C_{CH_4}}\right) \\
&= \left(\frac{1000\ \text{g/s}}{16\ \text{g/mol}}\right)\left(\frac{82\%}{18\%}\right) \\
&= 285\ \text{mol/s} \\
\dot{m}_{N_2} &= \dot{n}_{N_2} MW_{N_2} \\
&= (285\ \text{mol/s})(28\ \text{g/mol}) \\
&= 7970\ \text{g/s or } 7.97\ \text{kg/s}
\end{aligned}$$

Ignition Energies and Quenching Diameters

The energy required to ignite flammable mixtures is generally quite low, on the order of a few tenths of a millijoule (mJ) for near-stoichiometric mixtures in air and as low as a few thousandths of a millijoule in oxygen. Here again, preferential diffusion causes the minimum to occur for rich mixtures for fuels with molecular weights greater than that of air.[24] As the flammable limits are approached, the ignition energy increases sharply.

Several methods exist for preventing the initiation of an explosion. These include avoiding flammable mixtures, excluding ignition sources whose energy is greater than the minimum ignition energy, and enclosing any ignition sources in an enclosure that will not allow the propagation of the flame to the outside. We have already discussed the first of these. Some low-power electrical equipment can be designed such that the worst fault condition cannot produce the minimum ignition energy for a specified gas. Such equipment is termed "intrinsically safe" and may be used where there is a risk of a flammable atmosphere being formed.

Where this method is not feasible, the electrical equipment may be housed in an "explosion-proof" enclosure, which will not allow propagation of the flame out of the enclosure. This situation is accomplished by making the size of the openings small enough that sufficient heat is lost by the flame as it passes through the opening that it is quenched. The quenching distance is most often

determined by placing a pair of flanged electrodes in a gas mixture and attempting to ignite the gases. The flanges are parallel plates, and if the mixture can be ignited in the presence of the plates, the separation of the plates is greater than the quenching distance. The quenching distance with parallel plates, $d_{\parallel}$, is 65 percent of the quenching diameter in circular tubes. Figure 2-7.11[25] shows the relation of the quenching distance to the minimum ignition energy for a number of hydrocarbon/air mixtures. The relation can be expressed as $E_{min} = 0.06 d_{\parallel}^2$, where E_{min} is the minimum ignition energy in air given in mJ and $d_{\parallel}$ is the quenching distance in air given in mm.

Because the hot quenched flame gases in an enclosure will expand through the opening, they may autoignite outside the enclosure. It has been found that the minimum experimental safe gap (MESG) for most hydrocarbons is approximately half the quenching distance.[25]

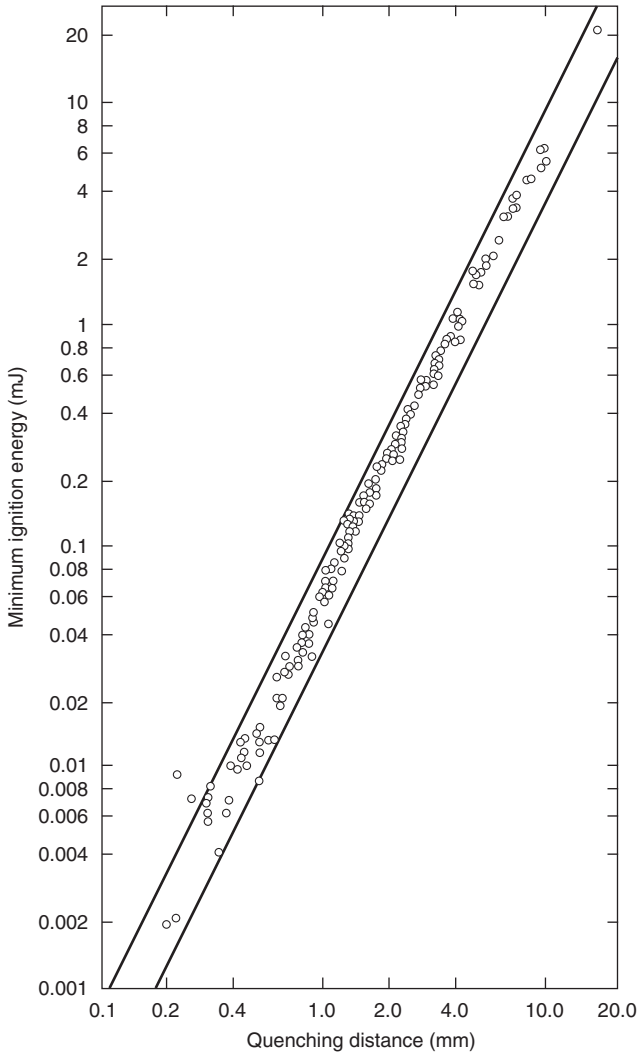

Figure 2-7.11. ***The relation between flat-plate quenching and spark minimum ignition energies for a number of hydrocarbon-air mixtures.[25]***

Dusts and Mists

The lower flammable limit of dusts and mists would be expected to be higher than their gaseous counterparts due to the need to volatilize the dust or mist. For very small particles with high surface-area-to-volume ratios, the lower flammable limit is independent of particle diameter, and the limit concentrations are approximately the same as the analogous gaseous fuel for fuels that volatilize completely. Hertzberg et al.[26] have shown that bituminous coal dusts with particle diameters of 50 μm or less and polyethylene dusts with particle diameters of 100 μm or less have lower flammable limits in air which are independent of particle diameter. Figure 2-7.12 shows the measured lower flammable limit concentration for Pittsburgh bituminous coal as a function of average particle diameter and oxygen concentration. Notice that the lower flammable limit in the small-particle limit is a function of the oxygen concentration, unlike gaseous fuels. Also note that the lower flammable limit concentration is much higher than 48 g/m^3, typical of gaseous hydrocarbons. These effects are due to the fact that not all the coal dust is volatilized. The fraction of dust which is volatilized is a function of the particle diameter and the oxygen concentration. As the oxygen concentration affects the maximum flame temperature and, hence, the heat flux to the particle, both the ability of heat to penetrate the particle and the rate of heating are affected. It is well known that the fraction of the material volatilized increases with the rate of heating. It is not expected that the lower flammable limit can be reduced below 50 g/m^3, even at 100 percent oxygen.

As the particle size increases, it would be expected that the lower flammable limit would also increase due to the difficulty of getting the fuel into the gas phase where combustion will take place. This result does in fact occur, but depending on the geometry of the test, the apparent

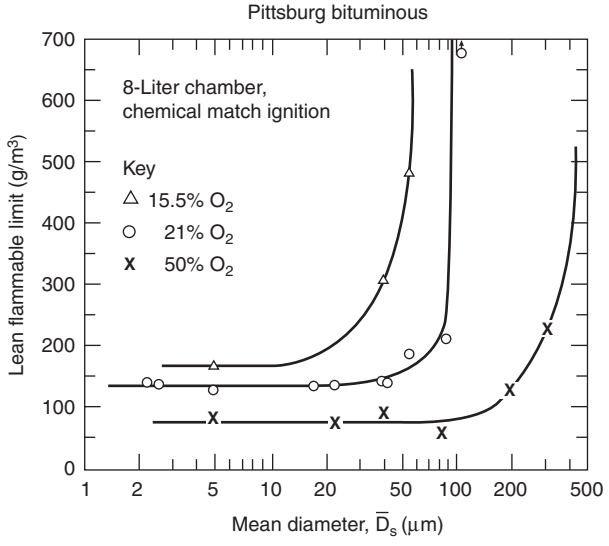

Figure 2-7.12. ***Lean flammability limit data for Pittsburgh bituminous coal as a function of particle size for three oxygen concentrations.[26]***

lower flammable limit of mists can actually decrease with increasing particle diameter due to the effects of gravity.[27] If the ignition source is at the bottom of the container and the aerosol is not kept well mixed, the particles can begin to settle out, causing the local concentration in the lower portions of the apparatus to be higher. This laboratory effect can also be expected to operate under actual conditions, depending on the degree of mixing of the aerosol.

While it is in principle possible for flame propagation to occur as a result of heterogeneous combustion of particles, this appears not to be an important mechanism for organic materials. Lower flammable limits of anthracite coal dusts with only a 20 percent volatile yield can be explained solely on the basis of gas-phase combustion.[28] Flame propagation by heterogeneous combustion is important for metal and graphite dusts.

Diffusion Flame Limits

The limits of flammability for diffusion flames were first examined by Simmons and Wolfhard.[29] In their experiments, they determined the minimum level of dilution of the oxidant stream necessary to prevent the stabilization of a diffusion flame for a variety of gas and liquid fuels. The oxygen mole fraction, X_{O_2}, of the oxidant stream at the flammability limit is known as the limiting oxygen index (LOI), or simply the oxygen index (OI). Simmons and Wolfhard's results are included in Table 2-7.3. They observed that the oxygen index of their diffusion flames equaled the ratio, $X_{O_2}/(X_{O_2} + X_{\text{diluent}})$, found in a premixed stoichiometric-limit mixture involving the same fuel. This result implies that the adiabatic flame temperature for the limit diffusion flame, calculated on the basis of stoichiometric combustion of the fuel and oxidant streams, is equal to the adiabatic flame temperature at the stoichiometric limit of a premixed system involving the same fuel, oxidant, and diluent.

Figure 2-7.13 graphically illustrates the relationship of the adiabatic flame temperatures at the lean, premixed limit in air, at the stoichiometric limit (premixed), and at the oxygen index (premixed). As the figure shows, the adiabatic flame temperature at the stoichiometric limit and the oxygen index are essentially equal, and the adiabatic flame temperature at the lower flammable limit in air is approximately 150 K less. Ishizuka and Tsuji[30] verified Simmons and Wolfhard's results for methane and hydrogen, and showed that the adiabatic flame temperature at the limit is the same whether dilution is of the fuel or oxidizer stream.

The information in Figure 2-7.13 forms the basis of a method for the evaluation of diffusion flame limits for fuel mixtures. In essence, the ability of a fuel and oxidant pair to react in a diffusion flame is evaluated by examining the flammability of a premixed stoichiometric mixture of the fuel and oxidant.

To do this, we assume that Le Chatelier's rule holds at the stoichiometric limit; that is,

$$\sum_{i=1}^{n} \left(\frac{C_i}{\text{SL}_i} \right) \geq 1 \tag{5}$$

and that the adiabatic flame temperature at the stoichiometric limit for each fuel is a constant. These lead to the expression

$$\sum_{i=1}^{n} \frac{(C_i/100)\Delta H_{c,i}}{\int_{T_0}^{T_{f,\mathrm{SL},i}} n_p C_p dT} \geq 1 \qquad (6)$$

where

C_i = volume percent of fuel species, i, when the fuel stream is mixed stoichiometrically with the oxidant stream

$T_{f,\mathrm{SL},i}$ = adiabatic flame temperature of the stoichiometric limit mixture for fuel species i
- = 1700 K for most hydrocarbons
- = 1450 K for carbon monoxide
- = 1080 K for hydrogen

T_0 = temperature of the stoichiometric mixture prior to reaction

$\Delta H_{c,i}$ = heat of combustion of fuel species
- = 620 kJ/mol for hydrocarbons (per carbon, assuming $H/C = 2$)
- = 283 kJ/mol for carbon monoxide
- = 242 kJ/mol for hydrogen

n_p = number of moles of products of combustion per mole of reactants (stoichiometric mixture of the fuel and oxidant streams)

C_p = heat capacity of the products of combustion

This approach has been successfully used to predict the flammability of the hot gas layer formed in enclosure fires.[31]

While the hot gas layer formed in enclosure fires can become flammable, under some conditions the oxygen concentration in the hot layer can cause extinction of flames fully immersed in the hot layer. Based upon the analogies between premixed and diffusion flames, one would expect the oxygen concentration in the layer at extinction to be approximately equal to the premixed LOC. In fact, comparing the nitrogen diluent in Table 2-7.2 with Table 2-7.3, one can see a very close correspondence between the LOC and the LOI.

Morehart, Zukoski, and Kubota[32] examined the oxygen concentration at extinction of flames by dilution of air with combustion products. They found that flames were extinguished at oxygen concentrations of 12.4 to 14.3 percent, with the lower value occurring for a 50-cm-diameter pool burner and the higher value occurring for a 9-cm pool burner. These results are consistent with diesel pan fire tests (0.62 m and 0.84 m diameters) conducted by Peatross and Beyler[33] in which oxygen concentrations below 14 percent could not be achieved during pool burning in a compartment. It is also consistent with the results of Back et al.[34] Back et al. measured oxygen concentrations at extinction in water mist extinguishment tests in obstructed machinery space fires. They found an average oxygen concentration of 14.5 percent for heptane spray fires and 13.5 percent for pool fires at extinction. Since the molar heat capacity of water vapor is midway between nitrogen and carbon dioxide, one would expect water mist and combustion product extinction limits to be between nitrogen and carbon dioxide.

All of the above results are for relatively quiescent conditions. It is well known that at higher strain rates, the oxygen concentration at extinction increases. This phenomenon can most easily be seen in counterflow diffusion flame extinction experiments such as Hamins et al.[35]

EXAMPLE 5:

As part of a hazard analysis of a particular room fire, the composition of the hot layer during fire development has been estimated. The results of the analysis indicate that the following composition represents the highest concentration of fuel gases expected:

Hot layer—700 K, 10 percent total hydrocarbons (THC), in the form of CH_2, 2 percent CO, 1 percent H_2, 15 percent CO_2, 2 percent O_2, 70 percent N_2

Cold layer—300 K, 21 percent O_2, 79 percent N_2

Will the hot layer burn?

SOLUTION:

The working equation is Equation 6. The first step is to write a balanced chemical equation for stoichiometric burning:

$$0.1CH_2 + 0.02CO + 0.01H_2 + 0.02O_2 + 0.7N_2 + 0.15CO_2 + x(O_2 + 3.78N_2) \rightarrow 0.27CO_2 + 0.11H_2O + (0.7 + 3.78X)N_2$$

We can find x by requiring that both sides of this equation have the same amount of oxygen:

$$\begin{array}{cccccccc} \mathrm{CO} & & \mathrm{O_2} & \mathrm{CO_2} & \text{air} & \mathrm{CO_2} & \mathrm{H_2O} \\ \frac{0.02}{2} & + & 0.02 & + & 0.15 + x & = & 0.27 + \frac{0.11}{2} \end{array} \rightarrow x = 0.145$$

The concentrations in the stoichiometric mixture can be determined from the balanced chemical equation:

$$\begin{aligned} C_i &= \left(\frac{n_i}{n_T}\right) \times 100\% \\ n_T &= 0.1 + 0.02 + 0.01 + 0.02 + 0.7 + 0.15 \\ &\quad + 0.145 + 0.145(3.78) = 1.693 \\ C_{\mathrm{THC}} &= \left(\frac{0.1}{1.693}\right) \times 100\% = 5.9\% \\ C_{\mathrm{CO}} &= \left(\frac{0.02}{1.693}\right) \times 100\% = 1.2\% \\ C_{\mathrm{H_2}} &= \left(\frac{0.01}{1.693}\right) \times 100\% = 0.6\% \end{aligned}$$

Similarly, the number of moles of products per mole of reactants can be determined from the chemical equation

$$n_p = \frac{[0.27 + 0.11 + 0.7 + 0.145(3.78)]}{1.693} = 0.962$$

This result is lower than typical values of 1 to 1.1, because the unknown hydrocarbon mixture is taken as CH_2. This choice is not an error, since CH_2 has been consistently used for the heat release and heat capacity as well. For convenience, we will use constant average specific heats taken from Drysdale:[3]

	C_p (J/mol·K)	C (%)[a]
CO_2	54.3	16.2
H_2O	41.2	6.6
N_2	32.7	77.2

[a]Calculated by the same method as the fuel gas concentrations.

$$\begin{aligned} n_p C_p &= n_p \sum \left(\frac{C_i}{100}\right) C_{p,i} \\ &= 0.96[(0.162)(54.3) + (0.066)(41.2) + (0.772)(32.7)] \\ &= 35.3 \text{ J/mol·K} \end{aligned}$$

Notice that the average specific heat is near that of nitrogen, since it is the major constitutent of the mixture. In calculating T_0, the initial temperature of the mixture, we will ignore variations in C_p between the hot and cold layers.

$$\begin{aligned} T_0 &= \frac{n_h Th + n_c Tc}{n_h + n_c} \quad n_h + n_c = n_T \\ &= \frac{(1)(700 \text{ K}) + (0.69)(300 \text{ K})}{1.69} = 537 \text{ K} \end{aligned}$$

where n_h and n_c are the number of moles originating in the hot and cold layers, respectively. Substituting into Equation 5,

$$\sum_{i=1}^{n} \frac{(C_i/100)\Delta H_{c,i}}{C_p(T_{f,\mathrm{SL},i} - T_0)} = \frac{(0.059)(620)10^3}{35.3(1700 - 537)} + \frac{(0.012)(283)10^3}{35.3(1450 - 537)} + \frac{(0.006)(242)10^3}{35.3(1080 - 537)} = 1.07 \tag{7}$$

Since the result is greater than one, the hot layer *will* ignite and burn.

While the approach to the onset of layer burning used in Example 5 has a great deal of generality, it requires a very detailed characterization of the upper and lower layers. It has been shown by Beyler[31] that a much simpler method can be used to evaluate the conditions required for layer burning.

The method[31] is based on the very simple chemical model

$$\text{Fuel} + \text{Oxidizer} \rightarrow \begin{cases} \text{Products} + \text{Excess Oxidizer for } \phi < 1 \\ \text{Products} + \text{Excess Fuel for } \phi > 1 \end{cases} \tag{8}$$

where the equivalence ratio, ϕ, is given by

$$\begin{aligned} \phi &= \frac{\dot{m}_f}{\dot{m}_{\text{air}} \cdot r} \\ r &= \left(\frac{m_f}{m_{\text{air}}}\right)_{\text{Stoichiometric}} \end{aligned} \tag{9}$$

According to this model, the fuel mass fraction in the upper layer is

$$\begin{aligned} Y_f &= 0 && \text{for } \phi < 1 \\ Y_f &= \frac{1 - 1/\phi}{1 + 1/\phi r} && \text{for } \phi > 1 \end{aligned} \tag{10}$$

Equation 6 can be expressed on a mass basis for this application as

$$\frac{Y_f \Delta H_c}{m_p C_p (T_{\mathrm{SL}} - T_0)} \geq 1 \tag{11}$$

where ΔH_c is the heat of combustion of the fuel, and m_p is the mass of products resulting from burning a unit mass of upper layer gases.

Substituting the $\phi > 1$ relationship for Y_f into Equation 6, expressing the heat release in terms of oxygen consumed using

$$\Delta H_c = \frac{\Delta H_{O_2} Y_{O_2}}{r} \tag{12}$$

and recognizing that

$$m_p = 1 + \frac{Y_f}{r} \tag{13}$$

yields

$$\left(\frac{1-1/\phi}{1+r}\right)\left[\frac{\Delta H_{O_2} Y_{O_2}}{C_p(T_{SL}-T_0)}\right] \geq 1 \qquad (14)$$

Equation 14 can be solved for the equality condition to give the equivalence ratio at which layer burning begins, ϕ_{ig},

$$\phi_{ig} = \frac{k}{k-r-1} \qquad (15)$$

where

$$k = \frac{\Delta H_{O_2} Y_{O_2}}{C_p(T_{SL}-T_0)}$$

T_0 is the precombustion temperature resulting from stoichiometric mixing of the air and fuel streams. Here, the upper layer contains the fuel and the lower layer contains the air. T_0 can be expressed as

$$T_0 = \frac{T_u + (Y_f/r)T_1}{1 + Y_f/r} \qquad (16)$$

Using Equations 15 and 16, a relationship between the critical ignition equivalence ratio and the layer temperatures can be developed. Using normal values for the semi-universal constants, $\Delta H_{O_2} = 13.4$ MJ/kg, $C_p = 1.1$ kJ/kg K, $T_{SL} = 1700$ K. Using air properties for the lower layer, $Y_{O_2} = 0.233$ and $T_1 = 300$ K. Using a typical $r = 0.07$ yields the relationship between ϕ_{ig} and T_u shown in Figure 2-7.14. The results shown in Figure 2-7.14 are consistent with the measurements of Beyler,[31] where ϕ_{ig} was found to be 1.7 for T_u of 500 to 600 K. Gottuk[36] found that external burning was first observed in flashes at $\phi = 1.4 \pm 0.4$, and sustained external burning was first observed at $\phi = 1.9 \pm 0.3$ when T_u was in the range 900 to 1100 K. While in Gottuk's[36] experiments it was difficult to observe burning at the layer interface due to soot deposits on the viewing ports, layer interface burning was generally observed shortly after the initiation of flashes in the exhaust. Because the exhaust flow was isolated from the inflow in the experiment, there is some issue of the availability of a pilot flame which does not arise in normal two-directional vents found in most fires. Thus, Gottuk's work is generally consistent with Figure 2-7.14.

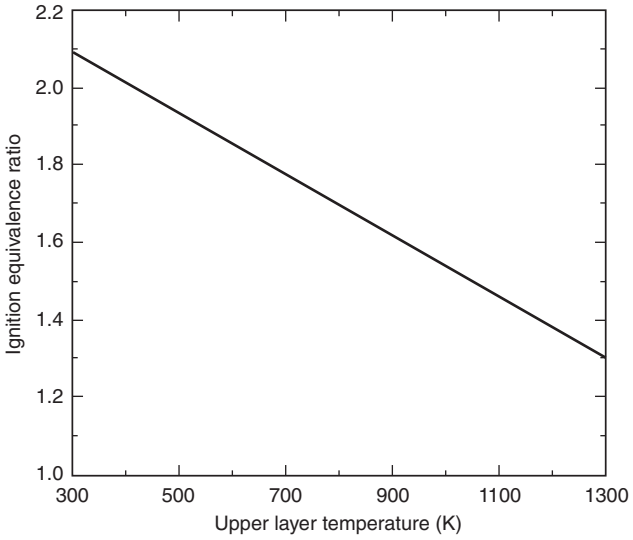

Figure 2-7.14. ***Equivalence ratio required for upper layer ignition as a function of the upper layer temperature determined using Equations 15 and 16 with typical properties. Using normal values for the semi-universal constants, $\Delta H_{O_2} = 13.4$ MJ/kg, $C_p = 1.1$ kJ/kg K, $T_{SL} = 1700$ K. Using air properties for the lower layer, $Y_{O_2} = 0.233$, $T_1 = 300$ K. Using a typical $r = 0.07$ yields the relationship between ϕ_{ig} and T_u.***

Oxygen Index Test Method

The original oxygen index test method, used to determine the oxygen index of liquid and gas fuels, utilizes a counterflow diffusion flame formed at the stagnation region of a porous cylinder or sphere through which fuel vapors are fed. A low-velocity oxidant stream passes over the porous body. This arrangement yields the most favorable aerodynamic conditions for flame stabilization. As such, fuel and oxidant streams that can burn in the low-velocity counterflow system may not burn under less favorable aerodynamic conditions characterized by higher velocities and shear.

It is also important to point out the difference between the oxygen index as measured for gas and liquid fuels and the oxygen index of solids as measured using a candle-type test.[37,38] The oxygen indexes of the gas and liquid fuels as tested by Simmons and Wolfhard[29] were governed by gas-phase effects. In the American Society for Testing and Materials test[33] for solids, the extinction can be caused by gas- and solid-phase effects. As such, the oxygen index of a solid fuel is not directly relevant to gas-phase diffusion flame limits and should not be used to calculate adiabatic flame temperature at the limit for use in the expressions presented here.

Nomenclature

AIT	autoignition temperature (C or K)
C	concentration (volume percent)
C_p	heat capacity (J/kg K)
LFL	lower flammable limit (volume percent)
M	mass (kg)
n	moles
r	stoichiometric fuel/air ratio
SL	stoichiometric limit (volume percent)
T	temperature (C or K)
V	volume (m^3)
X	mole fraction
Y	mass fraction
ΔH_c	heat of combustion (J/kg)
ϕ	equivalence ratio

Subscripts

c	combustion
i	species
ig	ignition
f	flame, or fuel
l	lower layer
L	liquid
m	mixture
N	nitrogen
NP	nitrogen point
O	initial or ambient
OI	oxygen index
p	products of combustion
SL	stoichiometric limit
U	upper layer

CHAPTER 8

Ignition of Liquid Fuels

A. Murty Kanury

Introduction

This chapter introduces the topic of liquid fuel ignition in air. A qualitative description of the physical and chemical steps leading to ignition makes possible a systematic identification of the factors of concern. Different measures of liquid fuel ignitibility are defined, and a comprehensive collection of data is presented. Simple mechanistic models are formulated for the piloted ignition (i.e., flash point) of liquids as well as for the autoignition of vapor and air mixtures. The results of these models are employed to highlight (1) the manner in which physics and chemistry play a complicated role to culminate in ignition, (2) the resultant dependency of the measurements on the specific apparatus test method, and (3) a number of dependencies of the measured ignition temperature on experimental conditions. These predicted dependencies are found to be consistent with the trends in reported data.

Liquid combustibles are ever-present in the context of mobile and stationary power plants as well as in an innumerable array of industrial processes. A variety of physical forms in which they arise can be identified. Dip tanks of paints or solvents, sprays, spills from a storage tank, flowing or creeping films, and pools in open pits are but a few examples. In almost all situations, air is in contact, or readily comes into contact, with the fuel to make the associated fire hazard obvious. The following questions arise in relation to fire safety in these situations:

1. Under what circumstances is ignition possible?
2. Under the conditions of possible ignition, what is the external impulse required to produce ignition within a given time? Alternately stated, given a set of conditions under which ignition is possible, how long an exposure is required to produce ignition?

The first of these questions is addressed here along with some cursory observations on the second question.

Ignition is defined as the onset or initiation of combustion, usually flaming. As such, ignition is indicated by the oxidation reaction attaining a rapidly increasing rate. The rapidity often makes the ignition phenomenon an abrupt event. In practice, ignition is noted by the appearance of a flame, by a significant increase in oxidative energy release, or by a corresponding large rise in temperature.

Three sets of conditions have to be fulfilled to ignite a condensed-phase material. First, sufficient quantities of combustible vapors and gases have to be emanated as a result of preheating the solid or liquid. Second, these vapors and gases have to be mixed with the oxidant in the gas phase. Third, the mixture has to be either at a high enough temperature to induce self-accelerative oxidation (i.e., *spontaneous* or *autoignition)* or to be provided with a pilot source (e.g., a small ignitor flame, a heated wire, or an electric spark) to locally heat a minimum quantity of the mixture to a temperature approaching the adiabatic flame temperature (i.e., *piloted* or *forced ignition*). These three sets of conditions enable a systematic enumeration of the factors influencing the ignition process.

Vaporization: A Contrast between Liquid and Solid Combustibles

All condensed-phase materials release vapors and gases in response to heating. As related to the first of the three steps mentioned above, this response is dramatically different between solids and liquids.

Liquids generally* vaporize in the sense of a thermodynamic phase change in which the chemical structure of vapor remains the same as that of liquid. Such a vaporization is usually a surface mass transfer phenomenon,

Dr. A. Murty Kanury is professor of mechanical engineering at Oregon State University. His professional activities are centered around teaching thermal science and research in fire and combustion.

*Some high molecular weight liquids are exceptional in that they exhibit a chemical breakdown in response to heating.

although intense (and internal) heating may produce bubbles within the liquid. In contrast, heating of solids generally* results in complicated destructive distillation (also known as thermochemical degradation or *pyrolysis*) to yield a complex combustible mixture of gases and vapors. Known also as pyrolyzate, this mixture is produced *within* the solid at a rate dependent upon the local instantaneous density and temperature. The pyrolysis process, thus, is volumetric and chemical rather than superficial and physical.

Pyrolysis of most solids leaves a carbon-rich porous residue, known as char, behind. Vaporization of most common liquids, in contrast, leaves no residue behind.

Upon heating a liquid body, internal convective currents develop with an intensity dependent on the heating rate, viscosity, surface tension, gravity, and geometry of the body. The heating of a solid, by definition, does not invoke the same sort of bulk flows. There does arise, however, an internal convection process associated with the outflow of the pyrolyzates through the partially or totally degraded porous solid. The temperature distribution within a liquid body can be made artificially uniform by mixing with a stirrer; the same is not possible within a solid body.

The ease with which vapors can be produced by heating a liquid is known as its volatility. A liquid is said to be highly volatile if its vapor pressure at a given temperature is high (i.e., its boiling point at a given pressure is low), and its *latent heat* (i.e., enthalpy of vaporization) is low.

Mixing of Vapors with Air

The vapors emanating from the surface of a heated liquid mix with the ambient gas, which is usually air at normal pressure. This mixing is dependent on such factors as whether the air is quiescent or in motion, whether the liquid reservoir is closed or open, the geometry relative to the gravity vector, the temperature of the liquid surface relative to the ambient, the molecular weight of the vapors relative to that of air, and the height and nature of the lip of the vessel containing the liquid.

Ignition of the Mixture

The mixture thus formed has to be rich enough in combustible content to be over the so-called *lean limit of flammability* to make a propagable flame possible from a localized pilot source. The location and nature of the pilot is of obvious importance. Generally, when ignition is possible, the flame would simply flash through the mixture, consume the combustibles in its sweep, and then go out. Only if the vaporization is copious enough, due to a higher bulk temperature of the liquid, does the flame become self-sustained. These flashing and self-sustainment concepts are central to the liquid fuel ignition process.

If the gaseous mixture temperature is sufficiently high, ignition may occur even without a pilot source. This is known as auto- or spontaneous ignition.

*Some solids, such as waxes, are exceptional in that they melt and vaporize in the manner of a simple liquid. Some other exceptional solids, such as camphor and sulfur, sublime to a gas phase.

Figure 2-8.1, the rudiments of which were first formulated by Zabetakis,[1] indicates the essence of the previous descriptions. Part (a) of Figure 2-8.1, familiar from elementary thermodynamics, exhibits the exponential dependency of equilibrium vapor pressure on the liquid temperature. The normal melting and boiling point temperatures are also shown in this figure. Part (b) shows that as the temperature is gradually raised, the vapor pressure of the combustible liquid gradually rises to yield, at a limit temperature, T_L, a lean limit mixture capable of supporting a propagable flame. At a higher temperature, the partial pressure may become too high and make the mixture too rich to support a flame. Furthermore, at relatively high temperatures exceeding T_a, ignition can occur even in the absence of a pilot source. As indicated, the lean and rich limits, as well as the autoignition limits, are generally temperature dependent. Part (c) shows that the features of ignition of a pyrolyzing combustible solid are similar to those of a combustible liquid, except for the fact that the pyrolyzates are evolved due to degradation over a range of temperatures.

Some Experimental Techniques and Definitions

Piloted ignition data are mostly measured in a number of American Society for Testing and Materials (ASTM) tests.[2] These tests involve either an open-cup (e.g., ASTM D1310 open-cup test or D92 Cleveland Test) or a closed-cup test (e.g., ASTM D56 Tag Closed Tester and D93 Pensky-Martens test) to hold the fuel to a prescribed level. This cup is then heated either directly by a prescribed, Bunsen-type laboratory flame, or indirectly by a water (or water and glycol mixture) bath. There are similar international tests under a variety of names, including Engler and Haass, Danish open, Tagliabue, Elliot, Luchaire, Treumann, Albrecht, Abel, Saybolt, and Parish, among others.

Mullins[3] presents a comprehensive review of a variety of methods by which the spontaneous ignition temperature, T_a, of combustible liquids is experimentally determined. A number of variations, in which the reaction vessel is a crucible, flask, furnace, bomb, or a compression device, are employed to precisely control the experimental conditions, to observe whether or not ignition will occur, and to measure the time to ignition (i.e., the ignition delay). Flow methods, as well as heating of the liquid by hot surfaces, are also frequently employed. The ASTM test standard D2155 holds the liquid in a flask, which is heated in a furnace to determine the autoignition temperature and ignition delay.

The finer details of these tests are not materially relevant to the scope of this chapter. Zabetakis[1] and the ASTM standards[2] do an excellent job of giving these details. It is important, however, to define certain measures of the volatility and ignitibility of liquid fuels as obtained from these experimental techniques.

The *bubble point (R : 1)* of a liquid fuel[4] is the temperature at which equilibrium exists between the wholly condensed fuel and an infinitesimal quantity of its vapor mixed with air in the ratio of 1 : R. When R is zero, the bubble point is the same as the normal boiling point.

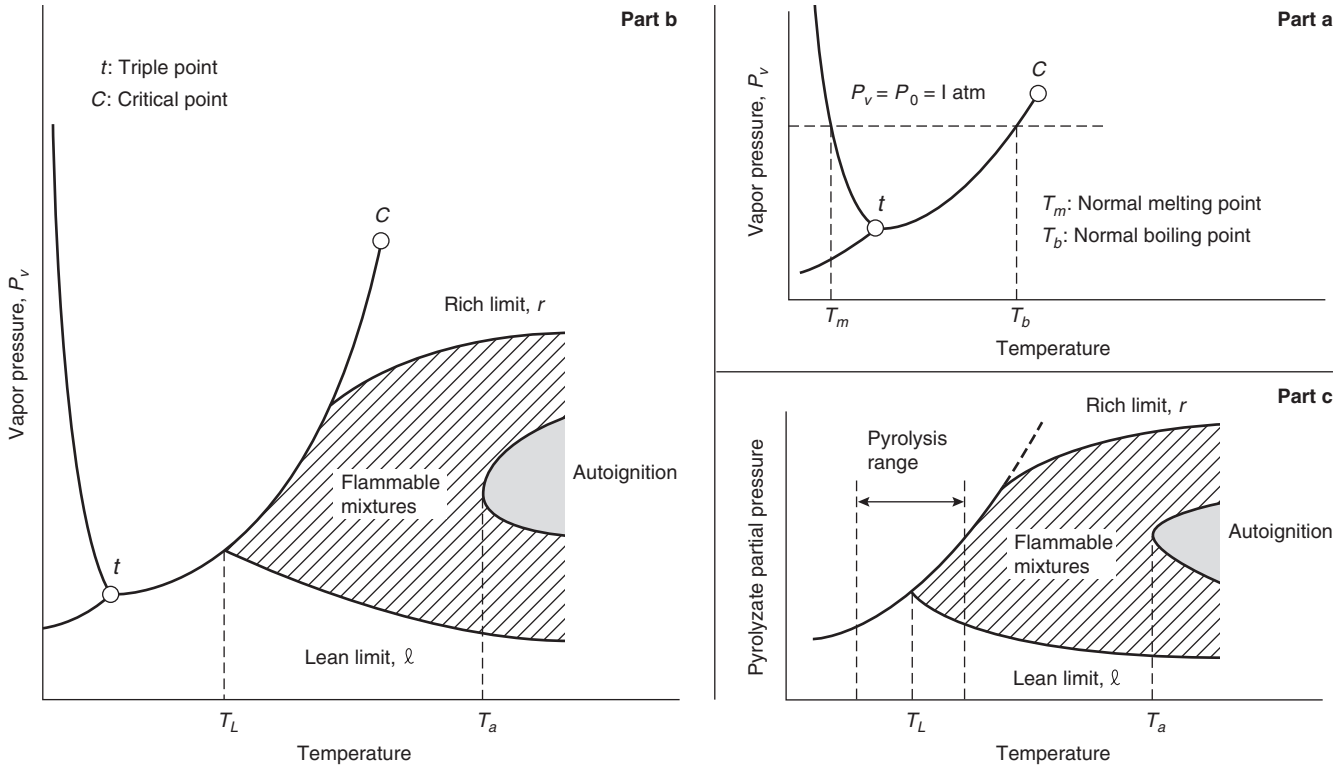

Figure 2-8.1. ***Phase-change diagram for: (a) an inert liquid; (b) a combustible liquid; and (c) a combustible solid.***

The *flash point* of a liquid fuel is its temperature (presumed to be uniform) at which the vapor and air mixture lying just above its vaporizing surface is capable of supporting a momentarily flashing propagation of a flame when prompted by a quick sweep of a small gas flame pilot near the surface. It is expected that the flash point is somehow related to the minimum temperature, T_L, for piloted ignition indicated in Figure 2-8.1(b).

The *fire point* of a liquid fuel is very similar in definition to the flash point, except that the flame does not merely flash and cease but must also be self-sustained, so as to continue burning the liquid.

The *autoignition temperature,* T_a, of a vapor (or gas) and air mixture is the minimum temperature at which the mixture is self-igniting.

Another property relevant in interpreting the significance of flash point is the *lean limit of flammability,* defined as the lowest *volume* percentage of fuel vapor (or gas) in the mixture with air (or oxygen) that will support propagation of a flame away from a pilot ignition source.

Example Data

The most extensive flash point and fire point data sources are the *International Critical Tables*[5] and the *Loss Prevention Handbook*.[6] Tables 2-8.1, 2-8.2, and 2-8.3 are excerpted from these two sources to note the typical values and to make several important observations.

Table 2-8.1 shows the flash points of a number of liquids in air measured by various test methods to indicate that the measurements depend quite strongly upon the apparatus employed. Although, as expected, the closed-cup tests (e.g., Pensky-Martens) produce flashing at a lower temperature than the open-cup tests (e.g., Cleveland). Other differences are neither small nor systematic.

Table 2-8.2 gives open- and closed-cup flash and fire points for a number of real-world combustibles of varying specific gravity. Two points are noteworthy: the fire point consistently exceeds the flash point by about 20 to 40°C, and heavier fuels tend to have higher flash points. Recalling that a higher flash point implies a lower saturation pressure and, hence, a lower volatility, this second observation is reasonable.

Table 2-8.3, adapted from *ICT*,[5] shows the closed-cup flash points as well as the minimum autoignition temperatures for a number of real liquids. The decrease in T_a due to high pressure is noteworthy.

Table 2-8.4, is a comprehensive collection of the flash points, lean limits, and autoignition temperatures for a host of liquid fuels in air at a nominal pressure of 1 atm. A number of other properties, useful in the following section, are also included. Besides serving as a practical reference dictionary, Table 2-8.4 also indicates a number of trends that are often vague or weak. Most of these trends are conceptually unsubstantiated to date. For example, in a given family of fuels, an increase in fuel molecular weight generally (but not always) indicates (1) a marked increase in the normal boiling point T_b°, (2) a slight decrease in the normal enthalpy of vaporization h_{fg}°, (3) an apparent increase in the flash point T_F°, (4) a modest and erratic decrease in the lean limit ℓ, and (5) a noticeable decrease in the minimum temperature for autoignition, T_a.

Table 2-8.1 ***Flash Points of Several Combustible Liquids Measured by Several Different Tests in Air***

	Flash Point (°C) as Measured in						
	Abel	Tagliabue	Elliot	Pensky-Martens	Cleveland	Luchaire	Open Cup

Theory and Discussion

Theoretical models are required in order to substantiate and understand these and other trends that may lie buried in elaborate data. The mechanisms culminating in the global effects of flashing and autoignition also elicit the way in which the measured properties depend on the apparatus used and the testing procedure followed. However, the physics and chemistry involved in open- or closed-cup flash point and autoignition testers is much too complicated, with numerous interacting thermodynamic, fluid mechanical, heat and mass transport, and chemical kinetic processes. Complete mathematical models capable of predicting the outcome of a specific test do not exist and are nearly impossible. Simple syntheses of the essential physical and chemical processes of the tests, are not only possible but enlightening.

Flash Point and Lean Flammability Limit

In principle, the problem involves transient analysis of heat and mass transfer with oxidative reactions in the gas phase lying above the liquid surface. In cup tests, the boundaries of the three-dimensional space of interest are the vaporizing liquid surface at the bottom, the open or closed top, and the side walls, which are probably cylindrical and therefore impervious to mass but conductive to heat. (The flash points and autoignition temperatures measured in cups or flasks whose walls are highly conductive are known to be higher.) If the cup were open, airflow and drafts in the room would be expected to alter the heat and mass transport processes of concern, and hence, the measurement. A closed cup minimizes these alterations by allowing air to stealthily leak into the region of interest.

[a]Estimate; ~ approximate line; — unavailable; $R = \bar{R}/M$; $\bar{R} = 8.314$ kJ/kmol K.

If the vapor were to be released at a constant rate at the hot liquid surface, beginning with time, t, equal to zero, it would transiently diffuse in the vertical direction, leading to a concentration profile* with the highest vapor concentration at the fuel surface and the least at the mouth of the cup. In the initial stages, the concentration everywhere is too low to support a flame. As time progresses, however, the temperature of the gas mixture near the surface rises beyond the minimum temperature limit T_L. (See Figure 2-8.1.) Equally important, the vapor concentration also increases to, and beyond, the lean limit. Later still, the thickness of the mixture layer that is beyond the lean limit increases due to diffusion. (If a pilot source were presented to this layer, a propagable flame could be generated. Thus, it is evident that the location and time at which a pilot is introduced are important in a test seeking the conditions of a propagable flame.) With continued time, the mixture at the surface becomes much too fuel-rich (oxygen-poor) to permit generation of a propagable flame with a pilot source. After longer periods of time, the spatial belt containing mixtures between the lean and rich limits broadens and propagates away from the surface.

This description of transient diffusion of vapor issued at a constant rate at the surface also holds, qualitatively, to a situation of a temporally variable vapor release rate, as in a typical flash point test.

As pointed out by Burgoyne and Williams-Leir[9] and Kanury,[10] the vapor release boundary condition is quite crucial in the flash point phenomenon. For a flame to flash over the surface of liquid fuel when presented with an ignition source, the vapor and air mixture (at the location and instant of the ignition source) has to contain sufficient fuel to be above the lean limit of flammability, ℓ. The partial pressure of the vapor in the mixture at the liquid surface is approximately equal to the saturation pressure, P_v, of the fuel at the surface temperature, T. The error associated with the assumption of thermodynamic equilibrium (at the surface across which mass transfer occurs at a nonnegligible rate) is known to be quite small. The $P_v(T)$ relation is given by the integrated form of the well-known[11] Clausius-Clapeyron equation of state†

$$\frac{P_{vs}}{P^\circ} = \exp\left[\left(\frac{h^\circ_{fg}}{RT^\circ}\right)\left(1 - \frac{T^\circ}{T_s}\right)\right] \tag{1}$$

where T° and P° are reference temperature and pressure. The subscript s denotes the surface. When T° is equal to the normal boiling point temperature, T°_b, of the liquid, the reference vapor pressure, P°, will become equal to the atmospheric total pressure. Equation 1 is generally written in the form $\ln P_{vs} = -\alpha/T_s + \beta$, where $\alpha \equiv h^\circ_{fg}/R$ and $\beta \equiv \ln P^\circ + \alpha/T^\circ$ are constants of the liquid. The *CRC Handbook of Physics and Chemistry*[7] gives extensive $P_v(T)$ tabulations for hundreds of liquids.

For many nonpolar liquids, the molar specific entropy of vaporization is found to be a universal constant, a consequence of the observed invariance of the ratio of normal boiling point to the critical temperature, so that

$$\frac{h^\circ_{fg}}{RT^\circ_b} \approx \text{a constant} = 10.18$$

Known as *Trouton's rule*,[13] this powerful relation enables one to estimate the normal enthalpy of vaporization h°_{fg} from a knowledge of the normal boiling point T°_b and the liquid molecular* weight, M. The last column of Table 2-8.4 indicates the validity of Trouton's rule; in general, Trouton's constant is larger than 10.18 for alcohols and smaller for acids.

Due to noninfinite diffusion effects, the molar (or volume) fraction, $X_v \equiv P_v/P^\circ$, of fuel vapor at stations away from the surface will be smaller than that at the surface, given by Equation 1. The solution of the diffusion equation, with Equation 1 serving as one of the boundary conditions, gives the following distribution. With y denoting the distance in the gas phase from, and normal to, the surface and t denoting time, let $g(y, t)$ be a distribution solution such that

$$\frac{P_v(y,t)}{P^\circ} = g(y,t)\,\frac{P_{vs}}{P^\circ} \tag{2}$$

The function $g(y, t)$ is dimensionless and smaller than unity in magnitude.

Suppose that a large enough pilot source is introduced at a height, y_p, and time, t_p. Recalling the definition of the lean limit, ℓ, the flame would then flash if the local instantaneous mole fraction, $P_v(y_p, t_p)/P^\circ$, is even marginally in excess of the lean limit, ℓ. Thus, the flash point and the lean limit are related by

$$g(y_p, t_p)\exp\left[\left(\frac{h^\circ_{fg}}{RT^\circ}\right)\left(1 - \frac{T^\circ}{T_F}\right)\right] \geq \ell \tag{3}$$

Taking the total pressure to be 1 atm, $T^\circ = T^\circ_b$, the normal boiling point. We denote the flash point in 1 atm air by T°_F. The inequality sign in this equation is quite close to an equality. Noting that g and ℓ are smaller than unity, Equation 2 can be rewritten as

$$\ln\left(\frac{1}{\ell}\right) \approx \left(\frac{h^\circ_{fg}}{RT^\circ_b}\right)\left(\frac{T^\circ_b}{T^\circ_F} - 1\right) + \ln\frac{1}{g(y_p, t_p)} \tag{4}$$

*The steady-state, one-dimensional diffusion version of this problem is known as the *Stefan problem* and can be found in Bird, Stewart, and Lightfoot.[12]

†With its genesis in the Maxwell relation $(\partial P/\partial T)_v = (\partial s/\partial v)_T$, Equation 1 arises from the facts: (1) equilibrium evaporation is a reversible process of constant pressure and temperature; (2) the heat addition in a constant temperature reversible process is equal to $T\Delta s$; and (3) the constant pressure heat addition is equal to Δh; and the assumptions: (1) the enthalpy change associated with the change of phase from saturated liquid to saturated vapor is independent of temperature so that $\Delta h = h^\circ_{fg}$, a constant; (2) the vapor volume far exceeds the liquid volume; and (3) the vapor behaves nearly as an ideal gas. The basic constraint of equilibrium, of course, is the equality of Gibbs' free energy of the saturated liquid and that of the saturated vapor.

*Recall that the gas constant R is related to the universal gas constant $\bar{R} = 8.314$ (kJ/kmol K) through the molecular weight M (kg/kmol) by $R \equiv \bar{R}/M$ (kJ/kg K).

The following comments can be made of Equation 4:

1. The lean limit of flammability, ℓ, as listed in the literature and in Table 2-8.4, is itself an apparatus-dependent property. The most notable factor influencing it is gravity (causing buoyancy in the limit mixtures and inhomogeneity of the fuel-air mixture). The approximate equality sign in Equation 4 is meant to highlight this point.
2. Most of the flash point data seldom point out explicitly that they have been determined in air and nominally at 1 atm total pressure.
3. If the ambient total pressure, $P°$, is higher than 1 atm, the flash point is expected to be higher also. A plot of $\ln P°$ versus $1/T_F^\circ$ is known to be a straight line, apparently parallel to the boiling point line for the same liquid. Thus, correction for the flash point dependency on pressure can be made the same way as for the boiling point dependency. Leslie and Geniesse refer in *ICT*[5] (p. 161) to a method by which the flash point is calculated as the temperature at which the liquid's vapor pressure is equal to $P°/kN$, where $P°$ is the total pressure, N is the number of moles of oxygen stoichiometrically required for complete combustion of 1 mole of the liquid, and k is an apparatus constant of about 8. The stoichiometry ratio, N, apparently is introduced through the lean limit, ℓ.
4. The question of the dependency of lean limit on whether the ambient gas is normal air or pure oxygen is a complicated one. If the oxygen/fuel ratio at the lean limit is assumed to be the same for both cases, then ℓ is expected to be numerically larger in pure oxygen than in air. Lewis and von Elbe[8] report a few values to confirm this expectation. A consensus exists in combustion literature that the percent of fuel in the limit mixtures is, more or less, independent of the presence of nitrogen. This, too, leads to a larger value of ℓ in pure oxygen than in air. Both these arguments, coupled with Equation 4, lead to the conclusion that the flash point of a liquid will be higher (and closer to the boiling point) in pure oxygen than in air.

   This conclusion is, however, contrary to common sense. Ignition is expected to occur more easily in the absence of the impeding inert nitrogen. Experience indicates that in pure oxygen atmospheres, the minimum ignition energies of combustible mixtures are lower, quenching distances are smaller, and flame temperatures and speeds are larger. Based on this experience, it is logical to surmise that the chemical kinetics of oxidation and thermochemistry underlying the concept of the lean limit are far more complex than mere mass conservation. The paper of Mullins[14] on combustion in vitiated air and the tome of Lewis and von Elbe[8] serve well as starting points for a much-needed research investigation into this important unresolved issue of limit mixtures.
5. When the cup is closed, the escape of the fuel vapor to the environment is prevented or minimized. Appearing as the second boundary condition in the diffusion equation, this results in a higher value of $g(y, t)$ at any location and time. For a given lean limit, Trouton's constant, and normal boiling point, Equation 4 indicates that the observed flash point will be lower than if the cup were open.
6. The effects of the cup being open and the air being in a state of motion due to gravity or due to disturbance are in the direction of increasing the observed flash point, all due to reduced $g(y, t)$.
7. Burgoyne and Williams-Leir[9] assume the dispersion function $g(y_p, t_p)$ to be unity to use a variant form of Equation 4 to predict the flash point from given ℓ, h_{fg}°, and T_b°.
8. Such a use of Equation 4 as a predictive tool is probably premature for several reasons. First, the transient convective-diffusion process underlying the g-function has a crucial role to play in determining T_F°. Second, even if one works out the solution to obtain $g(y, t)$, the flash point experiments do not clearly stipulate the $y = y_p$ and $t = t_P$ values; that is, they do not state the time and location at which the pilot is introduced. Thus, the estimates of $g(y_p, t_p)$ require subjective judgments. Last, as discussed in item 4, the lean limit, ℓ, is still an empirical extrinsic parameter whose dependence on fundamental properties of the system is not quantitatively known.

   Notwithstanding these reasons, by merely noting that the last term in Equation 4 is always positive, one concludes that

$$\ln\left(\frac{1}{\ell}\right) \geq \left(\frac{h_{fg}^\circ}{RT_b^\circ}\right)\left(\frac{T_b^\circ}{T_F^\circ} - 1\right)$$

   A plot of $\ln(1/\ell)$ on the y-axis and $(T_b^\circ/T_F^\circ - 1)$ on the x-axis should then yield all experimental points lying above a straight line of slope $(h_{fg}^\circ/RT_b^\circ) \approx 10.18$ and intercept zero. Figure 2-8.2 shows most of the data of Table 2-8.4 thus plotted. It is obvious that the hypothesis underlying Equation 4 bears merit. The general trend of data (especially for each family of fuels) indicates that Trouton's constant (or a like one) holds to describe the slope. The intercept, expected to be zero if diffusional effects are absent, indicates that $g(y_p, t_p)$ lies in the approximate range of 0.07 to 0.25, substantially smaller than unity, indicating the need for consideration of diffusion.
9. All through this discussion energy conservation has not been considered, although it may be important.

Autoignition Temperature

Whereas the piloted ignition in flash point tests involves a localized initiation of the flame and observation to see if it would propagate away from the ignitor, the autoignition is a self-induced initiation of the flame in a relatively larger volume of the reacting gases. As such, the autoignition is perhaps amenable to an easier description than the forced ignition. At the outset, it should be noted that the autoignition process pertains to the vapor (or gas) and air mixture, irrespective of the source of the vapor or gas. Figure 2-8.1, part (b), indicates that by the time the autoignition process becomes evident, the liquid fuel will be vaporizing vigorously and even boiling.

Consider the oxidation reaction in a vessel of known geometry. The initial temperature and mixture composition

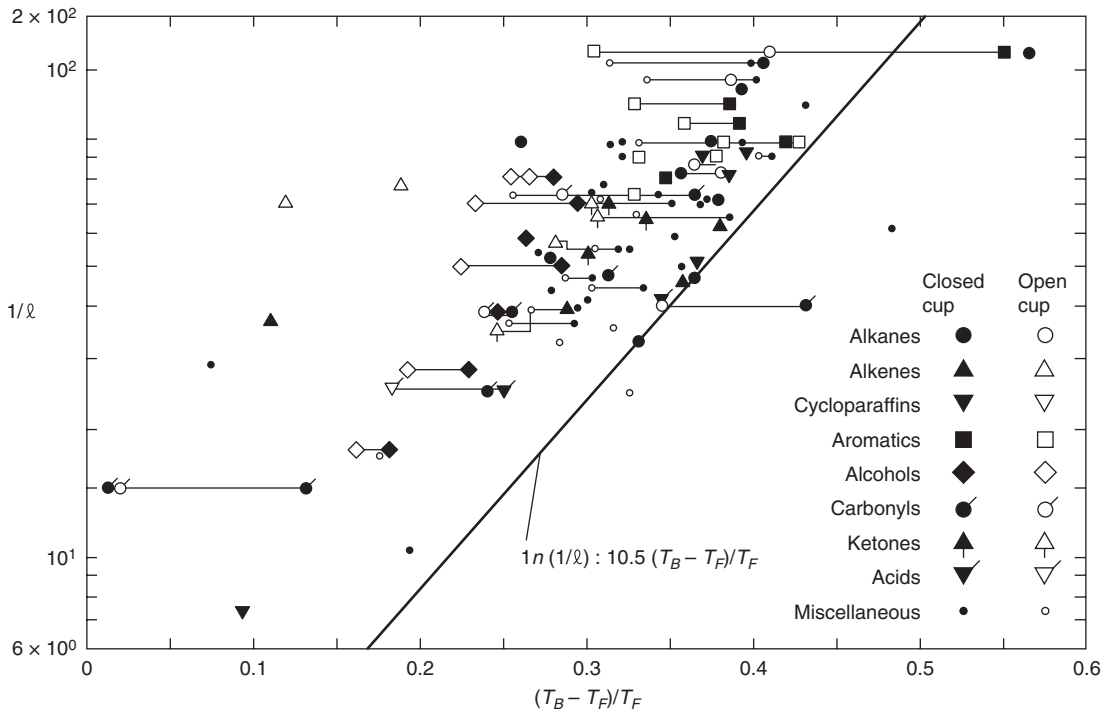

Figure 2-8.2. ***A relation between the lean limit, flash point, and boiling point.[10]***

are usually known. The mechanism of heat exchange between the reactive medium and the vessel walls constitutes the most important of the boundary conditions. Although the oxidation mechanism is probably composed of a complex set of elementary reaction steps, a global rate law for the fuel consumption rate generally suffices.

$$-\dot{W}_A''' = k_0 Y_A^n Y_B^m \exp\left(\frac{-E}{\overline{R}T}\right) \tag{5}$$

The quantity on the left side of Equation 5 is fuel consumption rate in kg/m³·s. The empirical kinetic constants k_0, n, m, and E are, respectively, the collision factor, orders with respect to the fuel (A) and oxygen (B), and activation energy (kJ/kmol). In principle, then, the equations of conservation of mass, momentum, energy, and species can be solved to obtain the transient fields of velocity, temperature, and composition. According to thermal theory,[15,16] ignition is inferred to have occurred at the instant when the temperature (usually, in the middle of the reactor) increases rapidly. Known as *thermal runaway*, this event also marks the onset of a rapid decrease in the reactant mass fractions, Y_A and Y_B. If the reactant consumption in the preignition period is ignored, then the autoignition is called a *thermal explosion.*

Solutions are available in the literature for this problem, with and without reactant depletion, for a number of geometries of the reactant mass and of boundary conditions. When the reactant depletion is ignored, the species equations become unnecessary. The convective mixing in gaseous mixtures is usually taken into account by defining an effective, augmented, thermal conductivity so as to obviate the momentum conservation and reduce the problem to one involving merely transient, reactive conduction. By considering the effective conductivity to be large (due to good mixing) and the heat loss from the reacting mixture to the vessel boundaries to be by convection, Semenov[15] solves the resultant transient, uniform reaction problem to predict thermal runaway conditions as

$$\frac{E(T_a - T_w)}{\overline{R}T_w^2} = 1$$
$$\mathrm{Da}_0 \equiv \frac{[h_c V(-\dot{W}_A''')_0]}{[hS(T_a - T_w)]} \geq 1/e \tag{6}$$

where

T_a = (critical) temperature of the reactive mass at the instant of explosion (see Figure 2-8.1)
T_w = vessel wall temperature
h_c = enthalpy of combustion (kJ/kg fuel)
h = heat transfer coefficient between the mixture and the walls (kW/m² K)
V/S = volume-to-surface ratio of the reactive mass
$(-\dot{W}_A''')_0$ = reaction rate given by Equation 5 at the initial conditions $T = T_0$, $Y_A = Y_{A0}$, and $Y_B = T_{B0}$
e = Naperian constant

Two points are immediately notable from Equation 6. First, the critical temperature T_a is quite close to T_w, since $\overline{R}T_w^2/\mathrm{E}$ is, generally, quite small. Thus, $T_a \approx T_w$. Second, due to the mixture being well mixed, the precise geometry of the reacting body is irrelevant; its V to S ratio suffices; $V/S = a/(j+1)$, where $j = 0$, 1, and 2, respectively, for an infinite plane slab geometry of thickness, $2a$, for an

infinitely long cylinder of diameter, $2a$, and a sphere of diameter, $2a$. Other implications of Equation 6 will be discussed later.

Frank-Kamenetskii[16] solves the problem by assuming that the effective conductivity, K, is small and seeks the conditions under which steady-state solutions are impossible. Thermal runaway is found to occur pursuant to the following critical conditions:

$$\frac{E(T_a - T_w)}{\overline{R}T_w^2} \qquad \begin{matrix} j=0 & j=1 & j=2 \\ 1.20 & 1.37 & 1.60 \end{matrix} \quad (7)$$

$$\mathrm{Da}_\infty \equiv \frac{a^3 h_c k_0 Y_{A0}^n Y_{B0}^m \exp(-E/\overline{R}T_w)}{a^2 K(T_a - T_w)/a} \qquad 0.88 \quad 2.00 \quad 3.32$$

This solution, as does Equation 6, indicates that $(T_a - T_w) \approx \overline{R}T_w^2/E$ is small. Vessels with a geometry resulting in a larger surface-to-volume ratio (e.g., a sphere) exhibit a larger critical temperature, T_a.

The nondimensional parameters Da_0 and Da_∞ of Equations 6 and 7, respectively, are known as Damköhler numbers. A Damköhler number is the ratio of the characteristic rate of energy release due to chemical reaction to that of physical dissipation (by convection in the Semenov problem and by conduction in the Frank-Kamenetskii problem).

The Semenov problem corresponds to the zero Biot number limit, while the Frank-Kamenetskii problem deals with the infinite Biot number situation. The finite Biot number problem has been solved by Thomas[17] and Kanury and Gandhi.[18] (An excellent review of this subject is presented by Gray and Lee.[19]) Equations 6 and 7 can be seen to be in mutual agreement if one notes that the heat transfer coefficient, h, is linearly proportional to the ratio of gas conductivity, K, to the vessel half-size, a.

Even more importantly, the pressure dependency of the collision factor is given by

$$k_0 \equiv k_0' M_A^{(1-n)} M_B^{-m} \left(\frac{PM}{\overline{R}T}\right)^{(n+m)} \quad (8)$$

where

k_0' = function only of the molecular collisional nature of species A and B

M_A and M_B = molecular weights, respectively, of the fuel (A) and oxygen (B)

M = mean molecular weight of the mixture

P = total pressure of the reacting mixture

The Damköhler number, Da_∞, from the criterion for explosion given by Equation 7 can then be recast to the form

$$\mathrm{Da}_\infty \equiv \left(\frac{k_0' \overline{R} M_B^{-m} M^{(n+m)} Y_{A0}^n Y_{B0}^m}{E^{(1+n+m)}}\right)\left(\frac{a^2 h_c P^{(n+m)} M_A^{1-n}}{K} f(T_a)\right) \quad (9)$$

where $f(T_a) \equiv [\exp(-E/\overline{R}T_a)]/(\overline{R}T_a/E)^4$. If the initial mixture composition (Y_{A0}, Y_{B0}) is kept fixed, the first bracketed quantity of Equation 9 is, more or less, a constant. For typical hydrocarbons reacting with air, $n \approx 0.5$, $m \approx 1.5$, and $E/\overline{R} \approx 15{,}000$ K. The function $f(T_a)$ monotonically increases with $(\overline{R}T_a/E)$, as indicated in Figure 2-8.3. The second bracketed term of Equation 9 and the explosion criterion constant of Equation 7 thus give the influence of a, h_c, P, M_A, and K on the minimum temperature for autoignition, T_a. Specifically, it is clear that the autoignition temperature is lower if the vessel size is larger, heat of combustion is larger, pressure is higher, fuel molecular weight is larger, or the mixture conductivity is smaller. This predicted pressure dependency is in excellent quantitative agreement with the data in Table 2-8.3. The influence of molecular weight appears corroborated by the data in Table 2-8.4. Not so evident from Table 2-8.4 is the effect of the heat of combustion, mainly due to the relatively minor variance of h_c within a family of fuels.

Ignition Delay

The discussion so far has centered on the threshold conditions below which ignition is not possible (i.e., question 1 of the Introduction). So far as the flash point and fire point are concerned, a more detailed analysis is required to go further. Concerning autoignition, however, a few further steps can be taken related to question 2 of the Introduction. First, note that the critical temperature T_a from Equations 6, 7, and 9 and Table 2-8.4 is the minimum temperature of the mixture that can produce autoignition, but marginally. This marginality implies that time to ignition at T_a is infinite. Any temperature greater than T_a will result in ignition within a finite time. The larger the temperature, the sooner the ignition.

Furthermore, as indicated in Figure 2-8.1, there exist upper and lower composition limits to autoignition at any $T > T_a$. The most quickly ignitible mixture at any T

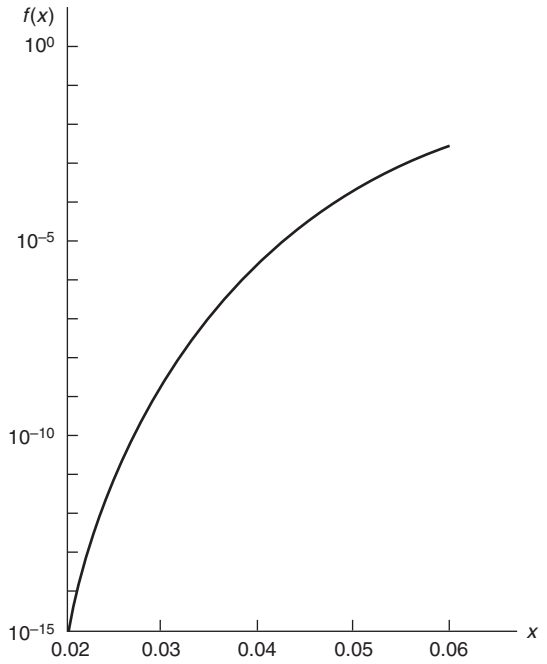

Figure 2-8.3. ***The monotonic nature of f(x) = [exp(–1/x)]/x⁴.***

will perhaps be near stoichiometric in composition. Thus, energy balance on the reacting mixture leads to the approximate ignition delay, t_i, of

$$t_i \approx \frac{(\rho C_p)(T - T_0)}{h_c(-W_A''')_{\text{ref}}} \tag{10}$$

where (ρC_p) is mixture volumetric heat capacity (kJ/m^3 K), T_0 is initial temperature of the mixture, and the reaction rate is estimated at the reference conditions of 0 for the Semenov (Biot number = 0) problem and w for the Frank-Kamenetskii (Biot number = ∞) problem. This rate also accounts for the mixture composition Y_{A0} and Y_{B0}. The Arrhenius dependency of the reaction rate on temperature makes the ignition delay, t_i, proportional to $\exp(-E/\overline{R}T_{\text{ref}})$. Thus, measurement of t_i at various T_{ref} values leads to determination of the activation energy, E. In the light of Equation 8, t_i will be approximately proportional to the inverse of the mixture pressure and to the square root of the molecular weight of the fuel. Since Da_0 and Da_∞ are about unity, the denominator of Equation 10 is proportional to $K(T - T_w)/a^2$ so that ignition delay is longer for higher conductivity mixtures, if all else is kept fixed.

If the consumption of reactants in the preignition reactions is significant, the problem becomes more difficult. The outcome, however, is that reactant consumption makes the limit temperature, T_a, somewhat higher than the estimates from Equations 6, 7, and 9, and the ignition delay is longer than that given by Equation 10.

Concluding Remarks

The concepts of piloted ignition of liquid fuels and the spontaneous ignition of their vapors mixed with air are examined in this chapter. Starting with a physical description of the ignition process and definitions, a number of experimental techniques were alluded to, and typical data were presented. The empirical trends were shown to be consistent with the predictions based on simple mechanistic models.

Although the flash point concept is useful in rating the volatility and ease of ignition of a variety of liquid combustibles, it must be noted that many practical situations involve heating of the liquid by a heat flux imposed on the evaporating surface. The heating process itself might then become a major topic of study to estimate the liquid surface temperature before examining whether this temperature is above or below the flash point at a given instant.

Nomenclature

a	vessel half-size (m)
C_p	specific heat (kJ/kg·K)
Da_0	Semenov's Damköhler number
Da_∞	Frank-Kamenetskii's Damköhler number
E	activation energy (kJ/kmol)
e	Naperian constant
g	dispersion function
h	heat transfer coefficient (W/m^2·K)
h_c	enthalpy of combustion (kJ/kg)
h_{fg}°	enthalpy of vaporization (kJ/kg)
j	geometry index
K	mixture thermal conductivity (W/m·K)
k	apparatus constant
k_0	collision factor (kg/m^3·s)
k_0'	collision parameter
ℓ	lean limit of flammability
M	molecular weight (unsubscripted for the mixture) (kg/kmol)
m	a reaction order
N	Stoichiometric molar O_2/fuel ratio
n	reaction order
P	pressure (atm)
P°	total pressure (atm)
P_v	vapor pressure (atm)
R	gas constant (kJ/kg·K)
$\overline{R}$	universal gas constant (kJ/kmol K)
S	surface area (m^2)
s	specific entropy (kJ/kg K)
T	temperature (K)
T_a	the least autoignition temperature (K)
T_b°	normal boiling point (K)
T_F°	flash point in air at 1 atm (K)
t	time (s)
V	volume (m^3)
v	specific volume (m^3/kg)
$\dot{W}'''$	reaction rate (kg/m^3 s)
Y	mass fraction
y	distance into gas phase from, and normal to, the vaporizing surface (m)

CHAPTER 9

Smoldering Combustion

T. J. Ohlemiller

Introduction

Smoldering is a slow, low-temperature, flameless form of combustion, sustained by the heat evolved when oxygen directly attacks the surface of a condensed-phase fuel. Smoldering constitutes a serious fire hazard for two reasons. First, it typically yields a substantially higher conversion of a fuel to toxic compounds than does flaming (though this occurs more slowly). Second, smoldering provides a pathway to flaming that can be initiated by heat sources much too weak to directly produce a flame.

The term *smoldering* is sometimes inappropriately used to describe a non-flaming response of condensed-phase organic materials to an external heat flux. Any organic material, when subjected to a sufficient heat flux, will degrade, gasify, and give off smoke. There usually is little or no oxidation involved in this gasification process, and thus it is endothermic. This process is more appropriately referred to as forced pyrolysis, not smoldering.

A burning cigarette is a familiar example of true smoldering combustion. It is also one of the most common initiators of smoldering in other materials, especially upholstery and bedding.[1] A cigarette also has several characteristics common to most materials that smolder. The finely divided fuel particles provide a large surface area per unit mass of fuel, which facilitates the surface attack by oxygen. The permeable nature of the aggregate of fuel particles permits oxygen transport to the reaction site by diffusion and convection. At the same time, such particle aggregates typically form fairly effective thermal insulators that help slow heat losses, permitting sustained combustion despite low heat release rates.

The physical factors that favor smoldering must be complemented by chemical factors as well. Like virtually all other cellulosic materials, tobacco in a cigarette, when degraded thermally, forms a char. A char is not a well-defined material, but typically it is considerably richer in carbon content than the original fuel; its surface area per unit mass is also enhanced. This char has a rather high heat of oxidation and is susceptible to rapid oxygen attack at moderate temperatures (≥670 K). The attack of oxygen (to form mainly carbon monoxide and carbon dioxide) is facilitated not only by the enhanced surface area but also by alkali metal impurities (present in virtually all cellulosic materials derived from plants) which catalyze the oxidation process.[2] Char oxidation is the principal heat source in most self-sustained smolder propagation processes; the potential for smoldering combustion thus exists with any material that forms a significant amount of char during thermal decomposition. (Char oxidation is not always the only heat source and it may not be involved at all in some cases of smolder initiation.)[3]

Various quantitative combinations of these physical and chemical factors can produce a material that will undergo sustained smoldering in some conditions. The enormous range of factors results in materials that will only smolder when formed into fuel aggregates many meters across, at one extreme, to materials that smolder when formed into aggregates only a few tens of microns across. Unfortunately, a theory that allows for the calculation of materials and conditions that are conducive to smoldering has been developed only for certain types of smolder initiation. (See Section 2, Chapter 10.) Conditions sufficient to yield smolder initiation, especially near an external heat source, are not necessarily sufficient to assure self-sustained smolder spread away from the initiation region. The potential transition of the smolder process into flaming combustion is even less correlated with factors determining smolder initiation.

This chapter is restricted to consideration of post-initiation behavior of smoldering. There are several models of smoldering combustion in the literature, but they are mostly numerical in nature, and do not shed much light on the practical aspects of the problem. Smolder

Dr. T. J. Ohlemiller is a member of the research staff of the National Institute of Standards and Technology, Building and Fire Research Laboratory. He has investigated a variety of solid fuel combustion problems, specializing in smoldering and the flammability of solid fuels.

modeling has been reviewed by Ohlemiller,[4] but the reader should be aware that there has been substantial activity since that review. Readers wishing to pursue the literature on modeling of one-dimensional smolder propagation should refer to References 5–16. Two-dimensional propagation models can be found in References 17–20. Distinctive features peculiar to one- and two-dimensional smolder propagation modes are described later. Lacking any definitive theoretical description, this chapter is largely restricted to examining typical experimentally determined behavior. In this overview of smoldering, an attempt is made to convey some of the qualitative interplay of processes that determines overall behavior, together with specific experimental results.

Self-Sustained Smolder Propagation

The smolder initiation process is dominated by the kinetics of the oxidation of the solid. Subsequent propagation of smolder is controlled to a large degree, however, by the rate of oxygen transport to the reaction zone. The control via transport rate occurs because the heat evolved during smolder initiation raises the local temperature and thus the local reaction rate, until all of the neighboring oxygen is consumed. Subsequently, the reaction continues to consume oxygen as fast as it reaches the reaction zone, yielding a very low oxygen level locally, which limits the reaction rate.

The subsequent evolution of the smoldering zone away from the initiation region is heavily influenced by oxygen supply conditions. If initiation occurs deep within a layer of fine particles (sawdust, coal dust), for example, it will slowly work its way to the nearest free surface at a rate dictated by oxygen diffusion through the particle layer. (The more coarse and loosely packed the particles, the greater the influence of buoyant flow through the fuel leading to predominant upward spread.) When the smolder zone reaches the free surface region, it will spread more rapidly over this region in response to local convective and diffusive oxygen supply conditions. As will be seen, when smolder spread over the surface region of a fuel layer is forced by airflow, its response also depends on heat transfer considerations.

In examining self-sustained smolder propagation and its response to oxygen supply conditions, dimensionality is important. It is necessary to distinguish one-dimensional from multi-dimensional configurations. Further, it is necessary to discern whether the smolder zone is spreading in the same or opposite direction as the net movement of oxygen.

One-Dimensional Smolder Spread

One-dimensional smolder spread is an idealized situation that is sometimes approximated in real fires. For example, the spread outward or upward from deep in a layer of fuel particles approaches this one-dimensional limit when oxygen diffusion dominates convection and any curvature of the reaction front is small compared to the reaction zone thickness. In practice, this curvature requirement would likely be met by spread about 0.10 to 0.20 m away from the ignition source. One-dimensional smolder can be characterized by the direction of smolder propagation relative to the direction of oxygen flow—forward and reverse propagation.

Reverse propagation: When oxygen diffuses to the reaction zone from the outer surface of the fuel layer, through the unburned fuel and toward the reaction front, it is moving opposite to the direction of smolder propagation. Such a case of relative movement is called reverse smolder.

Palmer[21] examined this diffusive reverse smolder case using layers of wood sawdust of various depths. The configuration was only roughly one-dimensional. Some of his results are shown in Figure 2-9.1. Note that the time scale is in hours. The time to smolder up through a layer 1-m deep is about two weeks, a surprisingly long time. Palmer

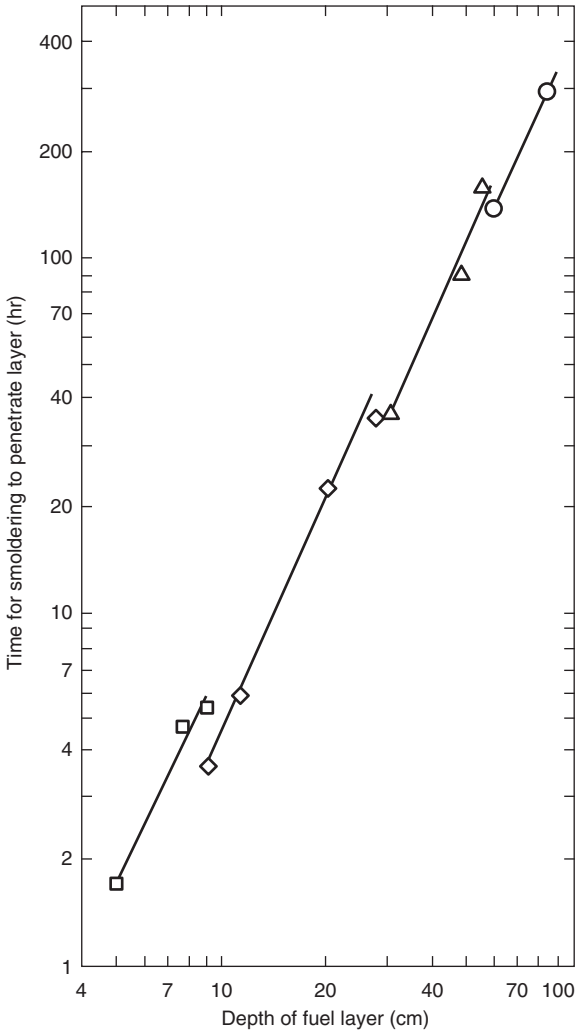

Figure 2-9.1. ***Smoldering upward from bottom within thick layers of mixed wood sawdust.[21] Squares: initiating layer 0.025 m deep, 0.3-m square box; diamonds: initiating layer 0.052 m deep, 0.3-m square box; triangles: initiation layer 0.052 m deep, 0.6-m square box; circles: initiating layer 0.052 m deep, 0.9-m square box.***

noted that in this configuration the smoldering process gave little hint of its presence until it was close to the surface of the fuel layer.

The slope in Figure 2-9.1 indicates that the time for smolder to penetrate a fuel layer in this mode is nearly proportional to the square of the layer depth.[21] Palmer showed that a second power dependence on layer depth would be expected if it is assumed that the smolder reaction zone propagation velocity is proportional to the one-dimensional diffusion rate of oxygen from the surroundings, through the unburned fuel, to the reaction zone. This results in

$$t_L = AL^2 \tag{1}$$

where t_L is the time for the smolder zone to penetrate the layer of thickness, L; and A is a constant that can, at present, only be determined by experimental measurement of at least one layer thickness.

This relation and Figure 2-9.1 imply that a 10-m fuel layer, such as might be encountered in a landfill or coal mine tailing pile, would require more than four years for smolder penetration. Such a deep layer is unlikely to be uniform in practice and the smolder front movement would be dominated by buoyant convective flow in regions of lesser flow resistance. However, this does illustrate how very slow some smolder processes can be.

A well-insulated reaction zone is a key factor in the existence of stable, self-sustaining smolder at such extremely low rates. The heat loss rate cannot exceed the heat generation rate. In this case, the same factor that is slowing the oxygen supply rate, and therefore the heat generation rate (i.e., the thick layer of wood particles over the reaction zone) is also slowing the heat loss rate.

In the previous example, the smolder propagation process is inherently unsteady because of the time-dependent oxygen supply process. If oxygen is instead continually supplied by a forced convective flow *through* the fuel layer, nearly steady propagation occurs. Such a configuration is encountered in some incinerators and coal burners but rarely in a smoldering fire. This configuration has been examined experimentally[8,9,22] and modeled,[5,6,8–12] and is a relatively well-understood smolder mode with underlying mechanisms qualitatively similar to the transient case just discussed.

In this mode of reverse smolder propagation, oxygen surrounds the fuel particles as they are heated by the advancing smolder reaction zone. Thermal degradation of some fuels in the presence of oxygen is exothermic. This exothermic degradation is particularly true of cellulosic materials and this heat can be sufficient to drive the smolder wave without any char oxidation.[22] In flexible polyurethane foams, the presence of oxygen during degradation plays another key role. Without oxygen many foams do not form any char,[23] although char oxidation is a necessary source of heat for these materials. In the reverse smolder mode, the net oxidation rate and net heat release rate are again directly proportional to the oxygen supply rate. The smolder zone spreads to adjacent material as fast as this generated heat can be transferred and radiated to it. An increased oxygen supply rate causes a greater rate of heat release and increased peak temperature in the reaction zone which, in turn, increases the heat transfer rate to adjacent fuel, thus accelerating the smolder spread rate. This sequence implies that the smolder reaction zone may well move through a layer of fuel without fully consuming the solid at any point. This unconsumed material, in fact, acts like an insulator for the reaction zone, increasing its stability. On the other hand, Dosanjh et al.,[6] point out that this mode of smolder propagation can achieve a steady-state only if, as a minimum, the energy released is sufficient to heat the incoming air supply; otherwise it will extinguish.

Figure 2-9.2 shows measured reverse smolder velocities for several types of fuel as a function of airflow velocity through the fuel bed. The bulk densities of the fuel bed are all low but typical for these types of materials. Note that the airflow velocity range is also quite low, although higher flows are sufficient to move the fuel particles in the bed (i.e., an upward flow higher than approximately 0.01 to 0.02 m/s would fluidize the fuel bed).

Despite the considerable variation in the chemical nature of these fuels, the smolder velocity is always of order 10^{-4} m/s. For the same air supply rate, the smolder velocities do not vary much more than a factor of 2. This is consistent with the idea that the oxygen supply rate, not reaction kinetics, dominates the propagation process. (If the oxidizer flow rate is forced upward sufficiently in circumstances where bed fluidization is prevented, the smolder velocity begins to drop as cooling effects dominate. See Reference 8 for an example.) The differences with fuel nature that do exist mainly appear to reflect variations in available heat and effective thermal conductivity.

Only limited information is available on toxic gas production from this mode of smoldering. The molar percentage of carbon monoxide in the evolved gases has been examined for two of the fuels in Figure 2-9.2. For the flexible polyurethane foam, the carbon monoxide was 6 to 7 mole percent for an air velocity of 1.5×10^{-3} m/s. The flow rate dependency was not examined.[23] For the cellulosic insulation material,[24] the carbon monoxide mole fraction varied from about 10 to 22 percent from the lowest to the highest air flow velocity in Figure 2-9.2. The mass flux of carbon monoxide from such a smoldering process (grams of CO/m^2 of smolder front/second) then is estimated as follows:

$$Y_{CO}(\dot{m}_{\text{air}} + \dot{m}_{GS}) \tag{2}$$

or

$$Y_{CO}[\rho_{\text{air}} v_{\text{air}} + (1 - \phi)\Delta\rho_s v_s] \tag{3}$$

Here Y_{CO} is the mass fraction of carbon monoxide in the evolved product gases (approximately equal to the mole fraction); m_{air} is the mass flux of air entering the smolder zone; m_{GS} is the mass flux of gaseous material evolved from the solid fuel; ρ_{air} is the density of the air at the point where its velocity, v_{air}, is measured; ϕ is the initial void fraction of the fuel bed; $\Delta\rho_s$ is the change in density of the fuel bed (for reverse smolder, typically 65 to 95 percent of the original mass is gasified); and v_s is the smolder front velocity.

Limited information is also available on the aerosol emitted by a reverse smolder source.[25] This is pertinent to

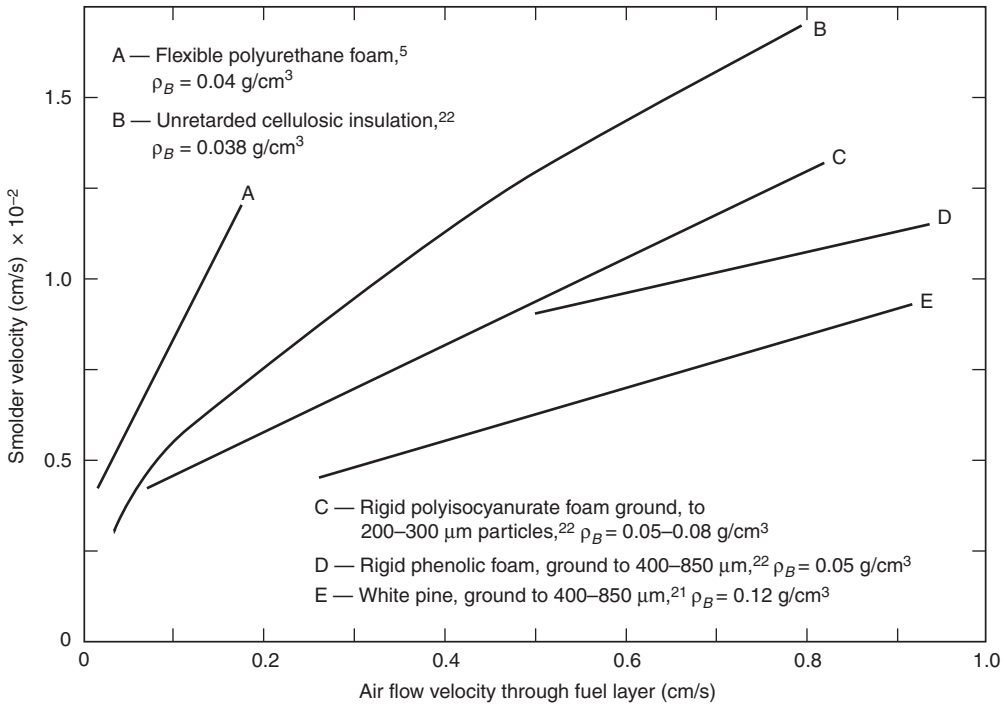

Figure 2-9.2. ***Smolder velocity versus airflow velocity into reaction zone for nearly one-dimensional reverse smolder. ρ_B is bulk density.***

detection of a smoldering fire. The source studied was essentially identical to that used to obtain the data for curve B in Figure 2-9.2. The fuel again was an unretarded cellulosic insulation. The mass mean particle size of the aerosol was 2 to 3 μm; this is about 5 times larger than cigarette smoke, and 50 to 200 times larger than the sooty particulate produced by flaming combustion. This large size explains the relatively poor sensitivity of ionization smoke detectors to realistic smolder sources. The residual solid left in the smolder wave and the original fuel both were found to be effective filters for this aerosol. This finding helps explain the observation by Palmer[21] that smoldering in a thick layer of fuel was not detectable until it neared the surface exposed to the ambient atmosphere.

The rate of heat release for this mode of smolder can be estimated from the total mass flux of products and their heat content (gas temperature typically 670 to 970 K). The result is a few kW/m^2 of smolder front. This translates to a few hundredths of a kW for a reverse smolder source 0.1 to 0.15 m in diameter. The strength of the heat source has a bearing on the behavior of the buoyant plume. (See Section 2, Chapter 1.) Sources as weak as those considered here generate plumes that may not reach the ceiling of a room.[26]

Forward propagation: The second limiting case of one-dimensional smolder propagation is called forward smolder. In this case the oxygen flow is in the same direction as the movement of the smolder front. The most familiar example (though not one-dimensional) of forward propagation is a cigarette during a draw. This limiting case is encountered in some industrial combustion processes but is unlikely to be found in its pure, one-dimensional form in a fire context (some elements of this mode are encountered in realistic cases, however). An approximate model of this process (in one dimension) has been presented by Dosanjh and Pagni.[7] They point out that this smolder mode will die out if the heat generated by char oxidation is insufficient to drive the drying and fuel pyrolysis reactions that precede char formation in the reaction zone. Other modeling studies of forward smolder propagation can be found in References 13–16. It is shown in Reference 14 that one-dimensional forward smolder is, in principle, capable of four differing modes of propagation depending on the oxygen concentration and supply rate. Two of these are limited by oxygen supply rate and two by reaction kinetics. Further experimental studies of forward smolder propagation through polyurethane foam can be found in References 27–28. A transient study of the requirements for the initiation of this smolder rate in polyurethane foam can be found in Reference 29.

Some characteristics of forward propagation are briefly mentioned here to describe the major effects that reversing the direction of oxygen flow can have on smolder propagation characteristics.

Forward and reverse smolder propagation have been compared experimentally.[22,24] The fuel was an unretarded cellulosic insulation. Forward smolder through this same fuel at the same air supply rate is about ten times slower than reverse smolder. The carbon monoxide mole fraction is independent of air supply rate and is about 0.09. Forward smolder also allows for more complete combustion

of the fuel. These and other differences between the two smolder modes can be explained in terms of the differing wave structures.[22]

An interesting aspect of a propagating, one-dimensional smolder wave is that the counterflowing materials (gas and solid, as viewed from the moving smolder front) form a system that retains the reaction heat and preheats the reactants with that heat.[13] This effect implies that the internal peak temperature can rise above the adiabatic reaction temperature. In Reference 16 an expression is given for limiting temperature in the reaction wave for the case in which there is only a single, net exothermic reaction. Whether this feature of forward smolder plays a role in the potential for transition into flaming has not been explored.

Frandsen[30] investigated the downward propagation of smoldering in horizontal layers of peat as a model fuel for the complex duff layer found on the floor of a forest. No external flow was imposed. This is essentially a diffusion-driven forward smolder process forced to be one-dimensional in this study; it normally is multidimensional in character. The influence of both moisture and inorganic diluents on the limits of smolder propagation was measured. At extremes, it was found that this cellulosic fuel will just smolder when it contains 50 percent water by weight and no inorganic diluents. When dry, it will just smolder when the mix contains 80 percent inorganic diluents. These results should be roughly indicative of the limits for other cellulosic fuels in the absence of a cross-flow over the fuel layer.

Multi-Dimensional Smolder Spread

Factors such as ignition source geometry, fuel geometry, and the strong influence of buoyant flow on oxygen supply usually interact to assure that a smolder reaction zone has significant gradients of temperature and species in two or three dimensions. The number of possible configurations becomes virtually limitless. The practical configurations that have been studied are few and they are usually two-dimensional; they do shed some light on most cases likely to be of practical interest.

Horizontal fuel layer: The configuration that has been studied most extensively is two-dimensional smolder propagation in a uniform horizontal layer of particles or fibers. Ohlemiller examined the structure of the smolder zone[31] in a thick (0.18-m) horizontal layer of cellulosic insulation in the absence of any forced airflow over the fuel layer. In these conditions, the flow induced by the buoyant plume rising above the smolder zone assures a constant supply of oxygen to the space above the layer. Oxygen penetrates the layer largely by diffusion.

If such a layer is ignited uniformly on one end, the smolder reaction zone soon evolves into a new shape dictated by oxygen supply rates.[31] The uppermost elements of the reaction zone, being closest to the free surface, and hence, ambient air, spread away from the ignition source the fastest. Successively deeper elements spread in the same direction but more slowly. The result is a smolder reaction zone that (viewed in vertical cross section) slopes upward from the bottom of the layer to the top, in the direction of movement. The steady-state length of this inclined smolder front is roughly twice the depth of the original fuel layer. This inclined reaction zone is several centimeters thick, and across this thickness there is a smooth transition from unburned fuel to ash. On the ash side (the free surface adjacent to air) oxygen diffuses down and inward in the same direction as the smolder front is moving and attacks the charred fuel; this is analogous to forward smolder discussed earlier. On the unburned fuel side of the inclined smolder front, oxygen diffuses in from the region ahead of the front to react with the fuel as it is thermally degraded by heat conducted from the char oxidation region. Oxygen here is moving opposite to the direction of smolder propagation, so this aspect of the overall reaction zone is analogous to reverse smolder. Remember that in cellulosic materials, this oxidative/thermal degradation is exothermic. Thus the two-dimensional horizontal smolder zone incorporates features of both forward and reverse smolder and is driven forward by the combined heat release from char oxidation and oxidative/thermal degradation.

The participation of oxidative/thermal degradation in driving the smolder process requires that oxygen have free access to the thermal degradation region. For a low-permeability fuel such as solid wood, this is not the case. Even though solid wood has basically the same reaction chemistry as cellulosic insulation (which consists mostly of wood fibers) and smolders with a qualitatively similar inclined reaction zone, it must be driven solely by char oxidation.

The low permeability and corresponding high density of solid wood has another consequence with regard to smolder. The self-insulating quality of the reaction zone is much less than with a low-density layer of fuel particles or fibers. A single layer of wood will not sustain smolder unless it is subjected to an additional heat input of about 10 kW/m^2.[36] This heat could come from some external radiant source or from another piece of smoldering wood that has an adequate radiative view factor with respect to the first piece.

In view of the strong role of oxygen supply rate in shaping the smolder process in a horizontal fuel layer, it is not surprising that smolder also accelerates in response to an increased oxygen supply rate produced by an airflow over the top of the smoldering layer. As with the one-dimensional propagation situation, two possibilities again exist: the airflow can travel in the same direction as the smolder front (again called forward smolder) or in the opposite direction (reverse smolder). Note, however, that now the actual fluxes of oxygen *within* the smoldering fuel bed may go in various directions. They are no longer constrained to being parallel to the smolder wave movement, as in the one-dimensional cases.

Palmer[21] examined both of the flow direction possibilities for relatively thin horizontal layers (3×10^{-3} to 5.7×10^{-2} m) of various cellulosic particles (cork, pine, beech, grass). Figure 2-9.3 shows some typical results. Note that the smolder velocities are less than or equal to those in Figure 2-9.2, despite the much higher air velocities. This is probably due to differing rates of actual oxygen delivery to the reaction zone, and to the fact that the near-surface region, which receives the best oxygen supply, is also subjected to the highest heat losses.

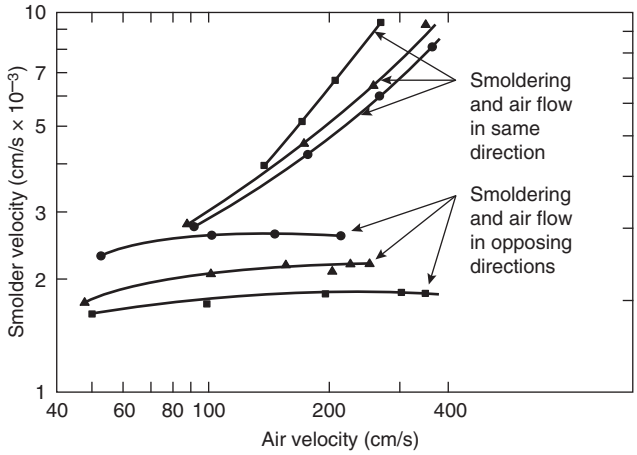

Figure 2-9.3. ***Dependence of smolder propagation rate through horizontal layers of beech sawdust on air velocity over top of layer.[21] Circles: 120 μm mean particle size; triangles: 190 μm mean particle size; squares: 480 μm mean particle size.***

The influence of two factors, fuel particle size and relative direction of airflow and smolder propagation is shown in Figure 2-9.3. Particle size has a relatively weak effect on smolder velocity but its effect depends on whether the smolder configuration is forward or reverse. The configuration itself (i.e., the relative direction of airflow and smolder propagation) has a much greater effect.

Ohlemiller[37] obtained comparable smolder velocities and dependence on configuration for 0.10- to 0.11-m thick layers of cellulosic insulation. It was found that the configuration dependence cannot be explained solely on the basis of oxygen supply rates. The mass transfer rate to the surface of the fuel bed was measured for forward and reverse configurations. It differed by only 20 to 30 percent (these differences were caused by changes in the bed shape due to shrinkage during smolder). It was pointed out that the observed dependence on relative direction of the airflow was consistent with there being a prominent role for convective heat transfer along the top surface of the fuel layer. This dependence occurs only if part of the smolder wave, that is, the region near the leading edge, is kinetically limited (and therefore highly temperature sensitive) rather than oxygen supply rate limited. This phenomenon explains the qualitative impact of both relative airflow direction and combustion retardants on smolder velocity. It also explains why forward smolder is faster than reverse smolder in the horizontal layer configuration, whereas the opposite was true for one-dimensional propagation. The role played by fuel particle size may be implicit in this view, but a quantitative model is not yet available.

In contrast to the monotonic enhancement of forward smolder velocity with increased airflow rate found by Palmer and by Ohlemiller, Sato and Sega[38] observed more complex behavior with thin (0.004 to 0.01-m) layers of a cellulosic mixture. Smolder velocity increased up to freestream air velocities of about 3 m/s and then remained constant to the highest air velocity examined (6 m/s). This plateau correlated with erratic behavior at the leading edge of the smolder reaction zone involving both periodic extinctions and mechanical disruptions. These authors also examined the thermal structure of their forced smolder waves. The results were qualitatively similar to those of Ohlemiller for buoyant smolder,[31] but the peak temperatures were appreciably higher due to the enhanced oxygen supply rates.

There is a minimum thickness below which a horizontal fuel layer will not undergo self-sustained smolder propagation. As the thickness of a fuel layer decreases, its surface-to-volume ratio increases (inversely with thickness to the first power). The ratio of the rate of heat loss to the rate of heat generation also varies in this manner so that ultimately the losses are overwhelming and extinction occurs. The exact thickness will depend on factors such as bulk density, fuel type and particle size, rate of oxygen supply, and so forth, influencing the heat generation per unit volume at a given thickness. The same considerations apply to other thin layers of fuel such as fabrics on upholstery and sheets of paper, wood, or particle board. Palmer[21] found that the minimum depth for sustained smolder in still air increased linearly with particle size for beech, pine and cork. For cork this dependence ceased above 2 mm, apparently because more complete oxidation of the char stabilized the process in the layers of larger particles. For very small particles, ($<$100 μm), the minimum depth dropped as low as 1 mm for cork dust, while 0.01 m was typical of small particles of beech or pine sawdust. Ohlemiller and Rogers[39] found the minimum depth in still air for an unretarded cellulosic insulation to be 0.035 m; a heavy loading of the smolder retardant boric acid roughly doubled this value. Since the insulation has a very small effective particle size and essentially the same chemistry as Palmer's sawdusts, most of the difference in minimum depth (for the unretarded material) probably lies in the bulk density, which is about four to five times less for the insulation compared to the sawdusts (40 kg/m^3 versus 180 kg/m^3). Palmer found that the minimum depth dropped rapidly with increased airflow over the sawdust layers, in keeping with the idea that a greater rate of heat release per unit volume stabilizes the smolder process.

Beever[32,40] has addressed a problem at the opposite extreme of layer thickness, that of underground fires in land fills, peat deposits, and mine tailings. These tend to be smoldering fires in roughly horizontal layers where the principal mode of oxygen access is from the top surface. Beever[32] studied this process on a laboratory scale using mixtures of fine sawdust or charcoal with an inert diluent, that is, diatomaceous earth, in a trough that was insulated on the sides and bottom but open to quiescent air on the top. The trough was 0.13 m by 0.38 m in cross section and 0.14 m deep. A deeper trough was used in separate experiments in which pure layers of the inert diluent were placed atop the combustible layer. Local ignition near the top of a layer yielded steady propagation over a limited depth at rates that varied only weakly with inert content. However, while 25 percent fuel content yielded smolder spread, 10 percent fuel content did not. (Frandsen[30] diluted peat moss and Douglas Fir duff with

powdered silica in his downward smolder propagation studies. He found sustained smolder in dry material at up to 80 percent inorganic loading, but the allowable inorganic level decreased strongly as moisture level was increased.) The depth to which Beever's spreading smolder zone reached increased with the cross-sectional dimensions of the fuel bed. Material below this depth, having been heated and partially decomposed by the smoldering zone above, could itself subsequently propagate a second wave moving in the opposite direction. It was pointed out that such behavior can make it possible for a landfill or similar fire to spread under a barrier intended to stop it. Similarly, inert covering layers may simply slow but not stop such fires. The true key to stopping a smoldering fire is getting the heat out of the fuel, but this can prove to be extraordinarily difficult. Oxygen removal is insufficient unless it is sustained until the fuel cools to a point where oxygen readmission will not cause reignition. For a landfill fire, the cooling period can be impractically large.

The duff layer on a forest floor was mentioned previously. This porous layer of decaying organic material is frequently ignited to smoldering by the passage of a forest fire. Smoldering in this layer is highly spatially irregular in extent. In addition to posing a threat of reignition of a flaming fire, this smoldering also has broad implications about the viability of dormant seeds and forest regeneration. This subject is reviewed in Reference 41.

Smolder propagation data on a few other fuels (including some that are inorganic) in horizontal layers can be found.[42] Unfortunately, no data are currently available on the yield of evolved products of horizontal layer smolder. For crude estimates on cellulosic materials the previous results for reverse smolder are adequate, but they should be applied here with caution.

The propagation of smoldering through a porous, horizontal fuel layer has been modeled numerically to a limited extent.[17] The predicted smolder wave shape was in qualitative agreement with experiment. The effects of variations in the reaction rate parameters on this wave structure and on the smolder propagation velocity were examined.

Other fuel configurations: Data on a few other multidimensional smolder configurations are summarized in Table 2-9.1. Again there is little more information available than the rate of smolder propagation. An exception to this is the smoldering cigarette, which has been extensively studied,[43–45] albeit usually in a manner most pertinent to its peculiar mode of cyclicly forced air supply. The cigarette smolder propagation process has also been numerically modeled one-[13] and two- dimensionally.[17,18] (Other two-dimensional and numerical smolder propagation models can be found in References 19 and 20.)

All the materials in Table 2-9.1 are fairly porous. As noted previously, solid wood, a low-porosity fuel, also smolders, given a configuration that limits heat losses.[36,52,53]

Ohlemiller[52,53] examined smolder spread along the interior surface of a three-sided channel constructed of either white pine or red oak. A controlled flow of air was introduced at one end of the channel; the products evolved from the other end were monitored as was the rate of smolder spread. For both types of wood, stable smolder was observed for only a narrow range of inlet air velocities, 0.05 to 0.20 m/s. (From limited data this appeared true for both forward and reverse smolder.) Below this range the smolder process extinguished and above it flaming eventually erupted. Both of these limits, but particularly the lower limit, are probably dependent on the specific conditions of the tests. Carbon monoxide typically comprised 2 to 3 percent of the gases leaving the channel or about 10 to 15 percent of the gases leaving the surface of the wood. The rate of heat release during smoldering was estimated from the oxygen consumption rate, correcting for carbon monoxide. This rate ranged from about 0.5 to 2 kW or roughly 10 to 30 kW/m^2, based on the approximate area visibly glowing.

The last type of smolder configuration referenced in Table 2-9.1 is quite pertinent to the scenario that makes smoldering a major contributor to residential fire deaths, that is, upholstery and bedding fires initiated by cigarettes. This is frequently a composite problem, with the smoldering tendency of both the fabric and the substrate (polyurethane foam, cotton batting) pertinent to the overall smolder behavior of the combined assembly.[54] Ortiz-Molina et al. have shown that the combination of a cellulosic fabric plus a polyurethane foam can smolder over a substantially wider range of conditions than can the foam alone.[55] The fabric smolder process supplies added heat to the foam smolder zone while simultaneously competing for oxygen. The full complexity of this interaction is yet to be explored. A considerable amount of empirical data on the tendency of cigarettes to initiate this type of smolder is available.[49,56–63] The factors influencing the smolder tendency of upholstery fabrics have been examined as well.[64–69]

The life hazard posed by smoldering bedding or upholstery within a closed room has been studied to some extent.[70–72] Data have been presented[70] on the buildup of carbon monoxide (near the ceiling) in a 2.4-m room on a side due to cigarette-initiated smolder in a cotton mattress. The smolder front was reported to spread radially at a rate of 6.3 10^{-5} m/s independent of the size of the smoldering area. In two out of five tests the smolder process underwent a transition to flaming combustion after 65 to 80 minutes, which is close to the time at which total carbon monoxide exposure was estimated to be lethal. Similar data are reported[71] for a greater variety of bedding and upholstery materials; these were ignited by cigarettes (and by flaming sources) in a room 4.3 $\times$ 3.6 $\times$ 2.4 m. Carbon monoxide and several other gases were sampled at three locations. Flaming developed from smoldering in several of the tests; this usually required 2 to 3 hours of smoldering first. Again, the total exposure to carbon monoxide from the smolder smoke approached or exceeded lethal levels. Lethal conditions due to carbon monoxide were reached in much shorter times in some cases.

All available data on the hazards of smoldering in a closed room were evaluated.[72] It was concluded that the probability of a lethal carbon monoxide dose and of transition to flaming are comparable for a period from 1 to 2½ hours after cigarette initiation of smoldering. A model is presented for buildup of carbon monoxide due to a smoldering fire;[72] the results generally show reasonable

Table 2-9.1 ***Data on Multi-Dimensional Smolder in Various Fuels***

Fuel	Fuel/Smolder Configuration	Air Supply Condition/Rate	Smolder Velocity (cm/sec)	Maximum Temp. (°C)	Reference	Comment
Pressed fiber insulation board, 0.23–0.29 g/cc	1.3 cm thick, horizontal strips, width large compared to thickness	Natural convection/ diffusion	$1.3–2.2 \cdot 10^{-3}$	NA	21	Smolder velocity increased ≈ 50% for strips with width ≈ thickness
Pressed fiber insulation board, 0.23–0.29 g/cc	1.3 cm × 1.3 cm strips varied angle to vertical	Natural convection/ diffusion	$2.7–4.7 \cdot 10^{-3}$	NA	21	Smolder velocity highest for upward spread; lowest for horizontal spread
Pressed fiber insulation board, 0.23–0.29 g/cc	1.3 cm × 5 cm strips forward smolder	Forced flow, 20 to 1500 cm/s	$3.5 \cdot 10^{-3}$ cm/s (20 cm/s air) $13.0 \cdot 10^{-3}$ cm/s (1400 cm/s air)	770°C (200 cm/s) 790°C (900 cm/s)	21	Some samples extinguished due to air cooling at air velocity > 1450 cm/s
Pressed fiber insulation board, 0.23–0.29 g/cc	1.3 cm × 5 cm strips reverse smolder	Forced flow, 80–700 cm/s	$2.8–3.5 \cdot 10^{-3}$ cm/s	NA	21	Extinguishment indicated above 900 cm/s
Pressed fiberboard (pine or aspen) 0.24 g/cc	1.3 cm × 30 cm sheets, horizontal, forward smolder	Forced flow, 10–18 cm/s	$0.7 \cdot 10^{-3}$ cm/s	NA	46	
Cardboard	Vertical rolled cardboard cylinder, downward propagation, varied dia. 0.19–0.38 cm	Natural convection, diffusion	$5.0–8.4 \cdot 10^{-3}$ cm/s	NA	47	Small dia. ≈ 2 × faster than large dia.; ambient temp. effect measured
Shredded tobacco	0.8 cm dia. cigarette, horizontal, in open air	Natural convection, diffusion	$3.0–5.0 \cdot 10^{-3}$ cm/s	820°C	48	
Cellulose fabric + 3% NaCl	Double fabric layer, 0.2 cm thick, horizontal, forward smolder	Forced flow, ≈ 10 cm/s	$\approx 1.0 \cdot 10^{-2}$ cm/s	770°C	49	Smolder behavior dependent on alkali metal content
Cellulosic fabric on substrates	Various weight fabrics horizontal on fiberglass, PU foam, cotton batting	Natural convection, diffusion	$\approx 3.0–75 \cdot 10^{-3}$ cm/s dependent on substrate and fabric	Reported values suspiciously low	50, 51	Smolder fastest on inert fiberglass substrate

agreement with experiment, though some of the input parameters must be forced slightly.

In contrast to the above result, a more recent study of the fire risks associated with upholstered furniture implied that the toxic exposure from a smoldering chair in an average house was rarely fatal; transition to flaming brought with it death due to thermal causes.[73] The methodology was indirect, and involved using the Hazard I smoke movement and tenability models in a reasonably successful effort to reproduce national fire statistics for upholstery fires. There are not as yet sufficient data on the toxicity hazards of smoldering upholstery materials to definitively resolve this issue.

A relatively common practical problem in smolder extinguishment occurs in grain silos.[74] Here the smoldering must be completely extinguished before emptying the silo, to avoid the possibility of a dust explosion. The practical problems are considerable due to the tendency of any extinguishing agent to follow higher permeability channels and thereby miss significant smolder zones. In Reference 74 a number of extinguishing agents were tested in small-scale tests. Gaseous CO_2, fed from the bottom, was found to be the most effective.

Transition to Flaming

The transition process from smolder to flaming in the above bedding and upholstery fires is essentially spontaneous. At room conditions both smoldering and flaming are possible in many such systems. Sato and Sega[33] explored the domain of overlapping smolder and flaming potential for cellulosic materials and noted a hysteresis in the spontaneous transition between these two combustion modes. The mechanism of such a spontaneous transition has not been investigated in detail. It has been suggested on the basis of small mock-up studies that a

chimneylike effect develops in the crevice between the horizontal and vertical cushions of a smoldering chair.[62] The enhanced air supply presumably accelerates local char oxidation, heating the char to the point where it can ignite pyrolysis gases. Such a mechanism is plausible but it has not been demonstrated to be operable in real upholstery or bedding, where the chimney effect may not develop so readily.

Transition to flaming (fast exothermic gas-phase reactions) requires both a mixture of gases and air that are within their flammability limits and a sufficient heat source to ignite this mixture. Furthermore, these two requirements must be realized at the same locus in space and at the same time. Any factor that either enhances the net rate of heat generation or decreases the net rate of heat loss will move the smoldering material toward flaming ignition by increasing both local temperature and rate of pyrolysis gas generation. Such factors include an enhanced oxygen supply, an increase in scale (which usually implies lesser surface heat losses per unit volume of smoldering material), or an increasingly concave smolder front geometry, which reduces radiative losses to the surroundings and enhances gaseous fuel concentration buildup. All of these factors may be operating simultaneously in the case of upholstery and bedding smolder. Sequential photos of smolder initiation, growth, and transition to flaming in an upholstered chair appear consistent with this idea.[62,75]

A further factor in this and in other systems involving cellulosic materials is secondary char oxidation. This process is quite similar to the afterglow seen in cellulosic chars left by flaming combustion. Intense, high-temperature (probably greater than 1070 K) reaction fronts propagate intermittently in seemingly random directions through the fibrous low-density char left by the main lower temperature smolder front. In charred fabrics, these glowing fronts can sometimes progress in a stable manner along the charred residue of a single fiber, despite very high heat losses per unit volume of fuel. Such a process requires the catalytic action of alkali metals that are frequently found naturally in cellulosics or left there during manufacture.[63–65,69,76] While in a very hot smolder front the size of a single fiber is unlikely to be sufficiently energetic to ignite flammable gases, the larger fronts (10^{-3} to 10^{-2} m in scale) may well be. An analogous process has been found to cause occasional flaming ignition of smoldering, unretarded cellulosic insulation.[31]

Babrauskas and Krasny[77] surveyed the available literature data on the buoyant smolder in upholstered chairs and beds. They found that about two-thirds of the tested items underwent a transition into flaming combustion. The reported times for this to occur varied from 22 min to 306 min after the initiation of the smoldering process.

The transition from smolder to flaming can also be induced, for example, by a forced increase in oxygen supply rate to the smolder reaction zone.[21,23,33,34,78] This effect was first studied quantitatively by Palmer[21] for airflow over horizontal layers of wood sawdust. This process, of course, is familiar to anyone who has started a camp fire from tinder and sparks. Transition to flaming was noted by Palmer only for airflow in the same direction as smolder propagation (forward smolder). Depending on the material, the transition occurred at airflow velocities from about 0.9 to 1.7 m/s. For these materials, flaming did not develop when the mean particle size was less than 1 mm. Ohlemiller[37,78] did obtain transition to flaming in layers of fibrous insulation materials of very small diameter (~25 μm) but again only with forward smolder. This result occurred at air velocities of about 2 m/s for unretarded insulation. Leisch[34] utilized ignition sources placed midway along the length of grain and wood particle fuel layers so that forward and reverse smolder zones were simultaneously obtained. Flaming was noted at 4 m/s air velocity only after the smoldering process produced a substantial depression or cavity in the surface of the fuel layer.

Ohlemiller[37,78] explained the weak response and lack of flaming transition in reverse smolder on the basis of heat transfer effects influencing the leading edge of the smolder reaction zone. These heat transfer effects intensify the smolder in the leading edge region for forward smolder. In the case of cellulosic insulation, the intensification leads to random development of small (a few cm) cavities near the leading edge which act as flame initiation regions and flame holders.

Ohlemiller[78] also found that both boric acid (a smolder retardant) and borax (a flame retardant) could each eliminate the transition to flaming when the retarded cellulosic insulation was the only fuel. However, the effectiveness of the acid and borax was substantially reduced if the smoldering fuel abutted unretarded wood (as it typically does in residential housing). Heat transferred from the smolder zone readily ignited the wood. Palmer[79] noted similarly that layers of fine dust that would not themselves undergo transition to flaming readily ignited adjacent flammable materials.

Smoldering solid wood undergoes a transition to flaming readily in a configuration that minimizes heat losses.[52,53] It was inferred that the limiting variable in the transition is the surface temperature of the smoldering wood, with the transition occurring when that temperature reached about 950 to 1000 K.

The transition from two-dimensional, forced flow smolder propagation, to flaming in polyurethane foam was investigated by Tse, et al.[80,81] The configuration involved a contained slab of foam with forced air across its outer surface. No fabric was involved. Smoldering ignition was on the upstream end so this was two-dimensional forward smolder propagation. A unique ultrasonic technique was used to follow the density distribution of the foam during the tests along with schlieren imaging of the gas flow near the foam surface. It was inferred that the transition to flaming in this system occurred not at the foam/air interface, but rather within the depth of the char left by the smolder front. Continued reactions there opened holes which allowed the onset of vigorous gas phase reactions. This is not greatly dissimilar to the mechanism found for the onset of flaming in a horizontal layer of cellulosic insulation subjected to an air flow over its top surface.[37] In a study of smoke explosions in a reduced-scale enclosure containing a smoldering wood crib, the transition from smoldering to flaming was hypothesized as the trigger of this explosion.[82] The evidence was indirect and not entirely unambiguous.

Conclusion

Smoldering is a branch of solid fuel combustion quite distinct in many aspects from flaming, but equally diverse and complex. Unfortunately it has not been studied nearly to the same extent as flaming. This is quite apparent in the lack of quantitative guidelines that can be provided here for estimating the behavior of realistic smolder propagation processes, smolder detection, toxic gas production, and the transition to flaming. The experimental data provided can be readily used for closely analogous situations. They must be used cautiously for dissimilar conditions. The reader should always bear in mind the strong role that the oxygen supply rate has on the smolder process. The other very important factor is the relative direction of movement of oxygen supply and smolder propagation. This can be somewhat obscure in many realistic configurations. The actual chemical nature of the fuel is relatively secondary, at least with regard to smolder rate. It may be important for toxic gas production rates, but the data here are quite limited.

CHAPTER 10

Spontaneous Combustion and Self-Heating

Brian Gray

Introduction

The term *spontaneous combustion* will be used here to refer to the general phenomenon of an unstable (usually oxidizable) material reacting with the evolution of heat, which to a considerable extent is retained inside the material itself by virtue of either poor thermal conductivity of the material or its container. Under some circumstances this process can lead to flaming combustion and overt fire in which case it is properly called *spontaneous ignition* and is regarded here as a special case of spontaneous combustion. This phenomenon has been responsible for significant losses of life and enormous losses of property.

Fire loss statistics from many sources show that spontaneous ignition is quoted as the cause in a much greater proportion of cases with multimillion-dollar losses than in smaller fires. Of course one should also note that the proportion of results having an unknown cause follows a similar trend, probably due to the greater degree of destruction and hence lost evidence in larger fires. In other circumstances, clearly delineated from the former, only relatively mild self-heating occurs. This occurrence may be referred to as *self-heating*, *spontaneous combustion*, or by research scientists as *subcritical* behavior. By the same token, spontaneous ignition would be referred to as *supercritical* behavior. The well-defined boundary between the two types of behavior is referred to as the *critical condition* and it plays an absolutely central role, both conceptually and pedagogically. It can crudely but pictorially be thought of as a watershed.

The critical condition is actually a whole set of combinations of parameters that affect the behavior. The most important of these are the ambient (surrounding) temperature, and the size and shape of the body of material involved. Thus for a given body of a particular material we would normally talk about the *critical ambient temperature (CAT)*. If we were dealing with a situation where the size of the body was always fixed by commercial practice, for instance, this term would be the normal statement of the critical condition. However, in the case of storage of a variable amount of material in a constant temperature environment, one would talk about the *critical size* or the *critical diameter* of the body for a given fixed temperature. The CAT is the most commonly used and stated critical condition.

For both fire prevention and fire cause investigation, it is essential to be able to identify the critical condition if spontaneous ignition is a possibility either before or after the event. It is also important to be aware of other possible factors operating in particular cases, such as solar irradiation in outdoor storage and preheating if recently manufactured or processed goods are involved. In cases such as hot laundry; hot new chipboard; hot, oily, porous food products (instant noodles, fried fish scraps); bagasse* the temperature of the material itself is a most important parameter affecting criticality in addition to the usual ones. In such cases we have to deal with and determine a critical stacking temperature (CST), which refers to the temperature of the material itself, not the ambient temperature. The CST is dependent on the CAT and the size of the body so such cases are a degree more complicated than the traditional ones involving, usually, agricultural materials stacked at ambient temperature. In addition, in such cases with preheated materials, the time to ignition (defined precisely later) is usually very much shorter than it is where the material is stacked at ambient temperature.

Since the basic processes competing with each other in spontaneous combustion are heat generation by chem-

Emeritus Professor Brian Gray has published extensively on spontaneous combustion and ignition of gases and solids, gas ignition, flame propagation, and related topics for many years. He now runs a combustion consulting company in Sydney, Australia, and was Professor of chemistry at Macquarie University, Sydney, from 1976 to 1998.

*Bagasse is the remainder of sugar cane after the extraction of sugar. It is cellulosic in nature and usually contains 50 percent water.

ical reaction and heat loss to the surroundings mainly by conduction, it is easy to see qualitatively why both a larger body and higher ambient temperature will favor ignition rather than subcritical behavior as they both decrease the rate of heat loss. Generally the temperature profile across the body itself is roughly parabolic in shape, with a peak at the center. Most chemical reaction rates increase almost exponentially with temperature whereas heat loss processes such as conduction increase only linearly. Thus the center of the body where the temperature is highest is the region where ignition, or *thermal runaway,* will commence if it is going to take place at all. Many bodies that have undergone spontaneous ignition show this telltale signature of charring or complete destruction to ash in the center while retaining almost pristine appearance on the outside, sometimes presenting rather dangerous situations for fire fighters in large-scale examples such as bagasse, woodchip, or peat piles. Similarly, the deep-seated nature of the burning started by spontaneous ignition can be difficult to extinguish completely, often reigniting days after apparent extinction.

The purpose of this article is to expound the detailed nature of the situations described above in a manner that approaches the relevant principles and minimizes mathematical formulation as far as is reasonable. The subject will involve relevance to fire cause and fire investigation and as such will refer mainly to solid systems. Many of the basic principles used were actually clarified by experimental work on gaseous systems; such systems still play a central role in current research on this topic, particularly ones where the chemical kinetics are simple and well understood in their own right.

A closely related aspect to be discussed here is the subject of *runaway reaction,* or *thermal runaway.* In the past two decades this topic has developed a literature of its own[1] and threatened to lose contact with the extensive literature on spontaneous combustion. These two terms, which can be taken as synonymous, are applied to supercritical conditions as defined above but only in the context of a chemical reactor. The reactor may be of batch, semibatch, or continuous flow type, but it will almost invariably be well stirred either mechanically or by deliberate turbulent mixing. Therein lies the attraction of such studies from a pedagogical point of view since the main difficulties in mathematical modeling of solid spontaneous combustion arising from spatial temperature variation and gradually decreasing concentration of reacting material are not present. Thus a mathematical theory describing such processes exactly serves as a first approximation, and a tractable one at that, to the more complex topic of solid spontaneous combustion. In addition, the difficult and messy "corrections" to the simplest possible theories due to Semenov[2] and Frank-Kamenetskii[3] are often impossible to apply in practical situations due to the dearth of data and/or their numerical uncertainties.

In addition, in the rare event that precise input data are available and detailed chemical kinetics are known, it is now entirely feasible for particular cases to invoke directly numerical integration of the relevant equations without use of the empirical and semiempirical curve fits involved in the classical corrections to the simplest theories. At the time of writing, average laptop computers were quite capable of such calculations for all but the most irregularly shaped bodies where finite element methods need to be invoked and custom written.

Accordingly we will spend some time here expounding the simplest possible theory (Semenov), which contains all the essential concepts for the understanding of criticality, the tangency between heat release and heat loss curves, and the existence (or otherwise) of stable and unstable steady states. We then move on briefly to the application of such ideas to more complex chemistry and the idea of thermal runaway in continuous stirred tank reactors (CSTR).

We then discuss the Frank-Kamenetskii version of thermal explosion theory, which considers temperature gradients within the self-heating body (thereby generalizing Semenov) and often gives better agreement with experiment for solid bodies with low thermal conductivity. For this reason it is much used in fire investigations, particularly when it is necessary to predict the CAT for a large-scale industrial body from small-scale laboratory tests. However this type of extrapolation requires great care in its application to all but the simplest chemistry.

We then present some ways in which corrections can be made to the predictions of the Frank- Kamenetskii theory occurring under conditions where some of its assumptions are not too accurate. This occurs when the heat of reaction is relatively small and/or when the resistance to heat flow in the boundary of the body (or container wall) is relatively large compared to that inside the body itself (case of small Biot number). Corrections are also necessary when more than one chemical reaction generates heat and when oxygen diffusion into the interior of the body is rate limiting.

All these factors are difficult to handle quantitatively, but fortunately none of them really alter the *qualitative* conceptual nature of what is going on. It is important in gaining an understanding of spontaneous combustion *not* to be confused by these corrections although in certain cases they can be quite large.

We will then move on to discuss experimental testing methods, both on a laboratory and a larger scale where possible. A large array of calorimetric methods can be used to obtain relevant information, but not all of them, particularly differential scanning calorimetry (DSC) and differential thermal analysis (DTA), can give other than very general information. Nevertheless such methods have their purpose when material of unknown origin and composition is involved. Sometimes one needs to know whether the unknown is capable of exothermic reaction at all as postulation of spontaneous ignition because a fire cause looks rather silly in its absence (this happens!).

A characteristic of fires where spontaneous ignition is suspected as the cause is that they often occur on premises that have been closed up or unoccupied for a significant period of time. A question of very great interest in such a context is, What is the time scale expected for a body of a given size in a given ambient temperature to reach ignition, that is, the appearance of overt flame? As one would expect, by application of Murphy's law, this question is very difficult to answer with confidence except in the simplest cases. The time to ignition is a parameter that is not only extremely sensitive to many factors,

which are often unknown, but also extremely sensitive to the degree of supercriticality, that is, how far the body is from the watershed. Not only does it depend on how far the body is from the watershed, but it depends sensitively on the direction as well. In other words, the term *degree of supercriticality* needs to be refined before any idea of time to ignition can be properly formulated.

A number of investigations of this problem have been carried out, and it is essential to recognize that most of the earlier ones addressed the question of time to ignition for the initial temperature of the body equal to the ambient temperature—such as would be the case in the building of a haystack. Hot, stacked material requires totally different considerations for the evaluation of times to ignition, and classical formulae cannot be used in such situations. Such bodies can ignite in times that may be an order of magnitude shorter than predicted by uncritically using classical formulae.

In the penultimate section of this article, we move on to discuss the actual fire where spontaneous ignition has been the cause, or suspected cause, of the fire. We discuss factors that would be either positive or negative indicators of spontaneous ignition, and also the appropriate examination of the aftermath of the fire for pointers as to whether or not spontaneous ignition was the cause. We then proceed to illustrate all the above with a number of case histories, some of them common and illustrative of the basic principles expounded here, others of a novel nature involving quite subtle and detailed investigations that nevertheless can give very definite results.

The Literature

There is a large and varied literature on this topic ranging from sophisticated mathematical theory to technical measurements on industrial and agricultural products. It is scattered over a very wide range of journals, magazines, and disciplines. The most comprehensive publication is probably the book written by Bowes,[4] *Self-Heating: Evaluating and Controlling the Hazards.* This book was published in 1984 and contains references to work published up to 1981, so at the present time it is in need of updating. However, it is the most useful reference available for those working, or commencing work, in the field, either from an academic or technical viewpoint.

Although much of the understanding of spontaneous combustion has come from the basic study of gas phase reactions, where it is generally referred to as *autoignition*, this article will be limited to spontaneous combustion of solid materials generally. Many advances have been made in the field of gaseous autoignition over the last decade or so, stemming from accurate and detailed kinetic measurements and considerable advances in computing power. The critical condition for gaseous systems is a very complex locus in the parameter space characterized by ambient temperature (as for solids), pressure, and composition. Many organic materials, such as hydrocarbons, exhibit more than one autoignition temperature and many also exhibit the phenomenon of igniting on *decreasing* ambient temperature. Many older tabulations of autoignition temperatures do not recognize these peculiarities and should be used with great caution. A detailed description of the reasons for such complexities and their importance in a hazard context is given by Griffiths and Gray[5] in the twenty-fourth Loss Prevention Symposium of the American Institute of Chemical Engineers (1990). A comprehensive list of references up to 1990 can be found in this article.

Reference to liquid reactions and related spontaneous ignitions and thermal instabilities will be given later in this article in the section on spatially homogeneous, or "well-stirred," systems. Otherwise references will be given at points throughout this text resulting in a reasonably complete bibliography.

The Concept of Criticality

During the last two decades the concept of criticality, which has been present in the thermal context for many years,[6] has been recognized as a branch of bifurcation theory,[7] an area of nonlinear applied mathematics that has grown rapidly and proven to be extremely powerful in solving nonlinear problems. In our case the nonlinearity comes from the temperature dependence of the chemical reaction (and therefore heat production) rate. The Arrhenius form for this for a single reaction is $Ze^{-E/RT}$ where E is the activation energy and R is the universal gas constant. T is the absolute temperature, of course. At temperatures rather less than E/R (which can typically be 10,000 K or more), the Arrhenius function is very convex; that is, it curves upward rather rapidly with temperature. In contrast, the rate of heat loss from a reacting body is generally only a linear function of temperature, for example, conduction. Although radiation losses are nonlinear functions of temperature, they are much more weakly nonlinear than the Arrhenius function and also generally rather small at the low temperatures involved in solid spontaneous combustion even though they are important in flame extinction. Typical heat generation and heat loss loci are shown in Figure 2-10.1.

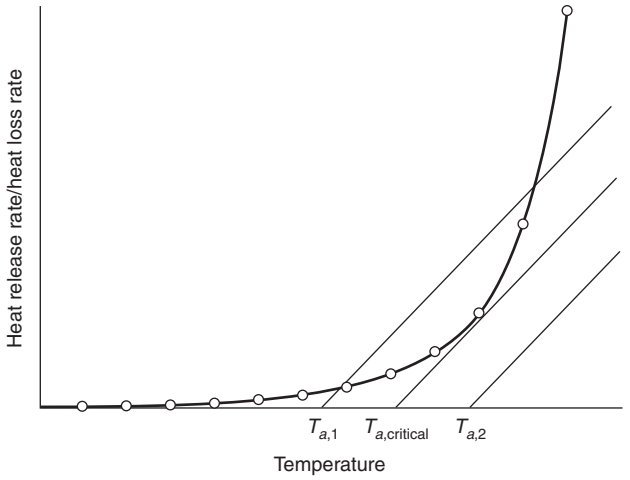

Figure 2-10.1. ***Typical Arrhenius heat-release and loss curves.***

The low temperature range of the Arrhenius curve is seen here to be rather convex and rapidly increasing with temperature. The three straight lines represent the rate of heat loss from a body of fixed given size at various ambient temperatures $T_{a,1}$, $T_{a,\text{critical}}$, and $T_{a,2}$.

At $T_{a,1}$ it can be seen that the heat production and loss curves intersect at two points. At $T_{a,2}$ they do not intersect at all and at $T_{a,\text{critical}}$ they intersect at only one point and, in fact, touch tangentially.

Since intersections represent conditions where heat production and loss balance exactly, we expect them to represent some sort of "equilibrium" or stationary point where the temperature of the body remains constant in time. It is important to remember that they do not represent equilibrium in any thermodynamic sense.

In the region of the lower intersection at $T_{a,1}$ it can be seen from the diagram that the temperature of the body will increase up to the balance point from below as heat release is greater than heat loss in this region. On the other hand, just above this balance point the temperature of the body will move down to it since the heat release is lower than the heat loss in this region. Thus the lower balance point occurring at ambient temperature $T_{a,1}$ is recognized as a *stable* balance, or stationary point. Small perturbations from it will be nullified and the body in this region will tend to stay at the balance point. Note that the temperature of the balance point is not $T_{a,1}$ but slightly above it, usually by 5–20°C. It represents subcritical self-heating and can cause loss of the material, but not by overt ignition or fire. It can appear as degradation or discoloration of many materials, making them useless for their required purpose. For example woodchips degraded in this way are not suitable for paper or cardboard production, and dried milk powder when discolored is unacceptable.

The second balance point at the ambient temperature $T_{a,1}$ can be seen by a similar simple analysis to be *unstable* in the sense that in the temperature region just below it, the heat production is *lower* than the heat loss, so the temperature tends to drop. In the temperature region just above it, the converse is true, so the body temperature tends to rise and leave the balance point. The latter acts as a watershed between two totally distinct types of behavior, that is, the temperature of the body dropping to the lower balance point or running away to the right of the diagram and much higher temperatures, representing ignition.

Here the temperature at the higher balance point would actually be the CST or *critical stacking temperature* for this particular body when stored at ambient temperature $T_{a,1}$. We can immediately see that if the ambient temperature is increased, that is, the straight line is moved to the right with fixed slope (which is determined by the size and shape of the body as we shall see later), the CST will *decrease*, a physically reasonable and intuitive result.

Thus this oversimplified but extremely useful model gives a simple understanding of what Bowes refers to as *thermal ignition* of the second kind, that is, what is probably better referred to as the *hot stacking problem*, a much more descriptive term. Not only that, but it also gives us a qualitatively correct picture of the more common or "normal" type of thermal ignition when the body self-heats from ambient to ignition without any preheating. At $T_{a,1}$ if we very slowly increase the ambient temperature after the steady state has been reached, we can see that the now "quasi-steady state" will also slowly increase until at $T_{a,\text{critical}}$ the quasi-steady state and the CST merge at the point of tangency. Beyond this ambient temperature there is no balance point, and in this temperature region the heat-release curve is now *always above the loss line* and therefore the temperature can only increase. Subsequent ignition will then occur. It will occur after some delay since the rate of temperature increase in this simple model is proportional to the imbalance between heat production and loss (i.e., the vertical distance between the two curves). This is initially quite small, increasing as the temperature rises. In this observation lie the seeds of the calculation of the *ignition delay* or *time to ignition (tti)* to be examined later.

Even more insights can be obtained from this simple type of reasoning. As we shall see later, the slope of the heat loss line is dependent on the surface area/volume ratio of the body in question. Thus for a body of given shape, the surface/volume ratio increases as the body gets smaller and decreases as the body gets larger. In Figure 2-10.2 we can see the effect of increasing the size of a body at a fixed ambient temperature. For this fixed ambient temperature we can speak of subcritical, critical, and supercritical sizes for the body, depending on whether any balance points exist.

Thus for a body with characteristic dimension r_{sub} we see the existence of both a CST and a balance point. For a larger body with dimension r_{super} we see that neither exist and we expect temperature rise to ignition. The critical condition, in this case expressed as a radius or body dimension, is given again by the tangency condition. This critical condition of course is identical with that obtained by thinking of quasi-static variation of the ambient temperature as well. The critical radius for a given ambient temperature will be identical with the CAT for a body of that same radius. How we describe it is simply a matter of where we are coming from.

Of course we do not usually continuously vary the size of a body, but we *do* often stack bodies together, for ex-

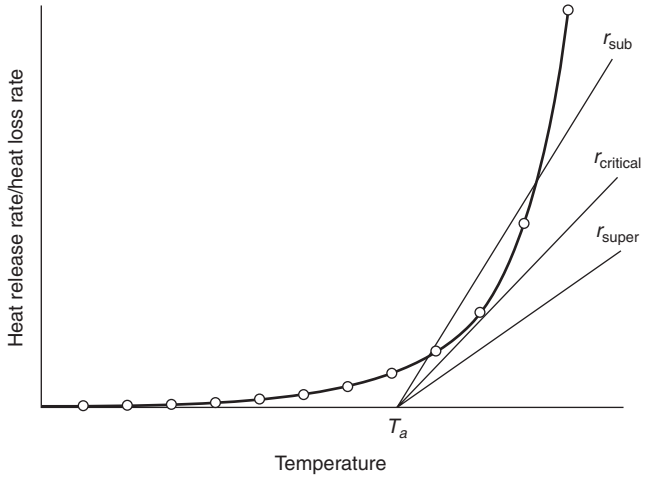

Figure 2-10.2. ***Disappearance of balance points with body size increase.***

ample, bales of cotton, bales of hay, and so forth, and allow larger than normal quantities to accumulate, for example, coal stockpiles. Even from the point of view of this very rudimentary theory, it is obvious that the CAT of two bales in contact will be considerably less than that for a single bale. Thus tests of the CATs of single bodies that are going to be stacked in groups either for transport or storage are useless unless a theory is available enabling calculation of the dependence of CAT on body size. The theory allowing this is thus extremely useful in relating practical tests on small bodies to be applied to storage of large numbers of them (with certain caveats to be discussed later).

To conclude this section it remains to show a convenient method of representing the behavior of the stable balance point and the unstable CST as a control parameter is varied (i.e., the ambient temperature or size of the body). This method enables a quick and convenient representation of the discussion given above on a single diagram (a bifurcation diagram) and also gives us a useful link to the mathematical developments of bifurcation theory.

Figure 2-10.3 shows what happens to the balance point temperature and the CST when T_a is varied continuously from below its critical value to above it. This takes place at constant body size. In this case the ambient temperature is known as the bifurcation parameter. We should note that even at very low ambient temperatures, the CST tends to a finite limit. In fact it becomes very insensitive to the ambient temperature, and no matter how cold the ambient temperature, there is no corresponding *rise* in the CST. Storing hot products in a cold warehouse does not help the problem much!

Conversely Figure 2-10.4 shows how the CST rises indefinitely as the size of the body decreases at fixed ambient temperature. Regardless of ambient temperature it does pay to keep hot stored bodies small! Figure 2-10.4 also shows how for sizes above the critical dimension there is no alternative but ignition. Of course the critical dimension depends on the ambient temperature, and as the latter goes down the critical dimension goes up. It is sometimes very useful to draw a critical dimension ver-

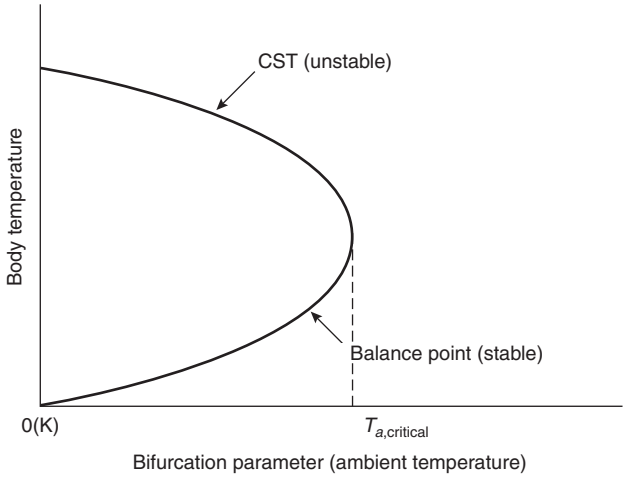

Figure 2-10.3. ***Variation of CST and stable subcritical temperature with ambient temperature, fixed body size.***

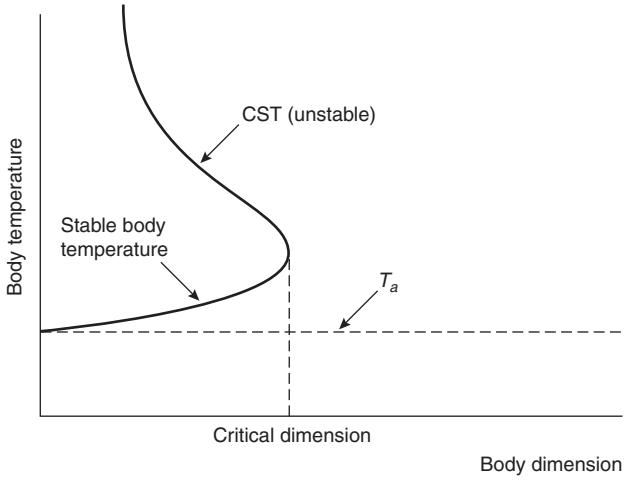

Figure 2-10.4. ***Variation of CST and stable subcritical temperature with body dimension, fixed ambient temperature.***

sus critical ambient temperature graph, and we will see how to do this later.

The whole discussion above assumes that we are dealing with a given material so that the thermal and chemical properties do not vary. The effects of varying thermal conductivity, heat-transfer coefficients, and density on the critical condition are also important but only when comparing different materials. The dependence of the critical condition on these properties will be enunciated in a later section.

One final point needs to be mentioned here. The Arrhenius function does actually level out to an asymptote at very high temperatures, which are off the scale in Figures 2-10.1 and 2-10.2. Thus, theoretically there is another balance point at very high temperature, but in fact this point is not physically significant as it usually occurs at many thousands of degrees, well beyond the region where the assumptions of the model are valid. It also gives rise to a high temperature branch of the curves in Figures 2-10.3 and 2-10.4, which is disjoint from the curves shown. Again it can be ignored from the point of view of low-temperature spontaneous ignition.

The Semenov (Well-Stirred) Theory of Thermal Ignition

The Semenov Theory represents the simplest mathematical formulation of the ideas presented above in qualitative form. As such it is a valuable introduction to quantitative aspects of spontaneous ignition without introducing the technical difficulties associated with more elaborate forms of theory where spatial variations of temperature and reaction rate within the body are considered. The assumptions for this theory follow.

1. The temperature within the reacting body is spatially uniform: A spatially uniform temperature implies either that the material of the body is well stirred (i.e., it would

have to be liquid or gas) or the resistance to heat flow within the body is so low compared to that within the container or boundary that it can all be assumed to be concentrated within the boundary. The latter results in a temperature discontinuity at the boundary of the material and is a good approximation in deliberately stirred fluids.[8]

It is not a good approximation for materials of vegetable origin where thermal conductivities of materials such as cellulose are low and of the order of 0.05 W/mK. Nevertheless, even for such materials semiquantitative conclusions can be drawn from this theory if the spatially averaged temperature of the body is used.

2. The heat generation is assumed to be due to a single chemical reaction of simple integral order: This assumption is often a reasonably good approximation, particularly when a "lumped" or empirically determined rate law has been measured independently. It does not mean that the chemical reaction taking place is only a single step reaction. In fact this empirical approximation works quite well in many cases that are not single step reactions.

3. Both the heat of reaction and activation energy are assumed to be sufficiently large to support ignition behavior: The reasons for these assumptions will become clearer later, but it is intuitively obvious that if there is zero heat of reaction, ignition cannot occur. Likewise with zero activation energy (acceleration of reaction rate with temperature increase), ignition cannot occur either.

With these assumptions we can write down two equations that determine the temperature and fuel concentration as functions of time (but uniform in space). These are simply the conservation of energy and the kinetic rate law respectively. They are

$$C_v \rho V \frac{dT}{dt} = VQf(c)e^{-E/RT} - S\chi(T - T_a) \tag{1}$$

$$\frac{dc}{dt} = -f(c)e^{-E/RT} \tag{2}$$

where

C_v = heat capacity at constant volume
ρ = density
V = volume
T = temperature of the reacting material (in K)
T_a = ambient temperature of the surroundings (assumed constant in time)
Q = heat of reaction per unit concentration of fuel
$f(c)$ = kinetic rate law
c = concentration of fuel
E = activation energy of the reaction
R = universal gas constant
S = surface area of the interface across which heat is lost to the surroundings
χ = heat transfer coefficient

The independent variable is time.

The first term on the right side of Equation 1 represents the rate of heat generation by the self-heating reaction. The second term represents the heat lost to the surroundings. The left side represents the difference between these two. Equation 2 simply expresses the fact that as the reaction proceeds, the concentration c decreases as the fuel is used up. The commonest and simplest form for $f(c)$ is Zc where Z is known as the preexponential factor, a constant. This case is known as a first-order reaction. These two terms are shown graphically in Figure 2-10.1 for any particular value of c.

Despite their apparent simplicity these two equations are not soluble by classical methods, so we cannot write down their solution. Nevertheless, we can in fact write down the critical condition exactly (and other important quantities) using bifurcation theory. We will illustrate this for the simplest possible case only, remembering that it can also be done for more realistic and complicated cases as well as within the confines of the Semenov theory.

First we write Equations 1 and 2 in dimensionless form (see nomenclature for details):

$$\frac{du}{d\tau} = \nu e^{-1/u} - \ell(u - u_a) \tag{3}$$

$$\frac{d\nu}{d\tau} = \varepsilon\nu e^{-1/u} \tag{4}$$

where u and ν are dimensionless temperature and fuel concentration, respectively, and ε is a dimensionless version of the ratio C_v/Q; that is, it is a measure of the amount of fuel decomposition required to produce a temperature rise of 1°C. τ is a dimensionless time and ℓ is a dimensionless heat transfer coefficient.

The most frequently used version of this theory, without fuel consumption, corresponds to taking the limit $\varepsilon \to 0$, thus maintaining ν at its initial value ν_0. We have only a single equation to deal with now, that is,

$$\frac{du}{d\tau} = \nu_0 e^{-1/u} - \ell(u - u_a) \tag{5}$$

Even this much-simplified equation is not analytically soluble. However, it relates exactly to Figure 2-10.1 and can be used to calculate the critical condition readily. We first note that the balance points in Figure 2-10.1 must satisfy the equation

$$\nu_0 e^{-1/u_s} - \ell(u_s - u_a) = 0 \tag{6}$$

For subcritical values of the ambient temperature, this equation will have three solutions for a given set of parameter values, ν_0, u_a, and ℓ. From Figure 2-10.1 it can be seen that at the critical condition ($T_{a,\text{critical}}$ corresponding to $u_{a,\text{cr}}$) not only do the two terms of Equation 6 balance, but their *slopes* also balance at this condition. Mathematically this means that their differential coefficients with respect to temperature must also be equal, that is,

$$\left[\frac{\partial(\nu_0 e^{-1/u})}{\partial u}\right]_{u=u_s} = \frac{\nu_0 e^{-1/u_s}}{u_s^2} = \ell \tag{7}$$

The critical value of u_s is then obtained by solving Equations 6 and 7 simultaneously, which interestingly can be done in closed form simply by eliminating the exponential, leaving a quadratic equation:

$$u_{s,\mathrm{cr}}^2 - u_{s,\mathrm{cr}} + u_{a,\mathrm{cr}} = 0 \tag{8}$$

From our definition of $u = RT/E$ and the general knowledge that $R/E \cong 0.0001$ for most combustion reactions, we can see that at normal ambient temperatures for ignition we will have $u_{a,\mathrm{cr}} \cong 0.02$, or in any case $u_{a,\mathrm{cr}} \ll 1$. Using the standard formula for the solution of a quadratic equation and expanding the radical occurring, we can derive

$$u_{s,\mathrm{cr}} = u_{a,\mathrm{cr}} + u_{a,\mathrm{cr}}^2 + \cdots \tag{9}$$

which is the lower of the two roots (the upper one is unphysical).

If we substitute this back into either Equation 6 or 7, we get a relationship between the parameters of the problem *which holds at criticality only.* Thus if we use Equation 6, we obtain, after some rearrangement,

$$\ell_{\mathrm{cr}} = \frac{\nu_0 e^{-1/u_{a,\mathrm{cr}}(1+u_{a,\mathrm{cr}})}}{u_{a,\mathrm{cr}}^2(1+u_{a,\mathrm{cr}})^2} \tag{10}$$

We can interpret this equation in a number of ways. Since ℓ_{cr} involves the size of the body as the only physically variable parameter, and ν_0 is proportional to the bulk density of the material, we can take this equation to give us the critical size body for a given ambient temperature and bulk density. $u_{a,\mathrm{cr}}$ is the only parameter here that cannot easily be made the argument of the equation.

Converting Equation 9 into dimensional form quickly gives us the relationship:

$$T_{s,\mathrm{cr}} - T_{a,\mathrm{cr}} \equiv \Delta T_{\mathrm{cr}} \cong \frac{RT_{a,\mathrm{critical}}^2}{E} \tag{11}$$

at the critical condition. ΔT_{cr} would typically be 20–30°C for ambient temperatures around 30–40°C. Not surprisingly, it is independent of the body shape, being dependent only on the total surface area through which heat is lost. Nevertheless, even this oversimplified result can be very useful in an emergency situation. If E is not known, it is a useful rule of thumb (especially for agricultural cellulosic materials) that self-heating of more than 30°C above ambient, that is, typically a body temperature of more than 60–70°C, represents imminent spontaneous ignition whereas an internal body temperature of 35–40°C represents subcritical heating that is unlikely to run away but quite likely to lead to degradation of the material.

Two further points need to be made before leaving this simplified model. First, in order that Equation 8 has real roots, it is necessary to require that

$$E \geq 4RT_{a,\mathrm{critical}} \tag{12}$$

Physically this means that the chemical heat generation rate is sufficiently accelerative to produce the phenomenon of criticality. If it is not satisfied, there is only a single stable balance point for all conditions and no abrupt change in behavior can occur.

Second, if we examine Equation 10, the critical condition, we should note that where the concentration ν_0 appears, in the case of gases we would normally convert this to pressure. Thus in this case Equation 10 gives a relationship between ambient temperature and pressure at the critical condition. This relationship is the familiar explosion limit curve extensively used in the study of gaseous explosions.

Inclusion of Fuel Consumption

If we do not make the assumption $\varepsilon \to 0$ in Equation 4, the clear distinction between subcritical and supercritical behavior no longer exists. We can no longer define the critical condition as the disappearance of two balance points. Equations 3 and 4 possess only a single balance point, $u = u_a$, and $c = 0$ for all possible parameter values, and this refers to the equilibrium state when all fuel has been exhausted and nothing is happening—clearly a condition of no interest. For the definition of criticality in such a case, it is helpful to examine the *experimental* or *phenomenological* definition. The experimentalist determines the critical condition by performing various tests at differing ambient temperatures (we will outline the details of test procedure in a later section) and by measuring the temperature/time history at the center of the sample. They will plot the maximum temperature attained against ambient temperature and will find there is a steep increase in slope over a narrow region of ambient temperature. The result is illustrated in Figure 2-10.5.

The distinction between points 1 and 2 is very clear both in terms of the maximum temperature attained and the physical condition of the material itself after the test is finished. Typically, at point 2 the material is hardly different visually from the initial condition, whereas at point 1 there is usually no more than a small amount of ash remaining. The temperature attained at point 1 is often of

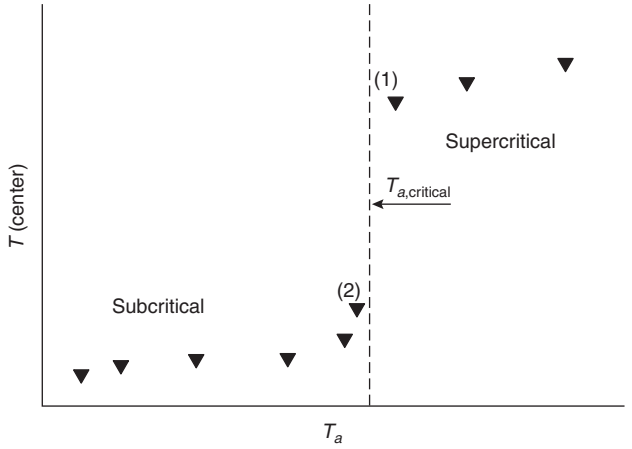

Figure 2-10.5. ***Typical experimental results for criticality tests.***

the order of hundreds of degrees above ambient compared with probably 30 degrees above ambient at point 2.

It is impossible to get points between 1 and 2 experimentally without wasting a great deal of time due to the extreme sensitivity in this region, so the convention is to define the CAT as the arithmetic mean of $T_{a,\ell}$ and $T_{a,2}$. With good equipment these will only be 3 or 4 degrees apart at the most.

From the point of view of theoretical calculation of the CAT in this case, we note that the points in Figure 2-10.5 can be joined by a smooth curve with a very steep region around an inflection point. It has been shown[9] that this definition of the CAT, when fuel consumption is significant, leads to a relation between the usual parameters, and this relation passes over smoothly to the one derived from the tangency condition as $\varepsilon \to 0$. For $\varepsilon \cong 0.05$ or less, which is the case for most practically important materials, the corrections arising from fuel consumption are not usually significant. This result is especially the case in fire investigations where a posteriori numerical knowledge of parameter values is rather limited, and this correction (and others) is not justified.

Extensive discussion of earlier work on the fuel consumption correction is given in Bowes's book.[4] Many empirical and semiempirical corrections were devised based on approximated integration of Equations 3 and 4. These corrections will not be discussed here since the advent of powerful PC and laptop computational capabilities has rendered them irrelevant. Equations 3 and 4 can be integrated with great speed and precision if accurate parameter values are available. Even so, it is necessary to have a definition of criticality when a computed or experimental version of Figure 2-10.5 has been obtained. With the definition given in Reference 9, allied with numerical integration, the problem can be regarded as solved for all practical purposes.

Extension to Complex Chemistry and CSTRs

Complex Chemistry

Other than elementary gas phase reactions, very few examples of chemical change occur via a single step as assumed above. As already remarked, the simple theory is more useful than might be expected because many complex chemical reactions behave as if they were a single step, over limited temperature ranges. This is usually because a single step does dominate the heat production rate, for example, when two reactions occur in parallel. If the activation energies are rather different, they will each in turn dominate the heat generation in two different temperature ranges and in each of these ranges the simple theory will hold. Of course, it will not hold in the changeover region.

Another case where the simple theory can hold unexpectedly is when a number of reactions are in series and one is particularly slow. The slow reaction will determine the overall heat generation rate and its parameters will dominate the critical condition. If none of the above conditions hold, it is still possible to derive a generalization of the theory that is conceptually very closely related. It is possible to prove[10] that if the heat release rate is defined as the sum of the heat release rates of all reactions taking place in the system, then the critical condition can be defined as the tangency of this quantity with the heat loss line. Thus a diagram like Figure 2-10.1 can be drawn and the same constructions used, provided the total heat release curve for all the reactions is used.

The heat release curve in this case can have a complex shape, and thus *more than one* critical condition can occur. This state of affairs is extremely important in the ignition of most organic vapors, particularly hydrocarbons[5] where some critical conditions occur on *decreasing* the ambient temperature. Also in the ignition of some commonly occurring solids, particularly when wet, more than one heat-generating reaction can be important, for example, in the spontaneous ignition of moist bagasse.[11] In this case there are two critical conditions, one where a jump from virtually no self-heating to self-heating of ~35°C occurs, and a second critical condition where this intermediate state jumps to full-fledged ignition. Modeling of such situations is possible but beyond the scope of this chapter; however, similar behavior is likely to occur in other moist cellulosic materials, including hay, chipboard, and so forth.

At this stage it is worth pointing out that for bagasse at least, microbial "heat production" is not a factor in these phenomena. Although natural bagasse contains large numbers of microorganisms, sterilization by various methods *does not affect heat production or self-heating* at all, as measured by Dixon[12] and predicted on the basis of bacterial microcalorimetric data by Gray.[13] Similar work on hay is under way.

CSTRs and Thermal Runaway

Strangely, this topic has become uncoupled from work on spontaneous ignition over recent years even though the basic principles and mathematical methods used are similar. It is a huge problem in the chemical process industry and receives much attention. For example, in 1998 the Joint Research Centre of the European Commission, Institute for Systems Informatics and Safety, produced a book describing the proceedings of a European Union seminar held in Frankfurt in 1994 that managed to avoid almost completely any reference to the fundamentals of the problem or related material. *Risk analysis* appears to have replaced fundamental scientific understanding in some aspects of this problem.

We will confine ourselves here to writing down the basic equations governing a single exothermic chemical reaction taking place in a CSTR (continuously stirred tank reactor) to exhibit their similarity to the equation describing a spontaneously ignitable material, that is, Equations 3 and 4.

The appropriate equations for this case are in fact 3 and 4 with terms representing inflow and outflow of reactants and products, that is,

$$V\rho C_v \frac{dT}{dt} = QVf(c)e^{-E/RT} - S\chi(T - T_a) - FC_v\rho(T - T_f) \tag{13}$$

$$V\frac{dc}{dt} = -Vf(c)e^{-E/RT} + F(c_f - c) \tag{14}$$

F is a volumetric flow rate and the subscript f refers to feed values. These equations can be cast in dimensionless form also. Here we simply note that they possess steady-state (balance point) solutions without making any approximations at all (such as neglect of fuel consumption) and Figure 2-10.1 can be applied directly in slightly modified form. The critical condition referred to earlier occurs here also, but it can now be stated in terms of the CAT or a critical feed temperature or, indeed, a critical flow rate.

A critical size also occurs and is particularly prominent in CSTR considerations where "scaleup" from prototype size to commercially viable size has resulted in exceeding the critical condition. Some references to scaleup are given in Reference 1, and there are many more in the chemical engineering literature and the study of self-heating in catalyst particles. See Aris[14] for an excellent discussion of this area.

The Frank-Kamenetskii Theory of Criticality

In its original form the Frank-Kamenetskii theory included a more realistic model of heat transfer within the reacting solid, that is, by incorporating the heat conduction law of Fourier. This law allows a calculation of the variation of temperature within the self-heating body itself and allows comparison of measured and calculated self-heating to take place. However, it sacrifices the simple description of time-dependent behavior given by the Semenov model because such considerations involve the solution of partial differential equations. This is now much faster than even a few years ago, in terms of numerical computation, and improving day by day. Nevertheless, such numerical solutions do not lend themselves to simple interpretation even with the use of rapidly developing file visualization techniques. Construction of appropriate meshes for finite element computation, necessary for practically occurring three-dimensional shapes, is also far from trivial.

As a result, the Frank-Kamenetskii theory is still mainly used for interpretation of testing experiments on self-heating and subsequent evaluation of parameters for individual systems. This is a viable proposition for materials with sufficiently large heats of reaction and activation energies. In such cases we shall see that the stationary (in time) conditions assumed in the Frank-Kamenetskii theory are indeed well approximated for the duration of typical tests in practical cases. In its original form this theory also neglects fuel consumption, as does the Semenov theory, with similar consequences. With these assumptions the equation describing the theory is

$$\kappa\nabla^2 T + Qf(c_0)e^{-E/RT} = 0 \tag{15}$$

with the boundary condition $T = T_a$ on the wall(s) of the body. T_a is the ambient temperature of the surroundings. This boundary condition assumes instantaneous transfer of heat from the surface of the body to the surrounding medium (usually air). When this is not approximately correct, very important consequences follow, as we shall see in a later section on the interaction of self-heating bodies with each other. In this formulation the shape of the body and its size both enter the mathematical formulation through the boundary condition only.

As usual, Equation 15 is not analytically soluble. However, by using an approximation to the Arrhenius function (Frank-Kamenetskii[3]), the modified equation can be solved analytically for a one-dimensional infinite slab of material. This same approximation was later shown to be analytically soluble for an infinite cylinder by Chambre.[15]

With this approximation, Equation 15 takes the form:

$$\nabla^2\theta + \delta e^{\theta} = 0 \tag{16}$$

with $\theta = 0$ on the boundary. θ is a dimensionless temperature defined by

$$\theta = \frac{E(T - T_a)}{RT_a^2} \tag{17}$$

that is, it is a measure of the temperature excess within the body at various points. The dimensionless parameter δ is defined by Equation 18:

$$\delta = \frac{QEr^2 f(c_0)e^{-E/RT_a}}{\kappa RT_a^2} \tag{18}$$

where the symbols are already defined apart from r, which is usually one-half of the smallest dimension of the body, that is, the radius of a cylinder, the radius of a sphere, or the half-width of a slab. Mathematical treatment of Equation 16, whether it is exactly soluble or not, indicates that a solution satisfying the boundary conditions exists only when $\delta \leq \delta_{\text{critical}}$ where δ_{critical} is some number depending on the shape of the body only. For an infinite slab of material $\delta_{\text{critical}} = 0.878$ and for an infinite cylinder it has the value 2.000. For other shape bodies the critical value has to be obtained either numerically or by semiempirical methods outlined in some detail by Bowes.[4] For convenience, a few of the values are listed in Table 2-10.1.

The tabulation of figures for infinite slab or infinite square rod is useful in so far as they are often rather good approximations for real bodies, provided one or more of their dimensions are much larger than the others. Thus for the rectangular box, if we take $r = l = 1$, $m = 10$, we get

Table 2-10.1 ***Values of $\delta_{critical}$ for Various Geometries***

Geometry	Dimensions	δ_{critical}
Infinite plane slab	Width $2r$	0.878
Rectangular box	Sides $2l$, $2r$, $2m$; $r < l, m$	0.873 $(1 + r^2/l^2 + r^2/m^2)$
Cube	Side $2r$	2.52
Infinite cylinder	Radius r	2.00
Equicylinder	Height $2r$, radius r	2.76
Sphere	Radius r	3.32
Infinite square rod	Side $2r$	1.700

$\delta_{critical} = 1.75$ compared to 1.700 for the infinite square rod. If we now look at Equation 18 for the particular case of a cube as an example, we get

$$\frac{QEf(c_0)r^2e^{(-E/RT_{a,\text{critical}})}}{\kappa RT^2_{a,\text{critical}}} = 2.52 \qquad (19)$$

at the critical condition. We have a number of choices as to interpretation of this equation depending on which parameter can be made the argument. If r is chosen as the argument, then the equation would be interpreted as giving a critical size for the body at a fixed ambient temperature T_a. Since c_0 depends on the density of the material, Equation 19 could be rearranged to give a critical density for that particular size body at ambient temperature T_a. What is not possible is isolation of T_a as the argument of the equation, and this is often the most easily varied parameter in a typical test oven.

This complex dependence of the critical condition on T_a is dealt with by rearranging Equation 18 and taking natural logarithms as follows:

$$\ln\left[\frac{\delta_{\text{critical}}T^2_{a,\text{critical}}}{r^2}\right] = \ln\left[\frac{QEf(c_0)}{R\kappa}\right] - \frac{E}{RT_{a,\text{critical}}} \qquad (20)$$

from which it can be seen that a plot of $\ln(T^2_{a,\text{critical}}/r^2)$ against $1/T_{a,\text{critical}}$ will be a straight line with slope $-E/R$ and intercept $\ln[QEf(c_0)/\kappa R\delta_{\text{critical}}]$. The traditional and recommended test protocol for spontaneous ignitions makes explicit use of this logarithmic form of the critical condition. Not only does it yield the activation energy from the slope, but the occurrence of a straight line plot assures us that the assumption of an Arrhenius temperature dependence for the heat-generating reaction is correct over the temperature range investigated.

Equation 20 can also be regarded as a scaling law, in principle enabling the prediction of CATs for large-scale bodies from measured CATs for much smaller laboratory-sized samples. However, as we shall see, it is necessary to ensure that the same chemical kinetics applies over the whole temperature range involved. Finally if it becomes necessary to estimate the CAT for a complex shape, not included in Table 2-10.1, an excellent and comprehensive discussion of approximation methods is given by Boddington, Gray, and Harvey.[16]

Experimental Testing Methods

Experimental testing methods are traditionally based on the scaling relationship (Equation 20). Appropriate containers (usually stainless steel gauze baskets) of various dimensions are used, being limited only by the size and heating capability of an accurately thermostatted oven, which must also have a spatially homogeneous ambient-temperature distribution (±1°C is recommended). The gauze containers may be any convenient shape, equicylindrical or cubic being preferred due to ease of construction. The gauze does not restrict oxygen ingress through the boundary, nor does it restrict egress of carbon dioxide and other product gases during combustion. If the air inside the oven is sufficiently turbulent, usually the boundary conditions of the Frank-Kamenetskii theory will hold quite well.

The boundary condition is easier to satisfy when the thermal conductivity of the material inside the gauze baskets is relatively low, as it is with many agricultural materials containing cellulose ($\kappa \sim 0.05$ W/mK). The efficacy of the boundary condition is determined by the heat transfer rate from the gauze to the oven air relative to the conduction rate within the material itself. This ratio ($\chi r/\kappa$) is known as the Biot number, and the larger it gets, the more accurate the Frank-Kamenetskii boundary condition ($T = T_a$) becomes. In practice a Biot number greater than 30 is effectively infinite as the CAT becomes extremely insensitive to it. We will return to this topic in a later section where the dependence of the critical condition on the Biot number is outlined.

The test procedure involves starting with the smallest basket and a trial oven temperature. The sample is equipped with one or more fine thermocouples placed at the center of the sample and, if desired, at various places along a radius if a spatial profile is wanted (this is generally not necessary). The sample is placed in the preheated oven and the center temperature followed as a function of time. If the oven temperature is well below the CAT, the sample will simply approach the oven temperature asymptotically. If it is slightly below, but getting close, it will cross above the oven (ambient) temperature and attain a maximum of the order of 1–30°C above ambient before declining. This oven temperature represents the subcritical condition.

The sample is discarded and replaced with a fresh, similar one. If the previous run was subcritical, the oven temperature will be increased usually by 20°C or less depending on the experience of the operator. The run is then repeated. If it is still subcritical, the procedure is again repeated until a supercritical oven temperature is attained. The arithmetic mean of the lowest supercritical temperature and the highest subcritical temperature is taken as the first estimate of the CAT. The uncertainty may be quite large at this stage, so the process is usually continued by testing at the estimated CAT. The process is repeated, halving the difference between highest subcritical and lowest supercritical temperatures each time until the desired errors are obtained. Typical temperature/time plots showing the critical separation are shown in Figure 2-10.6.

This reaction is an exothermic decomposition evolving oxygen. From these measurements one would conclude that the CAT was 55.2 ± 1.34°C. For greater accuracy the next test would be run at an ambient temperature of 55.2°C. After at least four or five such sets of runs have been carried out in differently sized containers, giving four or five CATs at various radii, then the next step is to construct the Frank-Kamenetskii plot of the scaling Equation 20. A typical plot is shown in Figure 2-10.7.

This plot shows a range of CATs for cylinders ranging in radius from 0.191 m down to 0.026 m, the larger radii corresponding to commercial containers. From the slope of this line, E/R can be read off directly and from the intercept; so can the dimensionless group occurring in the scaling equation. Sometimes components of this group may be known from independent measurements, for example, Q from calorimetry, κ from direct measurement, or $f(c_0)$ from kinetic measurements, in which case all the parameters can be obtained.

Special Cases Requiring Correction

The Presence of Water

When water is present in spontaneously combustible material, special considerations apply. First it is necessary to note that endothermic evaporation would be expected to partly offset some of the heat generation by the exothermic reactions taking place. While this expectation is true, it is often the case that at the high oven temperatures used in testing small samples, the low activation energy for evaporation (~40 kJ/mol) leads to rapid evaporation before the exothermic process has got fully under way. Many spontaneous combustion reactions have activation energies around 100 kJ/mol, particularly the group of reactions of cellulosic materials.

As a result, the high temperature CATs reflect the properties of the dry material, in particular the thermal conductivity. Consequently, extrapolations to temperatures well below 100°C will be questionable for this reason alone. In the lower temperature range the heat transfer will be significantly affected by the presence of water and its transport from the hotter to the cooler regions of the body by evaporation, diffusion, and condensation.

Many cellulosic materials are known to exhibit a "wet reaction"[19,20] in addition to the dry exothermic reaction. This reaction involves liquid water as a reactant and further complicates the picture as far as high-temperature testing is concerned. Simultaneous evaporation, diffusion, condensation, and reaction involving water have been modeled recently in connection with bagasse,[21,22] using an experimentally measured rate law for the wet reaction[23] giving results that are in good agreement with measured results for commercial-size piles of this material (minimum dimension 5–10 m).

The detailed nature of the wet reaction with a rate maximum around the 50–60°C mark has led to false identification with microbial activity. In bagasse at least it has been shown[24,25] that microbial activity does not contribute to self-heating to any significant degree. Piles sterilized by various methods showed self-heating rates indistinguishable from those of nonsterile piles. Microbial counts were carried out in all cases and large decreases did not affect the self-heating rates. It would be rather surprising if similar results were not obtained from tests on hay and straw where microbiological activity (but not necessarily heating) are known to occur, and it is surprising that such tests have not yet been carried out.

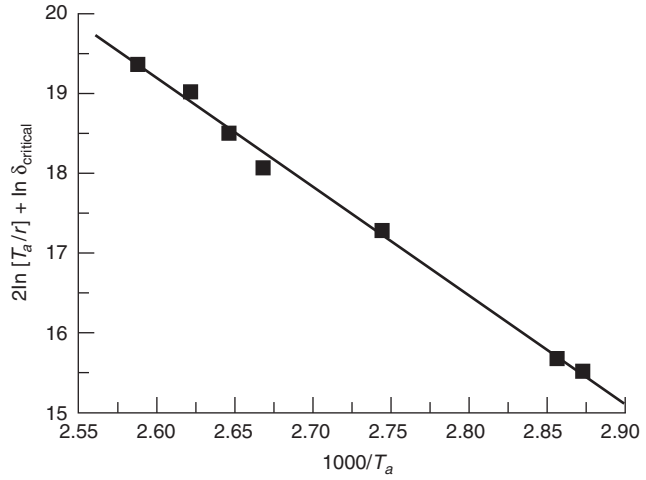

Figure 2-10.7. ***Typical Frank-Kamenetskii plot for anhydrous calcium hypochlorite from Uehara et al.[18]***

Parallel Reactions

If more than one exothermic reaction can take place in the material, and these reactions have rather different activation energies, then each will dominate in its own temperature range. Thus the higher activation energy reaction will cut in at higher temperatures and be insignificant at lower temperatures when the low activation energy reaction will dominate the heat generation. The wider the divergence in activation energies, the sharper the discontinuity in slope, that is, the narrower the temperature range over which both will contribute. Hydrated calcium hypochlorite shows a clear example of this, and it is reflected in a sharp break in the slope of the Frank-Kamenetskii plot where the changeover occurs. Figure 2-10.8 shows this plot. The low temperature activation energy for this system is about 48 kJ/mol while that of the higher temperature reaction is around 125 kJ/mol, the transition temperature being around 120°C.[17] Extrapolation of the high temperature line in this case gives CATs for large commercial-size containers that are seriously in error; that is, they are predicted to be much higher than they actually are. In the general case of two reactions with different activation energies, this will always be the case as the high activation energy is "frozen out" at low temperatures and the low activation energy reaction is "swamped" at higher temperatures.

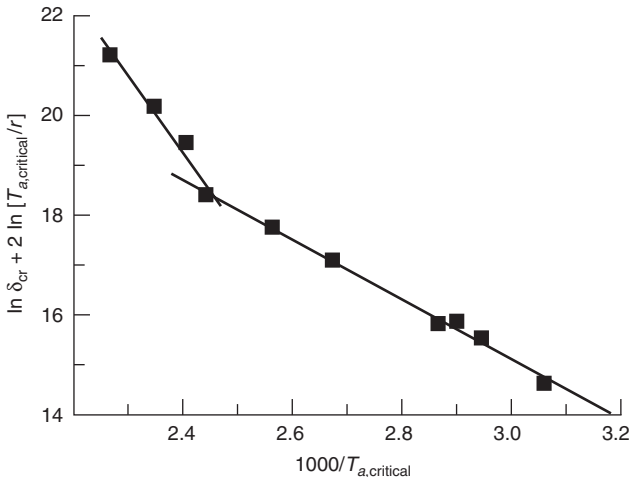

Figure 2-10.8. ***Frank-Kamenetskii plot for hydrated calcium hypochlorite with reaction mechanism change.***

Other examples of mechanism change are known and discussed by Bowes.[4] In such cases accurate predictions of CATs can still be made within each temperature range. This type of example emphasizes the need for tests covering as wide a range of temperatures as possible. Recent methods put forward as viable alternatives to the standard method, for example, Jones[26] and Chen,[27] are restricted to either measurement at a single temperature or over a limited temperature range and can give dangerously flawed results. Empirical tests such as the Mackey test[28] and the crossover test[29] are not reliable and cannot be properly related to the basic principles of spontaneous ignition theory.

Finite Biot Number

The Biot number is defined as

$$\mathrm{Bi} = \frac{\chi r}{\kappa} \tag{21}$$

where

χ = surface heat-transfer coefficient

r = smallest physical dimension of the body

κ = thermal conductivity of the material

It is the dimensionless measure of the ratio of the resistance to heat transfer within the body to that from the surface to the surroundings. Thus the Semenov theory is often referred to as *zero Biot number* and the Frank-Kamenetskii theory as *infinite Biot number.* They are both special cases of a more general (and more exact) formulation, as was originally pointed out by Thomas.[30,31]

In general the boundary condition at the edge of a self-heating body has the form of a *continuity condition,* which refers to the energy flux across the boundary. It states that the energy flux within the body (given by Fourier's law) and the energy flux from the body surface to the surrounding air must be equal, that is,

$$\kappa \frac{dT}{dn} = \chi(T - T_a) \tag{22}$$

In dimensionless form this becomes

$$\frac{du}{dn} = \mathrm{Bi}(u - u_a) \tag{23}$$

This boundary condition does not hold if there exist any heat sources on the boundary of the body itself, as can occur when there is incidence of radiation or when there is heat generated by friction during pulverization of materials capable of self-heating. Such cases (in the shape of an infinite cylinder) have been treated and the modified critical condition obtained.[32,33]

The values of the critical parameter δ quoted for the Frank-Kamenetskii theory are all for the limiting case $\mathrm{Bi} \to \infty$, and both Thomas and Barzykin have given semi-empirical functions exhibiting the dependence of $\delta_{\mathrm{critical}}$ on Bi, which are detailed in the book by Bowes. As the Biot number decreases, so does $\delta_{\mathrm{critical}}$ and hence so does the CAT, all compared with the standard Frank-Kamenetskii theory. For Biot numbers >30, the correction is rather small but is significant for smaller values. Typical heat transfer coefficients from smooth solid surfaces to rapidly stirred air (in a test oven for example) are of the order of 20 $\mathrm{W/m^2{\cdot}K}$, and thermal conductivities of typical cellulosic materials (such as sawdust) are around 0.05 W/m·K, giving a ratio of 400/m. Clearly for laboratory-size test bodies ($r \sim 0.1$ m), the Biot number is rather large.

For this reason a significant amount of work has simply *assumed* a sufficiently large Biot number without investigation of its actual numerical value. Sometimes the assumption is not justified, particularly where inorganic materials are involved, as their thermal conductivities can be quite large. For example, typical, inorganic salt thermal conductivities lie in the range of 0.2–3.0 W/m·K, giving for the ratio (χ/κ) a value of 7–100/m. Clearly for test bodies with $r \sim 0.1$ m, the Biot number will be only 0.7–10. The effect of the small Biot number on $\delta_{\mathrm{critical}}$ is to reduce it by a factor ranging from 0.21 to 0.83, respectively. Clearly for such materials, the more general boundary condition suggested by Thomas must be used, and it is good practice for all but the most strongly insulating materials to estimate the thermal conductivity (particularly in the presence of water) independently of the standard testing regime.

A further important feature of self-heating bodies with finite Biot number is that their CATs will be sensitive to the heat-transfer coefficient from their surface to the surrounding air. Thus the value of the CAT obtained may well be test-oven sensitive and be strongly influenced by air movement. For example, it has been shown for hydrated calcium hypochlorite[17] that in stirred air in a typical test oven the CAT is 60°C for a 0.175-m-radius container, but in still air the CAT is 55°C.

This observation raises serious questions about the value of empirical testing methods such as the SADT test for shipping self-heating materials[34] that determines

criticality-related parameters under vaguely defined conditions of forced airflow in a test oven. The results are then used to determine "safe" conditions for shipping such materials in *still air* inside, for example, a shipping container. Almost invariably many self-heating bodies are stacked inside the same still air inside a container, and they will interact with each other to a very significant extent if the transfer of heat through the container wall is not very rapid. In practice such transfer is rather slow, involving two successive air/metal transfers. As a result the self-heating bodies collectively heat the air inside the container and produce a "cooperative CAT," which can be tens of degrees lower than the CAT of a single body. The Semenov-type theory for this collective ignition has been formulated by Gray.[35] A more accurate version, where the individual bodies are assumed to obey the general boundary condition put forward by Thomas, has also been formulated (in preparation). The predictions of this theory have been compared to the experimental CAT for 18 14-kg equicylinders packed in a rectangular steel box with good agreement.[36] The CAT was reduced from 62.5°C for a single keg in still air to 54°C for 18 kegs in still air.

Times to Ignition (Induction Periods)

The terms *times to ignition* and *induction periods* tend to be used synonymously. Here we will abbreviate to *tti.* This represents the most difficult area of spontaneous combustion in so far as prediction is concerned. There are three principal reasons for this:

1. The theoretical treatment is much more difficult than that of criticality itself.
2. The actual definition has been greatly confused from case to case.
3. The *tti,* however defined, can be extremely sensitive to quantities that have hardly any effect on the position of the critical condition.

Theoretical Treatment

We refer the reader to Bowes[4] for discussion of earlier treatments. For illustrative purposes we will initially follow Bowes and define *tti* from Equation 5 by integration from ambient temperature to some value u_1, say,

$$\tau_i = \int_{u_a}^{u_1} [\nu_0 e^{-1/u} - \ell(u - u_a)]^{-1}\, du \qquad (24)$$

The equation is of course in dimensionless form. Our present interest is the implicit use of u_a as the lower limit; that is, it is the time for the sample to go from ambient temperature to some predetermined arbitrary figure, possibly the maximum temperature attained (it turns out that the integral is not sensitive to this limit, provided it is sufficiently high).

While the maximum temperature attained is a meaningful figure for laboratory tests under some circumstances, it does not always correspond to practical large-scale circumstances. For example, it requires recording the time taken for the center of the sample to heat up in a test oven to ambient temperature and using this as the reference time for *tti.* Unfortunately, when the center has reached this point, other parts of the body have often attained rather higher temperatures,[37] and the subsequent *tti* will be reduced compared to a large-scale body that may well have been built at ambient temperature and be quite uniform initially. Extrapolations of such laboratory tests will not then be reliable since the initial condition will not be appropriate.

The *tti* for the hot stacking problem is qualitatively different from that in which the body is formed uniformly at ambient temperature. Generally this time is *much shorter* than the *tti* for the more common case of initially ambient temperature throughout the body. The reasons have been given, with a comparison of the two cases, by Gray and Merkin.[38] Similar considerations apply when part of the body is at a high temperature (hot spot) and this case has been discussed in detail by Thomas.[39]

With the ready availability of powerful and fast numerical techniques, it is now feasible to integrate routinely the time-dependent heat conduction equation for this problem, which is probably the best solution. Zinn and Mader[40] were early participants in this effort, and more recently Gray, Little, and Wake[37] have noted that such numerical results can be usefully used to predict a very good lower bound to the *tti.* These results are desirable as they err on the side of safety.

Very close to criticality, perturbation treatments have been formulated,[41–45] but these are mainly of theoretical interest. At the critical condition the *tti* becomes infinite, and close to this condition it is extremely sensitive to the degree of criticality, so unless this is known accurately (hardly ever the case), use of such formulae is not advised.

In addition to the difficulties discussed above, which apply even when only a single simple reaction is assumed, there are others that are largely chemically kinetic. It has long been known that chain reactions, whether branching or not, can exhibit very long induction periods followed by very rapid onset of (sometimes non-explosive) reaction. Many exothermic, spontaneous ignition reactions do possess some chain characteristics even though these do not manifest themselves once the reaction is well underway. Thus it is feasible for complex chain mechanisms to determine the details of the *tti* but not be at all important in determining the critical condition where gross heat balance considerations are crucial. In many cases this leads to extremely irreproducible *tti*s without similar variation of CATs or other properties. In case this list of difficulties leads to an overly pessimistic view of the topic of *tti,* there are some things which can generally be relied on as far as the practical situation of fire investigation is concerned.

Very crudely speaking, notwithstanding the above discussion, the larger the body, the longer the *tti* will usually be. Thus a fire thought to have been caused by spontaneous ignition of a pile of linseed oil–contaminated rags contained in a wastepaper basket will usually appear within a few hours of the rags being placed there. On the other hand, a fire resulting from spontaneous ignition of thousands of metric tons of woodchips would only occur after some months of assembly, assuming the pile was

assembled at ambient temperature. For such bodies it is generally true that the *tti* increases with size in this manner. Accordingly haystacks tend to ignite (if they are supercritical) after a few weeks and coal stockpiles after a few months. However the *tti* can decrease dramatically if the body is very far beyond the CAT.

For hot stacked bodies on the other hand, times are generally much shorter and not particularly sensitive to the ambient temperature. Thus stacks of freshly manufactured chipboard with a volume of a few cubic meters can ignite much more quickly, that is, hours rather than days, than a similarly sized body self-heating from ambient. Beyond these general comments one has to treat each separate case on its merits with a careful eye for exceptions to any general rules. For example, the presence of any catalytic material, such as rusty metal (a common contaminant of many materials), can dramatically decrease the *tti.* This indicates the presence of free-radical or chain reactions and is fairly common, although the CATs and CSTs are only slightly affected.

In summary, in fire cause investigation, where spontaneous ignition is suspected, it is wise to be circumspect about time factors without a thorough investigation and detailed knowledge of the initial conditions likely to have existed when the body was put in place. Even the traditional linseed-oil rag example can be thrown out of the normal pattern by the presence of mineral turpentine, a very common diluent for oil-based stains. The evaporation of this from the rags can greatly prolong the *tti* by virtue of the consequent cooling effect and also the exclusion of air by the vapor. Depending on the circumstances, these factors could add two or three days to a *tti* that would normally be no more than a few hours.

Investigation of Cause of Possible Spontaneous Ignition Fires

From the investigative point of view it is well to list the practical factors which enhance the possibility of spontaneous ignition as a possible fire cause.

The size of the body of material: The larger the size of the body of material, the greater the likelihood of spontaneous ignition. By *size of the body* we mean the parts that are in thermal contact. A large pile of cotton bales with aisles through it would not necessarily be a large body in the thermal sense used here. This classification would be true even if (as often happens), once ignited, fire could spread easily from one section to the next.

High ambient temperatures: Since the air around the body in question has to act as a heat sink, the higher the ambient temperature, the more inefficient is the air as a coolant. Also, direct placement underneath a metal roof or adjacent to a northwest- (southern hemisphere) or southeast- (northern hemisphere) facing wall is a positive factor.

Thermal insulation: Sometimes spontaneously ignitable materials are stored in chemical warehouses or elsewhere packed against inert solids that prevent free airflow over the surface, thus reducing heat losses. This effect is evidenced by the appearance of maximum charring or self-heating that is off center and closer to the insulated side of the body. It also results in a reduced CAT.

Fibrous nature and porosity of material: Fibrous or porous materials allow greater access of air than otherwise (solid wood is not subject to spontaneous ignition at normal ambient temperatures, but woodchips and sawdust certainly are!). The concept that packing such porous materials by compression will increase the CAT by oxygen exclusion is badly flawed. This procedure increases the density (thus *lowering* the CAT) and has virtually no effect on the availability of oxygen. During the preflame development, the oxygen requirement is very low; by the time overt flame is observed, there are usually broad channels of destroyed material (chimneys) that will allow ready access.

Pure cotton in a test oven with a nitrogen atmosphere has been shown to undergo spontaneous ignition but with a longer induction period than in the presence of air.[46] This could be due to adsorbed oxygen on the cellulose fibers or due to exothermic decomposition of the cellulose in the absence of air.[47]

Otherwise "harmless" materials (i.e., liquids with very high flashpoints) can undergo spontaneous ignition at temperatures more than a hundred degrees below either their flashpoints or their so-called autoignition temperatures. The familiar drying oils (flashpoints around 230°C) spread on cotton afford such an example, igniting sometimes at room temperature under the appropriate conditions. In bulk such oils pose little threat of fire causation.

Similarly, hydraulic fluids, specifically designed for nonflammability and with extremely high flashpoints, can undergo spontaneous ignition if allowed to leak onto thermal lagging, such as mineral wool, fiberglass, and so forth, which are characterized by having particularly high surface area. Practical cases of this and experimental tests have been reported by Britton,[48] with particular reference to ethylene oxide fires. More recently a modeling project has been carried out[49,50] based on adaptation of the Semenov theory of ignition to a porous solid that was wetted with combustible liquid.

Temperature of stacking: The factor of temperature of stacking is simple—the hotter the worse! The main question is, How hot? The CST (critical stacking temperature) is only weakly dependent on the ambient temperature at low ambient temperatures, but it is sensitive to the size of the hot body. This situation arises with freshly manufactured products such as foodstuffs (milk powder, flour, instant noodles, fried batter, etc.), synthetic materials such as chipboard, cotton bales straight from the ginning process, bagasse straight from the sugar mill, fresh laundry (usually in commercial quantities), and so on.

To evaluate the CST requires full testing to obtain the parameters for the material (such as E, Q, κ, etc.) and then application of one of the methods in the literature for its calculation. Thomas[39] has given a method for hot spots of material, and Gray and Scott[51] have given a generaliza-

tion of this, removing the approximation to the Arrhenius function made by Thomas. A simpler method of calculation of the CST has been given by Gray and Wake.[52] It uses a spatially averaged temperature in the Arrhenius function and then obtains exact results for this simplified problem.

Length of time undisturbed: Material that has been in place for longer than usual is reason to suspect spontaneous ignition as a fire cause. Many industrial procedures involve the temporary storage of materials that are *normally* above their CAT but that are not left undisturbed for a period longer than or equal to their *tti.* Thus under normal circumstances fire does not occur even though the *tti* is regularly exceeded. If processes are slowed down for some reason, or storage is prolonged due to vacation, fire can occur even though no other parameters have been changed.

The Aftermath

There are very often characteristic signs of spontaneous ignition even after it has been the cause of a very large fire. Internal charring and ash is very characteristic in cellulose materials. Combustion starts in the well-insulated internal areas of the body, and warm or hot combustion products rise by convection through the path of least resistance (which is not always vertically upward) forming a "chimney" of discolored and partially combusted material. Since large bodies of material are rarely uniform in density or porosity, there can be more than one chimney formed and this is the norm. The occurrence of multiple chimneys and consequent discovery of more than one heavily charred or ashed area inside the body has led to erroneous charges of arson on the basis of the myth that more than one fire seat means the fire was deliberately lit. When a chimney reaches the edge of the body, smoke first becomes visible, then ingress of air causes flame. The latter may engulf more flammable materials in the building, and the whole structure can be destroyed while the spontaneously combusting material may well be chugging away slowly throughout most of its volume. This can even be the case after the fire has been extinguished. The result is then plenty of evidence as to the cause and origin of the fire. The author has measured temperatures as high as 200°C in buried, spontaneously ignited material more than two weeks after the extinction of the fire!

The internal burning of large piles or stacks of material can cause mechanical instability, and often the body collapses inward in the later stages of ignition. This inward collapse can cause some confusion in excavations, which should always be carried out if spontaneous ignition is suspected along with photographic and thermocouple temperature probe records at all stages.

It should be emphasized that the occurrence of significant amounts of unconsumed, spontaneously ignitable material does not mean that spontaneous ignition was not the cause of the fire. Frequently, oily rags are recovered almost intact from the bottom of waste bins that have been the seat of very large fires. The lower rags tend to be protected from incineration by a layer of char and also by lack of oxygen in the lower reaches of the bin.

Case Histories and Examples

Cottonseed Meal—Living Dangerously

A transit warehouse temporarily storing cottonseed meal to a depth of about 3 m burned down and was completely destroyed. The length and breadth of the building were much larger than the depth of the meal so the relevant physical dimension (for substitution into the formula for $\delta_{critical}$) was 3 m. Spontaneous ignition was suspected because of the known presence of unsaturated fatty acids prone to this. Standard CAT tests for small laboratory samples were carried out, and the extrapolation to lifesize was expected to be reasonably accurate since only small amounts of water were present and wet reaction was not suspected.

The body of meal in the warehouse turned out to be supercritical for the average ambient temperature in the area. The unusual factor in this particular case was the fact that the meal had been left undisturbed for much longer than usual due to a transport strike. It remained in place for longer than the *tti* although under normal circumstances it would have been moved on to customers well before significant self-heating could take place.

In this case an enlightened management installed underfloor ducting to produce a high-pressure air blast capable of rearranging the meal substantially from time to time. A similar solution has long been practiced for coal stockpiles, although in that case the disturbance is usually caused by a front-end loader.

Flaming Instant Noodles

Some years ago an instant noodle factory burned down soon after new management had taken over. New management was not satisfied with the throughput of the production line and wanted higher productivity. The latter was dependent on the speed of a single conveyer belt that conveyed the raw noodles through a hot oil bath, then under a number of powerful fans to remove excess oil and cool the cooked noodles for packing and palleting. Increasing the speed of the conveyer certainly increased the throughput in proportion, but the smaller length of time the noodles spent in the hot oil resulted in incomplete cooking. Thus the oil-bath temperature was increased substantially to compensate for this and again produce fully cooked noodles. However, the faster moving belt was now conveying cooked noodles to the packing area in a shorter time than before *and* they were also coming out of the fryer hotter than before. The result was that they were packed and palleted at a significantly higher temperature than under previous management.

Although the scientific and technological literature contained no reference to spontaneous ignition of noodles, their porous and oily nature indicated a possibility that this could occur. The suspicion was confirmed by

laboratory tests obtaining the CAT for a particular size noodle block. On this basis a full series of tests was carried out, and the parameters for the noodles obtained from the Frank-Kamenetskii plot in the usual way. With these parameters available it was possible to calculate the CST for a pallet full of noodle packages as these were shrink wrapped onto the pallets and completely encased in plastic, that is, the whole pallet full of noodles was in fact the body in question. The calculated CSTs (for a range of feasible ambient temperatures) turned out all to lie above the temperatures reached with the old process parameters but well below the temperatures reached with the new high-productivity parameters. The "bean counters" managed to achieve a productivity of zero until the factory was rebuilt.

Bagasse Storage—Some Complex Chemistry

The sugar industry in Australia wished to use bagasse containing the usual 50 percent moisture as a biomass for cogeneration of electricity as large excess tonnages are produced biannually. Removal of moisture increases the calorific (and hence monetary) value of the material as a fuel, provided it can be removed at no energy cost. At the same time it has been known for some time that large piles of bagasse are prone to spontaneous ignition and self-heating with consequent loss of value and also considerable pollution from the combustion products. An obviously desirable aim would be to create piles of bagasse that are not large enough to be supercritical but nevertheless large enough to self-heat significantly and hence drive off some of the moisture at no cost. Thus one would turn a dangerous energy release into a benefit. Clearly the balance would have to be just right. Consequently, a major research project was undertaken, both experimental and theoretical.

Application of the standard laboratory test methods to bagasse[52] results in a prediction of critical dimension for a pile at ambient temperature 30°C, which is an order of magnitude greater than the observed value. This is now known to be due to the fact that laboratory test CATs are above 100°C and simply drive off the moisture before the self-heating can get underway. The extrapolated results are therefore only good predictors for dry piles of material. In practice the water content of bagasse is close to 50 percent on a dry-weight basis, and this has recently been shown to be instrumental in partaking in a heat-producing reaction in addition to the one predominating in the dry material at higher temperatures.[19,20] This wet reaction has been characterized in isothermal calorimetric measurements over the temperature range 30°C to 90°C, and in this range the high-activation-energy dry reaction is almost completely shut down by the negative exponential in the Arrhenius function.

The wet reaction does not follow an Arrhenius temperature dependence at all, rather having a maximum rate at about 55–60°C. It also has a sharp, almost discontinuous dependence on water concentration, cutting out completely below 20 percent moisture. These characteristics are probably responsible for its occurrence being mistaken for microbiological activity. Inclusion of such complex chemistry in a generalization of the Frank-Kamenetskii theory for distributed temperatures, as well as the evaporation, condensation, and diffusive movement of water vapor through the pile, results in probably the most complex modeling yet of ignition phenomena.

Nevertheless this model describes quantitatively the behavior of real bagasse piles and answers the questions that led to its creation, that is, How does one choose a pile size in order to maximize the water removal without losing the pile to spontaneous ignition? The modeling is described in a number of publications (e.g., see Reference 11) and shows that present-day computing power coupled with appropriate knowledge of physical parameters enables quantitative or at worst semiquantitative modeling of spontaneous ignition situations with input of realistic chemistry and transport processes. Such developments have also taken place in the modeling of realistic chemistry in gas phase ignition of hydrocarbons and related organic materials dating back to the early work at the Shell Research Laboratories by Quinn et al.[53] and pursued by a number of workers, including Westbrook et al.[54]

It seems that we are not far from a situation where the simplified theories that have been useful tools for so long (with their empirical corrections) will be superseded by more detailed calculation of required properties such as CATs and CSTs. Nevertheless, the simplified theories will never lose their pedagogical value and will remain a firm conceptual foundation for more sophisticated models.

Milk Powder—A Numerical Example

The following example was given by Beever.[55] In a milk-drying plant air entering the spray dryer was heated to 200°C, and it was thought that surfaces in the region of the inlet may also reach this temperature. Any collection of powder on hot surfaces could cause spontaneous ignition, that would not only spoil the product but act as a source of ignition for a dust explosion. These have occurred in milk-drying plants with devastating consequences. Further down the dryer where there was deemed to be a greater likelihood of powder accumulation, surface temperatures of 80°C occurred. Three laboratory basket sizes were tested with half side-lengths of 0.025, 0.0375, and 0.050 m. The CATs of these were 171°C, 156°C, and 141.5°C, respectively. For a cube we can substitute the value 2.52 for δ_{critical} in Equation 20:

$$\ln\left(\frac{\delta_{\text{critical}} T_{a,\text{critical}}^2}{r^2}\right) = 41.85 - \frac{9497}{T_{a,\text{critical}}}$$

We can make r the argument of this equation and then substitute for $T_{a,\text{critical}}$ as required. If we require the critical temperature for a layer of material, we would use the value for δ_{critical} appropriate to an infinite slab, that is, 0.88. For such a flat layer with ambient temperature on each side of 200°C, a critical thickness of 0.017 m is obtained. For the cooler regions of the dryer at 80°C, a critical thickness of 0.4 m is obtained. It was decided that these critical thicknesses were sufficiently realistic to require regular cleaning inside the dryer to remove buildup. This problem is actually more complicated than indicated here since the critical parameters are rather sen-

sitive to moisture content, the critical thickness increasing significantly with moisture content, which can be up to 4 percent.[56]

Nomenclature

C_v	heat capacity at constant volume per unit mass (J/K·mol)
c	concentration (mol/m^3)
c_f	feed concentration in CSTR (mol/m^3)
CAT	critical ambient temperature (K)
CST	critical stacking temperature (K)
E	activation energy (J/mol)
F	feed rate in CSTR (m^3/s)
$f(c)$	chemical reaction rate (mol/m^3·s)
Q	heat of reaction (J/mol)
R	universal gas constant (J/mol·K)
r	characteristic radius
S	surface area (m^2)
T	temperature (K)
T_a	ambient temperature (K)
$T_{a,\text{critical}}$	critical ambient temperature (CAT) (K)
T_f	feed temperature in CSTR (K)
tti	time to ignition(s)
u	dimensionless temperature (RT/E)
u_a	dimensionless ambient temperature
V	volume of self-heating body (m^3)
ν	dimensionless concentration (c/c_0)
δ	Frank-Kamenetskii parameter
θ	Frank-Kamenetskii dimensionless temperature
ρ	bulk density (mol/m^3)
κ	thermal conductivity (W/m·K)
χ	heat-transfer coefficient (W/m^2·K)
ε	inverse dimensionless heat of reaction
τ	dimensionless time
ℓ	dimensionless heat transfer coefficient
Bi	Biot number ($\chi r/\kappa$)
$\partial(\,)/\partial n$	differential coefficient in a direction normal to the boundary of the body

CHAPTER 11

Flaming Ignition of Solid Fuels

A. Murty Kanury

Introduction

This chapter concerns flaming ignition of solid combustibles that are heated by either thermal radiation or convection. Different kinds of ignitions encountered in practice are defined. The existing empirical knowledge is highlighted by describing Martin's map of spontaneous ignition of radiantly heated cellulosic solids. The various physical and chemical processes that culminate in ignition of a heated solid are identified through a qualitative description and a simplified mathematical model. The typical assumptions underlying a theoretical model are systematically enumerated to point out the complexities involved in the ignition problem.
